Jalapinolic Ether, $C^{16}H^{14}O^2 = C^{16}H^{22}(C^2H^3O)^1$. *Scammonolic ether*.—When hydrochloric acid gas is passed into a solution of jalapinolic acid in absolute alcohol, and the resulting liquid is mixed with water, a yellow oil separates, which must be washed, after solidification, with cold alcohol, dissolved in boiling alcohol, mixed with carbonate of sodium, and after it has separated out on cooling, repeatedly precipitated from the alcoholic solution by water. It may also be obtained from scammony resin, by passing hydrochloric acid gas into the alcoholic solution. (Spirgatis.)

JALPAITE. A cupriferous silver-glance from Jalpa in Mexico. It has a blackish lead-grey colour, is malleable like ordinary silver-glance, and has a specific gravity of 6·877 to 6·890. According to an analysis by R. Richter, it contains 14·36 per cent. sulphur, 71·51 silver, 13·12 copper, and 0·79 iron, agreeing nearly with the formula, $\frac{3}{8}Ag^1\frac{1}{8}Cu^1S$. (Breithaupt, Jahresber. 1858, p. 682.)

JAMAÏCINE. An alkaloïd said to be contained in the bark of *Gcoffroya inermis*, a leguminous tree growing in Jamaica and in Surinam. (Hüttenschmidt, Geiger's Mag. Pharm. Sept. 1824.—Winckler, Pharm. Centr. 1840, p. 120.)

JAMESONITE. A sulphantimonite of lead occurring in trimetric crystals. $\infty P : \infty P = 101^\circ 20'$ and $78^\circ 40'$. Observed planes ∞P , $\infty P\infty$. Cleavage basal, very distinct; parallel to ∞P and $\infty P\infty$ less distinct. Sometimes capillary; also massive with columnar structure; particles delicate, straight and parallel or divergent. Hardness = 2 to 2·5. Specific gravity = 5·5 to 5·8 (Haidinger). Lustre metallic. Colour and streak steel-grey. Opaque. Sectile.

When heated in an open tube, it gives off dense white fumes of antimonious oxide; on charcoal before the blowpipe it decrepitates, fuses readily, and passes off almost wholly in fumes.

Analyses.—a. from Cornwall, mean of three analyses by H. Rose (Pogg. Ann. viii. 99).—b. from Estrenadura, by Schaffgotsch (*ibid.* xxxviii. 403).—c. from Tuscany, by Bechi (Sill. Am. J. [2] xiv. 60).—d. from Arany, Idka, by Löwe (Haidinger's Berichte, i. 62).

	S	Sb	Bi	Pb	Fe	Cu	Zn	Ag
a.	22·34	34·29	..	39·94	2·64	0·18	trace	.. = 99·39
b.	21·78	32·62	1·05	39·97	3·63	..	0·42	.. = 99·47
c.	20·53	32·16	..	43·38	0·94	1·25	1·74	.. = 100·00
d.	18·59	33·10	0·22	40·82	2·99	1·78	0·35	1·48 = 99·33

These analyses lead to the conclusion that Jamesonite is an isomorphous mixture of sulphantimonite of lead $2PbS.Sb^2S^3$, with the corresponding compounds of iron (copper, zinc, and silver). Such a mixture of one molecule of the iron-salt and three molecules of the lead-salt, viz. $2FeS.Sb^2S^3.3(2PbS.Sb^2S^3)$ or $(FePb^3Sb^4)^1S^6$, would contain 21·64 per cent. S, 32·55 Sb, 42·02 Pb, and 3·79 Fe.

Jamesonite occurs principally in Cornwall, associated with quartz and minute crystals of bournonite; occasionally also in Siberia, Hungary, Spain, and Brazil. (Dana, ii. 75; Rammeisberg, p. 68).

JAPONIC ACID. $C^{12}H^{10}O^2$.—An acid produced by exposing to the air a solution of catechin in caustic potash. The liquid slowly blackens, and on adding hydrochloric acid, a black precipitate of japonic acid is produced. The acid is soluble in water, but insoluble in alcohol. It forms with potash a black salt which produces black precipitates with metallic solutions. (Svanberg, Ann. Ch. Pharm. xxiv. 215.)

JARGIONITE. A variety of galena, crystallised in octahedrons. Specific gravity 6·932.

JARGON. Syn. with ZIRCON.

JAROSITE. A native ferroso-potassic sulphate from Baranco Jaroso near Sierra Amageru in Spain. Crystallises in yellowish rhombohedrons with basal cleavage. (Dana, ii. 389.)

JASPER. A sub-species of quartz of which the following varieties are enumerated by Jameson.

1. *Egyptian jasper*, which is red or brown. The first is flesh-red, blood-red, yellow and brown, in ring-shaped delineations; in roundish pieces, dull, with conchoidal fracture. Feebly translucent on the edges. Hard; easily frangible. Specific gravity, 2·63. It is found imbedded in red clay-ironstone at Baden, and is cut into ornaments.

The *brown variety* has its various shades of colour disposed in concentric stripes, alternating with black stripes. It occurs in the sands of Egypt, in spheroidal masses, with glimmering lustre. Fracture conchoidal. Feebly translucent on the edges. As hard as horn-stone. Specific gravity 2.6. Infusible. It is cut into ornaments.

2. *Striped jasper*. Colours grey, green, yellow, red, arranged in stripes, in flamed or spotted delineations. Massive, in whole beds. Dull. Fracture conchoidal. Opaque. Less hard than Egyptian jasper; rather easily frangible. Specific gravity 2.6. It occurs in secondary clay-porphry in the Pentland hills, and near Friburg in Saxony. It receives a fine polish.

3. *Porcelain jasper*. Colours grey, blue, yellow, generally of one colour, or with clouded delineations. Massive, and cracked in all directions. Lustre glistening. Fracture conchoidal. Opaque. Easily frangible, and not very hard. Specific gravity, 2.5, fuses into a white or grey glass. It is always found along with burnt clay and earth slags. According to Werner, it is slate-clay converted into a kind of porcelain, by the heat of a pseudo-volcano from beds of burning coal. It is found on the coast of Fifeshire, in Shropshire, and Warwickshire, and some parts of Germany, where immense beds of coal appear.

4. *Common jasper*. Colours red and brown. Massive. Lustre, from shining to dull. Fracture conchoidal. Opaque. Hard in a low degree; rather easily frangible. Specific gravity 2.6. Infusible before the blowpipe, becoming at last white. It occurs principally in veins as a constituent of agate. It is found in the Pentland hills, and in trap and transition rocks in Ayrshire and Dumfriesshire.

5. *Agate jasper*. Colours yellowish- and reddish-white. Massive, dull. Fracture flat, conchoidal. Opaque. Rather hard. It occurs in layers in agate-balls in many places.

The *iaspis* of the ancients, whence our word jasper is derived, appears to have included the green or blue variety, together with some other stones not of the jasper kind.

JATROPHA. A genus of euphorbiaceous plants, some of which contain intensely poisonous juices: the seeds of several species yield fixed oil.

The kernels of the seeds of *Jatropha Curcas* were found by Arnaudon and Ubal dini (Cimento, vii. 431) to contain 7.2 per cent. water, 37.5 oil, 55.3 sugar, starch, albumin, casein and inorganic matters. The kernels yielded 4.8 per cent. ash, and 4.2 per cent. nitrogen; the kernels and husks together, 6 per cent. ash and 2.9 per cent. nitrogen. The oil yielded by saponification, glycerin, and an acid which, as well as the unsaponified oil, produced octylic alcohol by distillation with hydrate of potassium.

The oil of the fruit of *Jatropha glauca* and of *J. glandulosa* is yellow, has a specific gravity of 0.963 and solidifies at 5°. (J. Lepinc, J. Pharm. [3] xl. 16.)

The root of *Jatropha Manihot* contains a large quantity of starch, which when freed from the poisonous juice of the plant by washing and torrefaction, constitutes Brazilian arrow-root (i. 359.)

JEFFERSONITE. A dark-green, crystallised, foliated variety of augite, containing zinc, from Mine Hill, Franklin, New Jersey. Specific gravity 3.6. Formula (Ca; Fe; Mg; Zn)SiO₃.

JELLETITE. An altered form of garnet, said to occur in rhombic prisms with angles of 60°, the supplement of which, 120°, is the angle of the rhombic dodecahedron. Specific gravity = 3.741. Hardness above 7. Occurs as a yellowish, slightly greenish incrustation, and is compact in its texture. Composition, according to Wright (J. Geol. Soc. Dublin, v. 119), 38.09 SiO₂, 33.41 FeO, 28.61 CaO = (100.11), which if a small part of the iron is regarded as protoxide, gives the formula of garnet. (Dana, ii. 194.)

JEFREINOFFITE or **JEWELINOWITE.** A variety of vesuvian from Finland, containing, according to Ivanhoff, 37.41 SiO₂, 34.20 CaO, 20.00 Al₂O₃, 4.60 FeO, 1.16 K₂O, and 1.70 Na₂O (= 99.07). It is usually yellowish-brown, but sometimes colourless. (Dana, ii. 506.)

JERKINSITE. Syn. with **HYDROPHITE** (p. 212).

JERVINE. An alkaloid discovered by E. Simon (Pogg. Ann. xli. 569), in the root of white hellebore (*Veratrum album*), in which it exists, together with veratrine. It is extracted by mixing the alcoholic extract of the root with dilute hydrochloric acid and precipitating with carbonate of sodium. The precipitate is dissolved in alcohol, the solution decolorised with charcoal, and the alcohol removed by distillation. The greater part of the residue then solidifies in a crystalline mass, from which the veratrine, being uncrystallisable, may be almost entirely removed by submitting it to pressure, moistening the resulting cake with alcohol, and pressing again. In this

manner jervine is obtained nearly pure. A further quantity may be obtained, in the form of sulphate, by evaporating to dryness the expressed liquid, which contains both jervine and veratrine, and treating the residue with dilute sulphuric acid, which takes up sulphate of veratrine, and leaves sulphate of jervine.

Jervine is colourless and crystalline; gives off 6.9 per cent. water of crystallisation (2 at.), at 100°, and melts at a higher temperature to a colourless oil, which decomposes when heated above 200°. It is insoluble in water, soluble in alcohol, very sparingly soluble in ammonia.

According to Will's analysis (Ann. Ch. Pharm. xxxv. 116), it contains 74.91—74.55 per cent. carbon, 9.57—9.74 hydrogen, and 5.38 nitrogen, whence Will deduced the formula $C^{66}H^{46}N^2O^2$ for which Gerhardt substituted $C^{66}H^{46}N^2O^2$ or $C^{33}H^{23}N^1O^1$ (calculation 74.7 per cent. C, 9.6 H, 5.7 N, and 10.1 O).

Jervine gives off ammonia when fused with potash.

Acetate of jervine is soluble in water. The sulphate, nitrate, and hydrochlorate are very sparingly soluble in water and in mineral acids. The chloroplatinate forms light yellow flakes which give by analysis 14.55—14.33 per cent. platinum, the formula $2(C^{33}H^{23}N^1O^1.HCl).PtCl_4$ requiring 14.3 per cent.

JET. A variety of bituminous coal, resembling cannel coal, but blacker, and with a stronger lustre. Specific gravity 1.3. It occurs, together with lignite, in beds, in floetz, trap, and limestone rocks, and in bituminous shale. It is found on the coast of Whitby, in Yorkshire, in the Isles of Skye and Faroe, in Hessian, Bavaria, Bohemia, and Styria. It is used for fuel and for making various ornamental articles.

It is the *Gagates* of Dioscorides and Pliny, a name derived from the river Gagae, in Syria, near the mouth of which it was found. U.

JEWREINOWITE. Syn. with JEFREINOFFITE.

JOHANNITE. Native uranous sulphate. See URANIUM.

JOHNITE. Syn. with Turquois.

JUGLANDIN. A substance contained in the juice expressed from the green shell of the walnut (*Juglans regia*). The fresh juice is nearly limpid, has a rough bitter taste, turns brown rapidly in contact with the air, and then loses its strong taste. By prolonged contact with the air, it deposits brown tasteless flocks, insoluble in water and alcohol, the juice at the same time losing its bitterness. The fresh juice reduces iron-salts; the browned juice, when mixed with potash, precipitates ferrous sulphate, losing its colour at the same time. With nitrate of silver it forms a precipitate which blackens rapidly, and contains metallic silver.

The extract of green walnut-shells consists of impure juglandin. It is used as a remedy in cutaneous and scrophulous diseases, also for dyeing the hair black. (*Gerh. Traité*, iv. 307).

JUNIPER. The berries of the juniper (*Juniperus communis*), which are used for flavouring gin, and in the form of aqueous decoction, also in medicine as a diuretic, contain, according to Trommsdorff, 1.0 per cent. essential oil of juniper, 4.0 wax, 10.0 resin, 33.8 sugar, together with acetate and malate of calcium, 7.0 gum and vegetable salts, 35.0 woody fibre, and 12.9 water.

The essential oil of juniper, obtained by distilling the berries with water, has the composition and vapour-density of oil of turpentine ($C^{10}H^{16}$); boils at 160°; turns the plane of polarisation to the left, but less strongly than oil of turpentine. It is very little soluble in alcohol of ordinary strength. It does not form a solid camphor with hydrochloric acid; but after the complete absorption of the gas, a liquid is formed which appears to contain $3C^{10}H^{16}.2HCl$.

The old and moist essence deposits crystals which appear to be identical with hydrate of turpentine. It is acid and contains formic acid.

By distilling unripe juniper-berries with salt-water, Blanchet obtained another oil, which boiled at 205°, but appeared to have the same composition as that just described. (*Gerh. Traité*, iii. 637.)

JUNKERITE. Spathic iron ore.

JURINITE. Syn. with BROOKITE.

K

KÄMPFERITE. A variety of pyrosclerite containing a considerable quantity of chromium. (See PYROSCLERITE.)

KÄMPFERIDE. A substance contained in the root of *Kempferia Galanga*. It may be extracted by ether, together with a brown, viscid, aromatic substance, which

may be removed by dissolving the product several times in alcohol, the brown substance separating first when the solution is left to evaporate.

Kempferide crystallises in yellowish nacreous laminae, without taste or smell. It melts at a temperature above 100°, dissolves in 25 pts. of ether at 15°, is less soluble in alcohol, and nearly insoluble in water. It dissolves in warm acetic acid, and the solution yields with ammonia a precipitate soluble in excess of that reagent. Sulphuric acid imparts to it a fine bluish-green colour. Caustic potash dissolves it with yellow colour; carbonate of potassium with effervescence.

Kempferide gave by analysis (calculated with the old atomic weight of carbon) 65.3 per cent. C, 4.3 H and 30.4 O. (Brandes, Ann. Ch. Pharm. xxxii. 312.)

KALISACCHARIC ACID. Syn. with GLUCIC ACID (ii. 848.)

KALYPTOTITE. A name given by Shepard (Sill. Am. J. [2], xii. 210) to some small black-brown crystals from Haddam, Connecticut, regarded by him as a new mineral. Dana, however, regards them as garnets.

KAMALA. A substance obtained from the fruit of *Rottleria tinctoria*, and used as an anthelmintic (see ROTTLERIA).

KANEITE. Arsenical Manganese. (See MANGANESE.)

KAOLIN. The Chinese name of porcelain clay (i. 1024).

KAPNITE. A variety of calamine containing more than 15 per cent. of ferrous oxide. The angle of the rhombohedron R : R is 107° 7' (Broithaupt).

KARLINITE. An oxysulphide of bismuth occurring, together with telluric silver, in the Sawodinsk mine in the Altai. It forms crude lumps, having a metallic aspect, a decidedly crystalline fracture, with prevailing cleavage in one direction, strong metallic lustre on the fractured surface, and lead-grey colour. Hardness = 2; specific gravity = 6.60. On treating the pulverised mineral with hydrochloric acid, a small quantity of admixed bismutite (i. 597) dissolves and pure karlinite remains undissolved. The latter heated in a test-tube gives off sulphurous anhydride, but no free sulphur, and forms a grey slag, from which globules of metallic bismuth ooze out; heated in an open tube, it also gives off sulphurous anhydride, and leaves a metallic regulus surrounded by a brown easily fusible oxide. Nitric acid easily decomposes the mineral, with separation of sulphur. The mineral gives by analysis 91.26 per cent. bismuth, 3.53 sulphur, and 5.21 oxygen, agreeing with the formula Bi_2SO_3 or $\text{Bi}_2\text{S}_3\text{Bi}_2\text{O}_3$. (R. Hermann, J. pr. Chem. lxxv. 448.)

KARPHOLITE. See CARPHOLITE (i. 806).

KARPHOSIDERITE. See CARPHOSIDERITE (i. 807).

KARSTENITE. Syn. with ANHYDRITE (i. 295).

KAWA-ROOT. The root of *Piper methysticum* (Forster). When dried between 110° and 120°, it leaves a residue amounting to 85 per cent.: after exhaustion with alcohol and with water, it leaves 75 per cent. of residue containing 26 pts. woody fibre and 49 starch. By exhausting the root with alcohol of 80 per cent. an extract having a peculiar smell and taste is obtained, the solution of which in warm alcohol deposits needle-shaped crystals, while a resin remains dissolved.

The crystalline substance called methysticin, forms, when purified by repeated crystallisation, small white silky needles, destitute of taste and smell. It is insoluble in water, sparingly soluble in cold alcohol and ether; reacts neutral; melts at 130°, and decomposes at a stronger heat; is dissolved by nitric acid with orange-yellow colour, by pure sulphuric acid with violet colour. It yields by analysis 62.03 per cent carbon, 6.10 hydrogen, and 1.12 nitrogen.

The resin kavin, contained, together with myristicin, in the alcoholic extract of the root, is a soft greenish-yellow substance, which has a strong aromatic taste and odour, melts at 50°, decomposes at a stronger heat, and produces a deep red colour, with sulphuric acid. 100 pts. of kawa-root contain 15 pts. water, 28 woody fibre, 49 starch, 1 methysticin, 2 acrid aromatic resin, 3 extractive and gummy matter, 1 chloride of potassium, and 3 magnesia, silica, alumina, and ferric oxide. (Gobley, J. Pharm. [3], xxxvii. 19.—O'Rourke, Compt. rend. l. 498.)

KAWAIN. A crystallisable non-azotised substance, from kawa-root; it contains 65.85 per cent. carbon and 5.64 hydrogen. (Cuzert, Compt. rend. l. 436; lii. 206.)

KAWIN. The resin of kawa-root. (See above.)

KEDRIA TERRESTRIS. Barbadoes tar. (See BITUMEN.)

KEILHAUTE. Syn. with YTTRITANITE.

KELP. Incinerated sea-weed. (See SEA-WEED.)

KERAMOHALITE. A hydrated sulphate of aluminium from near Königsberg

in Hungary, having the same composition as alunogen (i. 161). It occurs in crystalline crusts, and six-sided tables of the monoclinic system, with two angles of 92° , and four of 134° . Specific gravity = 1.6 to 1.7. Contains 14.30 per cent. alumina, 2.15 ferrous oxide, 36.75 sulphuric anhydride, 44.60 water, and 2.01 insoluble matter (= 99.81), agreeing approximately with the formula $Al_2(SO_4)^2 \cdot 18H_2O$.

KERAPHYLLITE. Syn. with CARINTHIN (i. 804).

KERARGYRITE or *Horn-silver*. Native chloride of silver (See SILVER).

KERASITE, *Cerasine*, or *Horn-lead*. A native compound of chloride and carbonate of lead. (See LEAD.)

KERATE. Syn. with KERARGYRITE.

KERMES (*Coccus ilicis*, Lin.) is an insect found in many parts of Asia, and the south of Europe. On account of their figure, these insects were a long time taken for the seeds of the tree on which they live: whence they were called *grains of kermes*. They also bore the name of vermillion.

To dye spun worsted with kermes, it is first boiled for half an hour in water with bran, then for two hours in a fresh bath with one-fifth of Roman alum and one-tenth of tartar, to which *sour water* is commonly added; after which it is taken out, tied up in a linen bag, and carried to a cool place, where it is left some days. To obtain a full colour, as much kermes as equals three-fourths, or even the whole of the weight of the wool, is put into a warm bath, and the wool is put in at the first boiling. As cloth is more dense than wool, either spun or in the fleece, it requires one-fourth less of the salts in the boiling, and of kermes in the bath.

The colour that kermes imparts to wool has much less bloom than the scarlet made with cochineal; whence the latter has generally been preferred, since the art of heightening its colour by means of solution of tin has been known. U.

KERMES, MINERAL. Amorphous trisulphide of antimony. (See ANTIMONY, SULPHIDES OF, i. 330.)

KERMESITE or **KERMESOME**. *Red Antimony*. *Antimony-blende*. *Pyramimonite*. *Pyrostilbite*. *Rothspießglanzcrz.*—A native oxysulphide of antimony, occurring in monoclinic crystals, cleaving parallel to the base; usually in tufts of capillary crystals, consisting of elongated, slender, six-sided prisms. Hardness = 1 to 1.5. Specific gravity = 4.5 to 4.6. Lustre, adamantine, inclining to metallic. Colour, cherry-red. Streak, brownish-red. Feebly translucent. Sectile. Thin leaves slightly flexible. Contains 74.45—75.66 antimony, 5.29—4.27 oxygen, and 20.49 sulphur (H. Rose, Pogg. Ann. iii. 453), answering to the formula Sb_2OS^2 or $Sb_2O^2 \cdot 2Sb_2S^2$. Before the blow-pipe on charcoal, it fuses readily, and is at last entirely volatilised. In nitric acid it becomes covered with a white coating.

This mineral, which results from the alteration of native sulphide of antimony, occurs in veins in quartz, accompanying grey and white antimony, at Mulackza near Posing in Hungary, at Bräunsdoff near Freiberg in Saxony, and at Allemont in Dauphiné. (Dana, ii. 141.)

KEROLITE. See CEROLITE (i. 836).

KETONES. See ACETONES (i. 31).

KHAYA. The bark of the *Cail-cedra* (*Khaya senegalensis* or *Swietenia senegalensis*), used in Senegal as a remedy against fever, contains a bitter principle, cail-cedrin, together with green fat, red and yellow colouring matter, gum, starch, a waxy substance, woody fibre, sulphate and phosphate of calcium, and chloride of potassium. Cail-cedrin, which may be extracted from the concentrated aqueous extract of the bark by chloroform, is a resinous mass containing 64.9 per cent. carbon, 7.6 hydrogen, and 27.5 oxygen. (Caventou, J. Pharm. [3] xvi. 356; xxxiii. 123.)

KIBDELOPHANE or *Axotomous Iron ore*. A variety of titaniferous iron, occurring sometimes in crystals, but usually massive, or in thin plates or laminae. R: R = $85^{\circ} 19'$. Hardness = 5 to 5.5. Specific gravity = 4.661 (Mohs); 4.723 to 4.735. (Breithaupt.)

KIFFERILL. See MEERSCHAUM.

KIESERITE. A name applied by Reichardt (Arch. Pharm. [2], ciii. 346) to a sulphate of magnesium, occurring in the shaft of the Stassfurth salt-mine near Magdeburg, and containing, according to his analysis, 21.66 per cent. MgO , 43.05 SO_4^2 , and 34.56 water (= 99.27), agreeing approximately with the formula $2MgSO_4 \cdot 3H_2O$.—Siewert (Zeitschr. f. d. ges. Naturw. xvii. 49) found in a much harder opaque specimen (mean) 28.56 MgO , 58.94 SO_4^2 , and 13.47 H_2O , together with from 0.26 to 0.66 of matter insoluble in nitric acid, answering to the formula $2MgSO_4 \cdot H_2O$. Similar results were obtained by B. Leopold (*ibid.* p. 51), who also

found that the salt contained from 0.5 to 1.2 per cent. of an insoluble borate (see SULPHATES); also previously by Rammelsberg (*Mineralchemie*, p. 264).

KILBRICKENITE. Geocronite from Kilbricken, Clare County, Ireland. (See GEOCRONITE, ii. 831.)

KILLAS. The Cornish miners' name for clay-slate.

KILLINITE. A mineral having the appearance of spodumene, found at Killiney Bay, near Dublin. According to Mallet, it affords by cleavage a prism of 136° , which is very nearly the angle between the diagonal and prismatic cleavages of spodumene, both of which are perfect. Hardness = 4. Specific gravity = 2.56. Lustre, vitreous, weak. Colour, greenish-grey, brownish, or yellowish. It has been analysed by Lehunt, Blythe, Mallet, and Galbraith (Dana, ii. 170; Rammelsberg's *Mineralchemie*, p. 837.)

SiO ²	Al ² O ³	FeO	CaO	MgO	MnO	K ² O	Li ² O	H ² O	
49.08	30.60	2.27	0.68	1.08	—	6.72	—	10.00	= 100.43 Lehunt.
47.93	31.64	2.33	0.72	0.46	1.25	6.06	—	10.00	= 99.80 Blythe.
52.89	33.24	3.27	1.45	—	—	4.94	0.46	3.67	= 99.92 Mallet.
50.45	30.13	3.53	—	1.09	—	4.81	0.95	7.58	= 98.54 Galbraith.
50.11	29.37	2.23	0.34	1.03	—	6.71	0.60	8.03	= 98.42 "

According to Rammelsberg, this mineral, and likewise pinité, giesckite, gigantolite, ibérite, and liebenérite, which are of somewhat similar constitution, are not definite compounds, but products of decomposition intermediate between an original mineral and mica, which often adheres to and partly penetrates their mass.

KINIC ACID. Syn. with QUINIC ACID.

KINO. This name is applied to four different drugs, bearing considerable resemblance to catechu, and consisting of dry brown lumps or grains, having a more or less astringent taste. Their aqueous extracts form green precipitates with ferric salts. The four varieties of kino are African kino, also called *Gummi gambiense*, or *G. Gambia*, from the *Pterocarpus erinaceus* (Lam.); Asiatic kino, from *Pterocarpus Marsupium*; New Holland kino, from *Eucalyptus resinifera* (white); and American kino, from *Coccoloba uvifera* (L.).

According to Vauquelin, African kino consists of 75 pts. tannin and peculiar extractive matter, 24 pts. red gum, and 1 pt. fibrin.

Kino is used in medicine as an astringent like catechu. (Handw. d. Chem. iv. 362.)

KINONE. Syn. with QUINONE.

KINOVOUS ACID. C²²H¹⁰O⁴ (?). An acid obtained, together with several other products, from the needles of *Pinus sylvestris*. (For the mode of preparation, see PIN-RESINS.) It is a white or slightly yellow brittle mass, converted by trituration into a strongly electric powder. The silver-salt contains 74.1 per cent. oxide of silver agreeing nearly with the formula 5Ag²O.C²²H¹⁰O⁴. (Kawalier, Wien. Akad. Ber. xi. 347.)

KINZIGITE. A name applied by H. Fischer to the mixture of red garnet, mica, and a triclinic felspar (oligoclase), which occurs in veins in primitive gneiss rocks; e. g. at Wittichen in the Kinzigthal, Schwarzwald, at Auerbach in the Bergstrasse, and other localities, and is regarded by him as an original formation. (Jahrb. Min., 1860, p. 796; 1861, p. 641.)

KIR. A fossil resin, found, with others, on the island of Tschelikün, in the Caspian Sea, and in other neighbouring localities.

KIRWANITE. A hydrated silicate of aluminium, calcium, and iron, occurring in basalt on the Mourne Mountain on the north-east coast of Ireland, in opaque, olive-green radiating fibres, having a specific gravity = 2.941 and hardness = 2. According to an analysis by R. D. Thomson, it contains 40.5 per cent. silica, 23.91 ferrous oxide, 19.78 lime, 11.41 alumina, and 4.35 water (= 99.95), whence Rammelsberg deduces the formula: 2[3(CaO.FeO).2SiO²].Al²O³.2SiO².2H²O; it is possible, however, that part of the iron may be in the state of ferric oxide.

The mineral blackens and fuses partially before the blow-pipe, and forms a brown glass with soda or borax.

KLAFFROTH. Syn. with LAZULITE.

KLINOCLEASE. Syn. with ANICHITE.

KNEBELITE. A mineral of unknown locality, closely related in composition to olivin, but differing from it considerably in its properties. According to Döbereiner's analysis (Schw. J. xxi. 49), it contains about 32.5 per cent. silica, 32.0 ferrous oxide, and 36.0 manganous oxide, agreeing nearly with the formula (Mn²⁺; Fe²⁺)²SiO⁴, or

2(MnO; FeO).SiO₂.—It is massive, with an uneven and cellular surface, and quite hard. Specific gravity, 3·714. Brittle, with imperfectly conchoidal fracture. Colour, white to greyish-green, or brown-red and brown. Lustre glistening.

KOBELLITE. A mineral found in the cobalt mine of Hvena in Sweden. It consists, according to Setterberg's analysis (*Berzelius Jahresber.* xx. 215), of 17·86 sulphur, 9·24 antimony, 27·05 bismuth, 40·12 lead, 2·96 iron, 0·80 copper, and 1·45 matrix (= 99·48), numbers which may be approximately represented by the formula: $2 \left[\text{Pb}^{\frac{1}{2}} \text{Sb}^{\frac{1}{2}} \right] \text{S}^{\frac{1}{2}} \cdot 3 \left[\text{Pb}^{\frac{1}{2}} \text{Bi}^{\frac{1}{2}} \right] \text{S}^{\frac{1}{2}}$, or $(\text{Pb}^{\frac{1}{2}} \text{Sb}^{\frac{1}{2}} \text{Bi}^{\frac{1}{2}}) \text{S}^{\frac{1}{2}}$, the lead being partly replaced by iron and copper. It resembles grey antimony, but has a brighter lustre and radiated structure. Specific gravity, 6·29—6·32. Soft; of blackish lead-grey to steel-grey colour, with black streak. Dissolves in strong hydrochloric acid, with evolution of sulphydric acid. (Dana, ii. 82; Rammelsberg, *Mineralchemie*, p. 106.)

KOENIGITE. Syn. with BROCHANTITE (i. 664).

KOENLITE. A fossil resin resembling scheererite, found in brown coal at Uznach, at Redwitz in Bavaria, and in the Fichtelgebirge. It contains, according to Schrötter's analysis (Pogg. Ann. lix. 37), 92·43 per cent. C, and 7·71 H, agreeing with the formula nC_H . It occurs in soft white crystalline folia and grains, of specific gravity 0·88; melts at 114° (Kraus, Pogg. Ann. xliii. 141), at 107·5° (Frommsdorff, Ann. Ch. Pharm. xxi. 126). Very slightly soluble in cold alcohol, more so in hot alcohol, still more in ether.

KOENLITE. A fossil resin from the brown coal of Fassa, in the Eger Valley. It occurs in thin plates, consisting of an aggregate of crystalline scales, perfectly soluble in alcohol and ether, also in strong sulphuric acid; partly soluble in ammonia and in oil of turpentine. (Koenigott, *Mineralogische Untersuchungen*, ii. 111.)

KÖTTIGITE. Native arsenate of zinc, $\text{Zn}(\text{AsO}_3)_2 \cdot 8\text{H}_2\text{O}$, or $\text{ZnO} \cdot \text{As}_2\text{O}_3 \cdot 8\text{H}_2\text{O}$, containing also nickel and cobalt, with a trace of lime.

As ₂ O ₃	ZnO	CoO	NiO	H ₂ O	
37·17	30·52	6·91	2·00	23·40	= 100

according to Naumann, and isomorphous with cobalt-bloom. Massive or in crusts, with crystalline surface and fibrous structure. Cleavage perfect in one direction. Specific gravity = 3·1. Hardness = 2·5—3. Lustre of fracture-surface, silky. Colour, light carmine-red and peach-blossom red, of different shades. Streak, reddish-white. Translucent to subtransparent. (Köttig, J. pr. Chem. xlviii. 183; Naumann, *ibid.* 256.—Dana, ii. 418.)

KORSCHAROWITE. A crystalline mineral occurring with ultramarine, and sometimes intergrown with it. It exhibits two very distinct directions of cleavage, inclined at an angle of 124°. Hardness = 5 to 5·5. It is sometimes colourless, with a strong lustre, sometimes brown and less lustrous. When heated, it becomes darker in colour, and easily melts to a white semitransparent glass (Nordenskiöld Jahresber. 1857, p. 681).—A specimen from the Sludanka valley, near Lake Baikal, was found by R. Hermann (Jahresber. 1862, p. 726) to contain 45·99 per cent. silica, 18·20 alumina, 2·40 ferrous oxide, 12·78 lime, 16·45 magnesia, 1·06 potash, 1·53 soda, and 0·60 matter lost by ignition (= 99·01). Specific gravity = 2·97.

KORITE. See PALAGONITE.

KOURISS. A vinous liquid, which the Tartars make by fermenting mare's milk. A somewhat similar beverage is prepared in Orkney and Shetland.

KOUFROLITE. Syn. with PREHNITE.

KRABITE. Syn. with BAULITE (i. 520).

KRAMERIC ACID. An acid said by Peschier (J. Pharm. vi. 34; x. 348) to exist in rhatany root (*Krameria triandra*). It is crystalline, has a sour and astringent taste, and is not volatile. Its alkaline salts are crystallisable, and their solutions form a white precipitate with lead-salts, yellow with ferric salts. The barium-salt is said not to be decomposed by sulphuric acid or soluble sulphates.

Other chemists who have looked for this acid in rhatany root have not been able to find it.

KRANTZITE. A variety of retinite from the lignite of Lattorf, near Bernburg. (See RETINITE).

KRAURITE. Syn. with DUFRENITE.

KRITTOWITE. Syn. with SPINEL.

KREMERSITE. Ruby-coloured octahedral chloride of potassium, from Vesuvius. Contains 55·15 per cent. chlorine, 16·89 iron, 12·07 potassium, 0·16 sodium, 15·66 ammonia and water. (Kremers, Pogg. Ann. lxxxiv. 79.)

KRISUVIGITE. Brochantite, from Krisuvig in Iceland.

KROKOITE. Syn. with Crocoisite (ii. 109.)

KUPRAPHITE. Syn. with Tyrolite.

KYANETHINE. Syn. with Cyanethine (ii. 188).

KYANETHINE. Syn. with Cyanethine (ii. 189).

KYANITE or *Cyanite*. A silicate of aluminium, $Al_2O_3 \cdot SiO_2$, occurring in triclinic prisms, $\alpha P : \infty P \infty : \infty P' : \infty P' : 2P \infty$. Crystals usually bladed. Angles $\alpha P : \infty P \infty = 93^\circ 15'$; $\alpha P : \infty P \infty = 100^\circ 50'$; $\alpha P : \infty P' = 98^\circ 58'$; $\alpha P : \infty P' = 96^\circ 42'$; $\alpha P \infty : \infty P \infty = 106^\circ 16'$; $\infty P : \infty P' = 97^\circ 4'$; $\infty P \infty : \infty P' = 145^\circ 41'$; $\infty P \infty : \infty P' = 131^\circ 23'$; $\infty P \infty : 2P \infty = 159^\circ 18'$. Cleavage perfect parallel to the smoother lateral plane; imperfect parallel to the base. Twins, of two kinds, with face of composition $\infty P \infty$, and planes $\infty P \infty$, meeting at an angle; in one kind the planes αP are coincident, in the other they form a re-entering angle. Also coarse-bladed, columnar; also fibrous. Hardness = 6 to 7.25. Specific gravity = 3.659; of white kyanite 3.675; of blue transparent kyanite from the Tyrol, 3.661 (Erdmann). Lustre vitreous to pearly. Colour generally pale blue, often deeper along the middle of the prisms; sometimes white or blue, with white margins; also grey, green, and black. Streak uncoloured. Translucent and sometimes transparent. The crystals may often be easily scratched on the lateral surface, while they are very hard at the extremities.

Kyanite remains unaltered when simply heated before the blowpipe; melts to a transparent, colourless glass with borax, and gives a deep blue colour with cobalt-solution.

Pure kyanite would contain 37.5 per cent. silica, and 62.5 alumina. The following analyses show that it does not deviate much from this composition:

	Arfvedson.		Smith and Brush.	Marignac.	Erdmann.	Smith and Brush.
	Röss.	St. Gothard.	New York.	St. Gothard.	Röss.	New York.
Silica . . .	36.4	36.9	37.03	36.60	34.40	37.20
Alumina . .	63.8	64.7	61.90	62.60	61.86	59.02
Ferric oxide	0.84	0.52	2.08
Cupric oxide	0.19	. . .
Water	0.85	1.03
	100.2	101.6	99.78	100.10	96.97	99.33

Kyanite occurs principally in gneiss and mica-slate. Transparent crystals are found at St. Gothard, in Switzerland; at Greiner and Pfäfers, in the Tyrol; also in Styria, Carinthia, and Bohemia; at Pontivy, in France; and at Villa Rica, in South America. It occurs also in many localities in the United States: the specimens analysed by Smith and Brush were from Monroe County, New York.

Bamlite (i. 499), from Bamle, in Norway, and xenolite (*q. v.*), have nearly the same composition as kyanite. Woerthite, from near St. Petersburg, containing 40.6 per cent. SiO_2 , 58.50 Al_2O_3 , 1.00 MgO and 4.63 water, and Thomson's hydrobucbolite (probably from Sardinia), which contains 41.35 SiO_2 , 49.53 Al_2O_3 , 4.85 water and 3.12 gypsum, are probably hydrous kyanites. Kyanite has also been observed altered to talc and stentite. (Dana, ii. 265.)

KYANOL. Syn. with Phenylamine.

KYMATIN. Syn. with Hornblende.

KYAPHENINE or **CYAPHENINE.** $(C^2H^3)^mN^2$.—A compound polymeric with cyanide of phenyl (benzonitrile), C^2H^3N , obtained by heating pulverised cyanate of potassium with chloride of benzoyl:

It is a hard neutral substance, exhibiting a crystalline fracture; melts at 224° , and distils without alteration at or a little above 350° ; is soluble in water, slightly soluble in alcohol and ether. When heated with caustic potash, it decomposes, with copious evolution of ammonia. Sulphuric acid dissolves it, forming an acid whose barium-salt is soluble in water. Strong hydrochloric acid does not dissolve it, even at the boiling heat. Nitric acid of ordinary strength is also without action upon it; but fuming nitric acid dissolves it, with great rise of temperature, but without evolution of gas; and by evaporating the solution or mixing it with water, nearly the whole of the cyaphenine is precipitated in the form of a nitro-compound, $C^2H^3(NO^2)N^2$, which crystallises in needles.

KYMATIN. Syn. with Hornblende.

KYNURENIC ACID. (Liebig, Ann. Ch. Pharm. lxxxvi. 125; cviii. 354.)—An acid sometimes deposited from the urine of dogs. From the urine of a dog which had been fed on fat alone, or on fat mixed with a small portion of meat, Liebig obtained it by evaporating, adding hydrochloric acid and leaving the liquid to stand for some time; the urine of dogs fed exclusively on lean meat yielded only traces. The deposit dissolves in lime-water, and on diluting the solution with water, and adding hydrochloric acid, kynurenic acid is deposited in very slender, colourless needles; from concentrated solutions, as a powder.

Kynurenic acid reddens litmus; when heated in a glass tube, it melts to a brown liquid, which then sublimes completely, forming a white silky crystalline sublimate, and leaving a trace of charcoal. The precipitated acid is insoluble in alcohol and in ether; the sublimed acid dissolves in alcohol. It dissolves easily in boiling hydrochloric acid (whereby it is distinguished from uric acid), and in dilute sulphuric and nitric acids (in the latter without perceptible alteration, even on boiling). Cold concentrated sulphuric acid dissolves it without alteration; but on heating the solution, it turns brown, and, on addition of water, deposits a lemon-yellow, amorphous precipitate, often mixed with crystals of the unaltered acid.

Kynurenic acid is a very weak acid. It dissolves easily in caustic alkalis, and, with aid of heat, in alkaline carbonates, lime-water and baryta-water, neutralising the bases and forming crystallisable salts. The *barium-salt* forms plumose groups of nacreous needles; the *calcium-salt*, stellate groups of short hard needles. Both salts are sparingly soluble in water.

The acid is precipitated from the solution of the barium-salt by carbonic acid. It gave by analysis 61.6 to 61.9 per cent. carbon, 4.7 to 4.4 hydrogen, and 8.7 to 9.4 nitrogen. When heated alone or with lime, it yields a volatile oil, having the odour of benzonitrile.

KYPHOLITE. Syn. with SERPENTINE.

KYROSITE. White iron pyrites from the mine Briceius, near Annaberg.

L.

LABDANUM or **LADANUM.** A resin which exudes in drops from the leaves and branches of the *Cistus creticus* and *C. cypricus*, shrubs growing in Greece and Turkey. It is generally black, solid, tenacious, and somewhat moist; softens between the fingers, and exhales an odour like that of ambergris. A sample analysed by Guibourt (*Histoire des Drogues*, iii. 601) contained 86 per cent. resin and volatile oil, 7 wax, 1 aqueous extract, and 6 earthy matter and hairs. Commercial labdanum is often largely adulterated with black sand. According to Johnston, labdanum-resin contains 73.2 per cent. carbon and 10.0 hydrogen; a composition which may be approximately represented by the formula $C^{22}H^{30}O^3$ (calc. 75.5 C, 9.4 H, and 15.1 O).

Labdanum in sticks is prepared in Portugal, Spain, and the South of France, by boiling the leaves and branches of *Cistus ladaniferus*.

LABRADORITE. *Labrador Felspar.* *Anhydrous Scolecite.* *Manillite.* *Silicite.* *Scolezerosite.*—A mineral species belonging to the felspar group, and represented by the formula $M^2O \cdot Al^2O^3 \cdot 3SiO^2$, or $(Al^{12})^{11} \left\{ \begin{smallmatrix} (Si^4)^{11} \\ M^2 \end{smallmatrix} \right\} O^{19}$, where M denotes calcium and sodium, and occasionally also magnesium and potassium.

Labradorite occurs in triclinic crystals, in which $2P : \infty P \infty = 86^\circ 32'$; $oP : \infty P = 114^\circ 48'$; $\infty P \infty : oP = 119^\circ 16'$. It forms twins like those of albite (ii. 621). Cleavage perfect parallel to oP ; distinct parallel to $\infty P \infty$, in which direction also the faces are usually striated; indistinct parallel to $\infty P'$. Also massive, with distinct cleavage. Hardness = 6. Specific gravity = 2.67 to 2.76. Lustre of oP pearly, passing into vitreous; elsewhere vitreous or subresinous. Colour usually grey, of various shades; also greenish, reddish, or yellowish. Some varieties, especially that from Labrador, exhibit a beautiful play of colours when viewed in certain directions: this effect is best seen in cut and polished specimens. Streak uncoloured. Fracture glistening. Translucent in a low degree. Less easily frangible than common felspar.

Before the blowpipe on charcoal it fuses, with less difficulty than orthoclase, to a colourless glass. With oxide of nickel and borax it forms a blue bead. When pulverised, it is entirely dissolved by hydrochloric acid, which does not attack either orthoclase or albite.

Analyses: *a.* From Campsie in Scotland, where it occurs in porphyritic greenstone (Lehmann, Ed. N. Phil. J. 1832, p. 86). *b.* From Etna, where it occurs as a constituent of lava (v. Waltershausen, *Vulkanische Gesteine*, 1863, p. 24). *c.* From Farø, (Forchhammer, J. pr. Chem. xxx. 385). *d.* From Labrador (v. Waltershausen *loc. cit.*). *e.* From Egersund, in Norway; violet-grey with brilliant play of colours (Kersten, Pogg. Ann. lxiii. 123). *f.* From the hypersthene-rock of Neurode, in Silesia; bluish-grey (v. Rath, Pogg. Ann. xcv. 538). *g.* From the gabbro of the same locality; bluish-white (v. Rath, *ibid.*). *h.* From the melaphyre between Botzen and Collman, in the Tyrol; light greyish green. (Delesse, J. pr. Chem. xliii. 447; xlv. 219). *i.* From the trachydolerite of Guadaloupe (Deville, *Rammelsberg's Mineralchemie*, p. 698). *k.* *Scoloxeros*, from Pargas, Finland (Nordenskiöld, Schw. J. xxxi. 417). *l.* *Silicite*, from Antrim, Ireland. (Thomson, Phil. Mag. 1843, p. 417.)

<i>k.</i>	54.13	29.23	...	15.45	1.07	= 99.88
<i>l.</i>	54.8	28.4	4.0	12.4	0.6	= 100.2

If the number of molecules of lime be supposed to be three times as great as that of the soda, the above formula, which then becomes $\frac{3}{2}\text{Ca} \left\{ \frac{1}{2}\text{Na} \right\} \text{O} \cdot \text{Al}_2\text{O}_3 \cdot 3\text{SiO}_2$, gives 53.1 per cent. SiO², 30.1 Al²O³, 12.3 CaO, and 4.5 Na²O.

Labradorite is more subject to alteration than other felspars; perhaps because it contains both potash and soda. Partial decomposition is shown, either by the diminished quantity of these bases, or by the consequently increased proportion of silica. The best examples of unaltered labradorite in the preceding table are perhaps *c*, *f*, *g*, *h*, and *i*; *k* and *l*, if the analyses are correct, afford decided indications of decomposition. For numerous analyses of labradorite, and of felspars allied to it, see *Rammelsberg's Mineralchemie*, pp. 597—603.

Labradorite is a constituent of some lavas, as those of Etna and Vesuvius; of many porphyries, as the oriental *verd antique* of Greece; of dolerite; of certain hornblende-granites, granites, and syenites; of some porphyritic greenstones, as at Campsie in Scotland; of melaphyres, as in the Tyrol. On the coast of Labrador, whence it was originally brought, it is associated with hornblende, hypersthene, and magnetic iron ore. (Dana, ii. 238.)

LABURNIC ACID. An acid said to be contained, together with cytisine (ii. 311) and two neutral bitter principles, in the seeds, bark, and other parts of *Cytisus Laburnum*. (T. Scott Gray, Arch. Pharm. [3] xlii. 160.)

LAC is a substance well known in Europe under the different appellations of stick-lac, shell-lac, and seed-lac. The first is the lac in its natural state, encrusting small branches or twigs. Seed-lac is the stick-lac separated from the twigs, appearing in a granulated form, and probably deprived of part of its colouring matter by boiling. Shell-lac is the substance which has undergone a simple purification, as mentioned below. Beside these we sometimes meet with a fourth, called lump-lac, which is the seed-lac melted and formed into cakes.

Lac is the product of the *Coccus lacca*, which deposits its eggs on the branches of a tree called Bihar, in Assam, and other parts of India. It appears designed to answer the purpose of defending the eggs from injury, and affording food for the maggot in a more advanced state. It is formed into cells, finished with as much art and regularity as a honeycomb, but differently arranged; and the inhabitants collect it twice a year, in the months of February and August. For purification, it is broken into small pieces, and put into a canvas bag of about four feet long, and not above six inches in circumference. Two of these bags are in constant use, each of them being held by two men. The bag is placed over a fire, and frequently turned, till the lac is liquid enough to pass through its pores; then taken off the fire, twisted in different directions, and at the same time dragged along the convex part of a plantain tree prepared for this purpose; and while this is being done, the other bag is being heated, to be afterwards

By ebullition with potash, it is decomposed into ammonia and ethyl-lactate of potassium:

G. O. F.

LACTAMIC ACID. Syn. with ALANINE (i. 63). It is also produced by the action of very strong solution of ammonia on chloropropionate of ethyl at 100°. (Kolbe, Ann. Ch. Pharm. exiii. 220.)

Lactamate of ammonium (so called), $\text{C}^{\text{H}^1}\text{N}^1\text{O}^1 = \begin{array}{c} \text{H}^1 \\ (\text{C}^{\text{H}^1}\text{O})^{\text{H}^2} \end{array} \begin{array}{c} \text{N} \\ \text{O} \end{array}$.—Formed by

the action of ammonia-gas on lactic anhydride (DILACTIC ACID, p. 461) (Pelouze); or by saturating a solution of lactic anhydride in absolute alcohol with dry ammonia, and evaporating the solution. Tabular crystals, very easily soluble in water and alcohol. On adding dichloride of platinum to the solution, freed by boiling from excess of ammonia, only part of the nitrogen is precipitated as chloroplatinate of ammonium; but after boiling the filtrate for an hour, it gives a further precipitate with dichloride of platinum—a proof that part only of the nitrogen exists in the form of ammonium-salt. (Laurent, Compt. chim. 1846, p. 161.) G. O. F.

LACTAMIDE. $\text{C}^{\text{H}^1}\text{NO}^1 = \begin{array}{c} \text{H} \\ (\text{C}^{\text{H}^1}\text{O})^{\text{H}^2} \end{array} \begin{array}{c} \text{O} \\ \text{N} \end{array}$. (Isomeric with alanine or lac-

tamic acid (i. 63), $\text{C}^{\text{H}^1}\text{NO}^1 = \begin{array}{c} \text{H}^1 \\ (\text{C}^{\text{H}^1}\text{O})^{\text{H}^2} \end{array} \begin{array}{c} \text{N} \\ \text{O} \end{array}$.)—Obtained—1. By the action of ammonia gas on lactide (Pelouze; Wurtz and Friedel, Ann. Ch. Phys. [3] lxiii. 108). —2. By the action of an alcoholic solution of ammonia on lactide (Wurtz and Friedel, loc. cit.).—3. By saturating monethylic lactate with ammonia and leaving the liquid to stand. (Brüning, Ann. Ch. Pharm. civ. 197.)

It forms small prisms, which dissolve easily in water and alcohol, but do not combine either with acids or bases. It is decomposed, by boiling with alkalis or acids, into ammonia and lactic acid.

The above formula represents lactamide as derived from the double molecule $\begin{array}{c} \text{H}^1\text{O} \\ \text{H}^1\text{N} \end{array}$ by the substitution of the radicle $\text{C}^{\text{H}^1}\text{O}$ for H^1 . The substances described under the names lactamethane (p. 462), and lactethylamide (*vid. inf.*), are ethylised derivatives of lactamide; the former by the substitution of C^{H^1} for the hydrogen-atom of the water-residue contained in lactamide, the latter by the substitution of C^{H^1} for one of the hydrogen atoms of the ammonia-residue. These relations are expressed in the rational formulae by which lactamethane, lactethylamide, and lactamide are respectively represented at the places referred to. G. O. F.

LACTETHYLAMIDE. $\text{C}^{\text{H}^1}\text{NO}^1 = \begin{array}{c} \text{H} \\ (\text{C}^{\text{H}^1}\text{O})^{\text{C}^{\text{H}^1}\text{H}} \end{array} \begin{array}{c} \text{O} \\ \text{N} \end{array}$. Isomeric with lactame-

thane (Wurtz and Friedel, Ann. Ch. Phys. [3] lxiii. 110). Formed by the action of ethylamine on lactide. When these two substances are brought together, the ethylamine immediately begins to boil. If the operation is performed in a close vessel, and with anhydrous materials, the whole solidifies to a crystalline mass. This product, when purified by one crystallisation from alcohol, melts at 48°, and may be cooled to 40° without freezing; but as soon as crystallisation has commenced, the thermometer rises to 46.5°. Lactethylamide distills without alteration at 260°. Its formation is represented by the equation

Alkalis decompose it into ethylamine and alkaline lactate.

G. O. F.

LACTIC ACID. *Milchsäure*, $\text{C}^{\text{H}^1}\text{O}^1 = \begin{array}{c} \text{C}^{\text{H}^1}\text{O}^1 \\ \text{H}^1 \end{array} \begin{array}{c} \text{O}^1 \\ \text{O}^1 \end{array}$. (Gm. xi. 472).—This acid was discovered by Scheele in sour milk, and first recognised as a peculiar acid by Berzelius. Braconnot found in the wash-liquor of the preparation of wheat-starch, in the fermented juice of mangold-wurzel, and other fermented vegetable extracts,

an acid which he designated *nanceic acid*, but which was afterwards shown to be identical with the acid of sour milk. Berzelius demonstrated the presence of the same or an isomeric acid in the juice of the flesh of animals recently killed—a result which was confirmed by Liebig in his classical investigation of flesh-juice (see SARCOLACTIC ACID, p. 457). More recently, the chemical relations of lactic acid have been investigated by Strecker (Ann. Ch. Pharm. lxxxi. 247; xci. 352), Wurtz (Ann. Ch. Phys. [3] lix. 161), Wurtz and Friedel (*ibid.* lxiii. 101), and Kolbe (Chem. Soc. Qu. J. xii. 15); and the lactates have been chiefly studied by Pelouze (Ann. Ch. Phys. [3] xiii. 257), and by Engelhardt and Maddrell (Ann. Ch. Pharm. lxii. 83; lxx. 241).

Formation.—1. By a peculiar fermentation, the *lactic acid fermentation*, of various kinds of sugar, and of dextrin: this fermentation precedes the butyric acid fermentation. As all the substances of the sugar tribe have the same proportional composition as lactic acid, with a few atoms of water more or less, the transformation is easily explained: thus, with milk-sugar:

The lactic fermentation requires a temperature between 20° and 40° C., and the presence of water and of certain ferments, viz., albuminoid substances in a peculiar state of decomposition, such as casein, gluten, or animal membranes, particularly the coating of the stomach of the calf (rennet), or dog, and bladder.

2. Tritylglycol, in presence of platinum-black, is converted into lactic acid by the oxygen of the air (Wurtz):

3. Chloropropionic acid yields chloride of silver and lactic acid, when it is heated with water and oxide of silver. (Wurtz, Ann. Ch. Phys. [3] lix. 165):

Similarly, bromopropionic acid yields lactic acid and bromide of silver, when treated with oxide of silver in presence of water (Friedel and Machuca, Ann. Ch. Pharm. cxx. 286). Iodopropionic acid (formed by the action of iodide of phosphorus on glyceric acid) appears to yield a peculiar modification of lactic acid when treated as above. (Beilstein, *ibid.* p. 234.)

4. By the action of nitrous acid upon alanine; as when the vapours evolved from a mixture of starch and nitric acid, after being passed through a cold vessel which stops any undecomposed nitric acid, are conducted into aqueous alanine; the action is attended with copious evolution of nitrogen:

5. Pyruvic (pyraccenic) acid, treated in aqueous solution with sodium-amalgam (Wislicenus, Ann. Ch. Pharm. cxxvi. 227), or with zinc in presence of dilute acetic acid (Debus, Chem. Soc. J. xvi. 260), is converted into a salt of lactic acid:

6. When hydroxycyanide of ethylene, $\begin{array}{c} (\text{C}^2\text{H}^3)^{\text{CN}} \\ \text{H} \end{array} \text{O}$ (obtained from hydroxychloride of ethylene by double decomposition with cyanide of potassium), is boiled with aqueous alkalis, it is resolved into ammonia and (sayco-) lactic acid. (Wislicenus, Ann. Ch. Pharm. cxxviii. 6):

Ethylloxycyanide of ethylidene, $\begin{array}{c} (\text{C}^2\text{H}^3)^{\text{CN}} \\ \text{C}^2\text{H}^3 \end{array} \text{O}$ (obtained by digesting ethylchloride of ethylidene [ii. 600] with cyanide of potassium in a sealed tube), yields ordinary lactic acid, and a small quantity of ethyl-lactic acid, when similarly treated. (Wislicenus, *op. cit.* p. 14.)

7. Oxychloride of carbon combines directly with ethylene, forming chloride of lactyl:

whence lactic acid can be obtained by well-known processes. (Lippmann, Ann. Ch. Pharm. cxxix. 81; Ann. Ch. Phys. [4] i. 485.)

Preparation.—a. *From various kinds of Sugar.*—1. An aqueous solution of 100 pts. of grape-sugar (cane- or milk-sugar), exhibiting the density of 8° to 10° Bm., is mixed

with 8 or 10 pts. of fresh sour cheese, as purchased in the market, or 100 pts. of sugar are dissolved in 100 to 150 pts. of milk, and such a quantity of water that the liquid exhibits a density of 10° Bm.; and either of these mixtures is placed, together with 50 pts. of chalk, in an open vessel, and exposed to the sun for several weeks, with frequent agitation, till the resulting lactate of calcium begins to change into butyrate (Pelouze and Gellis). As lactate of calcium is much less soluble than butyrate, the conversion of the former into the latter may be recognised, when strong solutions of sugar are used, by the diminution of the crystalline mass produced at first. If the process be too soon interrupted, a large quantity of sugar remains unaltered.

2. Six pounds of cane-sugar and half an ounce of tartaric acid (which serves to convert the cane-sugar into glucose) are dissolved in 26 pounds of boiling water; 3 pounds of levigated chalk added after two days, together with 4 ounces of stinking hand-cheese, suspended in 8 pounds of sour milk (decaying cheese favours the production of lactic acid and retards its conversion into butyric acid); the mixture set aside at a temperature between 30° and 36° , and well stirred every day till, in the course of six or eight days, it is converted into a stiff paste of lactate of calcium; this paste is boiled for an hour with half an ounce of quicklime and 20 pounds of water; the solution strained through a cloth filter and evaporated to a syrup; the crystalline mass which forms in four days, pressed, first by itself, then three or four times, after having been each time stirred up, with $\frac{1}{10}$ pt. of cold water; and the lactate of calcium thus purified is dissolved in twice its weight of boiling water. To the solution of every 32 pts. of the calcium-salt there is then added a mixture of 7 pts. oil of vitriol and 7 pts. water; the lactic acid, while still hot, is strained through linen to separate it from sulphate of lime; the filtrate obtained from 7 pts. of oil of vitriol is boiled with $1\frac{1}{2}$ pts. carbonate of zinc for a quarter of an hour (by longer boiling a very sparingly soluble basic salt is formed); the liquid is filtered boiling hot; the colourless crystalline grains of lactate of zinc which separate on cooling, are freed from sulphuric acid by washing with cold water; and additional quantities of crystalline grains are obtained by evaporating the mother-liquor, almost to the end. Lastly, 1 pt. of the zinc-salt is dissolved in $7\frac{1}{2}$ pts. of boiling water; sulphuretted hydrogen passed through the solution as long as sulphide of zinc is precipitated; and the filtrate boiled and evaporated on the water-bath to a syrup, whereupon 8 pts. of the zinc-salt yield 5 pts. of syrupy lactic acid (Bensch, Ann. Ch. Pharm. lxi. 174). By this process, 100 pts. of cane-sugar yield 117 pts. of lactate of calcium, which, if the sugar was white, is colourless, and does not require to be purified by pressure. If the carbonate of zinc contains lime and magnesia, these bases pass over to the lactic acid, which, after being evaporated to a syrup, must be dissolved in ether, and separated from the lactates of calcium and magnesium by filtration and evaporation. The calcium-salt may, however, without first preparing the zinc-salt from it, be freed by repeated crystallisation from a nitrogenous substance which obstinately adheres to it; its solution in the smallest possible quantity of water, mixed with a quantity of pure sulphuric acid not quite sufficient to decompose it; the mixture heated with alcohol till the sulphate of calcium is completely separated; the filtrate evaporated to a syrup; the syrup dissolved in ether; and the ethereal solution filtered and evaporated. (Engelhardt and Maddrell.)

Lautemann (Ann. Ch. Pharm. cxiii. 212) recommends the following modification of Bensch's process of preparation:—Retaining the proportions of sugar, tartaric acid, milk, and cheese indicated by the latter, he takes one-third more water, uses 1,200 grms. oxide of zinc (commercial zinc-white) instead of levigated chalk, and keeps the temperature as constantly as possible between 40° and 45° during the fermentation. After eight or ten days, the inside of the vessel is lined with white crystals of lactate of zinc, which can be obtained pure by one or two crystallisations from boiling water. The lactic acid prepared from the zinc-salt generally contains mannite, which does not completely crystallise out from the concentrated acid. To separate this, the aqueous acid is shaken up with ether, and then the ethereal layer is pipetted off and evaporated; it then leaves pure lactic acid.

3. The solution of 300 grms. of milk-sugar in 4 litres of milk is placed in the open air at a temperature of 25° to 30° , and neutralised with acid carbonate of sodium as often as it becomes sour, perhaps every two days; boiled when it no longer turns acid; filtered from the curd; carefully evaporated to a syrup; and the syrup dissolved in moderately warm alcohol of 38° Bm. By treating this filtered alcoholic solution of lactate of sodium with sulphuric acid to precipitate the sodium, and saturating the filtered lactic acid with chalk, crystallised lactate of calcium is obtained, and may be purified by further treatment. (Boutron and Frémy, J. Pharm. xxvii. 341.)

b. *From milk which has turned sour.*—1. Scheele evaporates sour whey to $\frac{1}{2}$; filters the liquid from the curd; precipitates the phosphoric acid from it with lime; filters; dilutes with 3 pts. water; precipitates the lime by careful addition of oxalic acid; filters; evaporates to the consistence of honey; extracts the lactic acid with alcohol;

filters; dilutes with water, and evaporates. Berzelius digests the acid thus obtained with carbonate of lead; filters; precipitates the dissolved lead with sulphydric acid, filters, and evaporates.—2. The filtered solution of sour whey evaporated nearly to dryness, in strong alcohol, is mixed with alcoholic tartaric acid, as long as any precipitate of tartrate of potassium, sodium, and calcium is formed; the liquid decanted after 24 hours, and evaporated; the residue dissolved in water; the solution digested with carbonate of lead, till lead dissolves in it; the filtrate evaporated, neutralised with carbonate of barium, again filtered, and diluted with water; the whole of the barium precipitated with sulphate of zinc; and the filtrate evaporated till lactate of zinc crystallises out (Berzelius, *Lehrb.* Aug. 5, v. 241. For the earlier methods of Berzelius, see *Pogg. Ann.* xix. 26). W. Engelhardt (*Zeitschr. Chem. Pharm.* 1861, p. 643) gives the following process for the preparation of lactate of zinc, from which he then obtains lactic acid by decomposing the hot solution of the zinc-salt with sulphydric acid, filtering and evaporating. Sour whey, to which $\frac{1}{10}$ of its weight of powdered milk-sugar has been added, is exposed to the proper temperature for the lactic fermentation, and every one or two days the free acid is neutralised with crushed carbonate of sodium taken from a previously weighed quantity. When at last the acid reaction does not reappear after two or three days, the liquid is heated to boiling, and sulphuric acid is added, drop by drop, so as to produce a distinct acid reaction. A quantity of sulphate of zinc equal in weight to the carbonate of sodium used is then dissolved in twice its own weight of water, and mixed with the other boiling liquid; the cheesy portions which immediately separate at the surface are removed by filtration through flannel-bag and the clear liquid is set aside to crystallise. After a day or two, the crystalline deposit of lactate of zinc may be removed and washed with cold water. The quantity remaining in the mother-liquor is insignificant. (For Cap and O. Henry's process, see *J. Pharm.* xxv. 138; also *Ann. Ch. Pharm.* xxx. 106.)

Properties.—Lactic acid is a colourless liquid of syrupy consistence, and specific gravity 1.215 at 20.5° C. It is inodorous, but has an intensely sour taste. It absorbs moisture from the air; dissolves in all proportions in water and alcohol, somewhat less freely in ether. It does not solidify at -24° C.

Decompositions.—1. *Dry distillation.* The acid, when very gradually heated, becomes less viscid; gives off at 130°, slowly and without evolution of gas, colourless water, together with a small quantity of lactic acid, and leaves a pale yellow, solid, easily fusible, extremely bitter residue of *lactic anhydride* (dilactic acid), $C^4H^4O^3 = 2C^2H^2O^2 - H^2O$. This residue remains unaltered up to 250°, but from 250° to 300°, at which temperature the decomposition is complete, gives off carbonic oxide gas, mixed at first with 4 or 5, and at last with 50 per cent. of its volume of carbonic anhydride (altogether a quantity of gas amounting to 33.1 per cent. of the lactic anhydride), and yields a distillate amounting to 90 per cent. of the anhydride, and consisting of *lactide*, $C^4H^4O^4 = 2C^2H^2O^2 - 2H^2O$ (p. 464), which crystallises out on cooling and likewise sublimes, of *lactone* (p. 464), with small quantities of acetone, and an odoriferous oil insoluble in water, whilst a quantity of difficultly combustible charcoal remains, amounting to 6.9 per cent. of the anhydride (Pelouze). The anhydride, which remains undecomposed after heating to 240°, gives off, when kept for some time between 250° and 260°, carbonic oxide mixed with 3 or 4 per cent. of its bulk of carbonic anhydride (without any carburetted hydrogen); yields a yellowish distillate, which deposits crystals of lactide, and contains, in addition to the lactide (amounting to 14.9 per cent. of the anhydride), nothing but ordinary lactic acid, citraconic acid, aldehyde (amounting to 12.2 per cent. of the anhydride), but neither acetone nor lactone; and leaves 1 or 2 per cent. of shining, easily combustible charcoal. The aldehyde and the citraconic acid [?] are perhaps merely products of decomposition of the lactide, $C^4H^4O^4 = 2C^2H^2O^2 + 2CO$. The ordinary lactic acid is formed from a portion of the anhydride by addition of the water set free by the conversion of the remainder into lactide. If the anhydride be distilled at 300° instead of 260°, less lactic acid and lactide are obtained, and more aldehyde (Engelhardt). Lactic acid, when heated, gives off pungent vapours which excite coughing, and yields a brown empyreumatic oil, together with an acid liquid, the acid of which is neither lactic nor acetic acid, but forms a viscid uncrystallisable salt with oxide of zinc (Braconnot, *Ann. Ch. Phys.* l. 375). It yields a watery distillate continually becoming more acid, the first portion of which, however, assumes a syrupy consistence when evaporated *in vacuo*, and if then gently heated in contact with the air, deposits crystals of lactide; it afterwards yields an oil and then a buttery mass, which solidifies in the neck of the retort, and when exhausted with cold ether, leaves scales and ultimately rhombic laminae. Lastly, there remains a shining, tumeffed charcoal. The acid which remains after partial distillation likewise contains a certain quantity of lactide; and on boiling this acid with ether and cooling the liquid, the lactide crystallises out (Corriol). By continued heating to between 180° and 200°, the acid is much more quickly converted into the anhydride, and yields a much more copious distillate of the unaltered acid, than between 130° and 140°;

and if a platinum wire be immersed in the liquid, the lactic acid may be distilled over quite unaltered, and with regular ebullition (Engelhardt). If the lactic acid contains a small quantity of sulphuric acid, it yields only carbonic oxide gas, no carbonic anhydride (Pelouze). If it contains the smallest quantity of impurity, albumen for example, it does not yield any sublimate of lactide (Gay-Lussac and Pelouze). Lactic acid, heated slowly in contact with the air, boils gently, emitting a suffocating odour, swells up, blackens, and leaves a spongy charcoal. (Berzelius.)

2. Lactic acid (or ferrous lactate), mixed with a sixfold quantity of oil of vitriol, and gently heated, froths up briskly, acquires a dark-brown colour; gives off about $\frac{1}{2}$ of its weight of pure carbonic oxide gas; and at a higher temperature, yields about $\frac{1}{3}$ of its weight of a humus-like substance. (Pelouze.)

3. Boiling nitric acid converts lactic into oxalic acid. (Jules Gay-Lussac and Pelouze.)

4. Lactic acid and its salts, distilled with small quantities of common salt, peroxide of manganese, sulphuric acid, and water, yield chiefly aldehyde; with larger quantities, principally chloral. (Städeler, Ann. Ch. Pharm. lxi. 332.)

5. With aqueous alkaline hypochlorite, or chlorous acid, lactic acid is converted, first into oxalic acid, then, with effervescence, into carbonic anhydride. (Cap and Henry.)

6. When treated with peroxide of barium or of lead, it is converted chiefly into oxalic acid. (Cap and Henry.)

7. Distilled with dilute sulphuric acid and peroxide of manganese or peroxide of lead, it yields a large quantity of aldehyde, together with carbonic anhydride. (Liebig.)

8. Lactate of calcium distilled with pentachloride of phosphorus, yields chloride of lactyl (C^3H^4O). Cl^2 :

9. Hydriodic acid, or a mixture of di-iodide of phosphorus with a small quantity of water, reduces lactic acid to propionic acid:

(Lautemann, Ann. Ch. Pharm. cxiii. 217.)

10. The action of fuming sulphuric acid upon lactic acid or lactate of calcium produces di-sulphometholic acid. (Strecker, Ann. Ch. Pharm. cxviii. 291.)

Sarcolactic or Paralactic Acid. In 1806, Berzelius discovered an acid in muscular flesh which he believed to be identical with the lactic acid prepared from milk. In 1847, Liebig (Ann. Ch. Pharm. lxii. 278 and 326) showed that this acid, though similar to the acid of sour milk in composition and in many other respects, nevertheless exhibited distinct differences from it in some of its salts. He therefore distinguished it by the name Sarcolactic acid (*Fleischmilchsäure*), in place of which Paralactic acid was proposed by Heintz (Pogg. Ann. lxxv. 391). In 1858, it was found by Strecker (Ann. Ch. Pharm. cv. 313) that, by heating paralactic acid for a long time to 130° or 140° and dissolving the resulting lactic anhydride in water, this acid may be transformed into ordinary lactic acid.

Preparation.—Chopped flesh is exhausted with cold water or dilute alcohol; the infusion is mixed with baryta-water; the albumin is coagulated by boiling, and removed by filtration; and the clear liquid is concentrated by evaporation. Sulphuric acid is added to the syrupy residue, and it is shaken with ether, which then leaves paralactic acid when evaporated.

The difference between sarcolactic and ordinary lactic acids is most distinctly marked in their calcium- and zinc-salts (see below, Lactate of calcium and Lactate of zinc): the acids themselves are hardly to be distinguished.

Thebolactic acid. This is another modification of lactic acid found, by T. and H. Smith, of Edinburgh, in the mother-liquors of the preparation of morphine. Some of its salts are said to differ in certain respects from ordinary lactic acid (see THEOBOLACTIC ACID).

Lactates. The best known salts of lactic acid are of the form $C^3H^5MO^2$; there are also acid salts containing $C^3H^4MO^2.C^3H^4O^2$, and double salts, $C^3H^4MO^2.C^3H^5MO^2$. The existence of these acid and double salts led Gerhardt and other chemists to double the formula of lactic acid, making it $C^6H^{10}O^4$, and regarding the neutral salts as $C^6H^{10}M^2O^8$, and the acid salts as $C^6H^{10}MO^4$. But the relations between lactic and propionic acids have induced chemists in general to return to the lower formula of lactic acid, and to regard the acid lactates as constituted like the acid acetate of potassium (i. 17). Moreover, Wurtz's discovery of the diethylic lactate would render it necessary to regard the acid with the higher formula as tetrabasic, for which there is no warrant.

The crystalline lactates do not effloresce on exposure to the air, but give off water *in vacuo*, and the whole of it at 100° , excepting the acid nickel salt which retains it till heated to 130° . They sustain a heat of 150° to 170° without decomposition; the

zinc-salt may be heated even to 200°. They are for the most part sparingly soluble in cold water, and effloresce rapidly from their solutions: they are all insoluble in ether.

LACTATE OF AMMONIUM.—Obtained by neutralising the acid with ammonia. Forms prismatic crystals which deliquesce and give off ammonia when exposed to the air.

LACTATE OF ANTIMONY.—Oxide of antimony dissolves in lactic acid or in acid lactate of potassium, but does not form a crystalline salt.

LACTATE OF BARIUM.—The *neutral salt* is uncrystallisable and very soluble in water. The *acid salt*, $\text{Ba}''(\text{C}^3\text{H}^5\text{O}^3)^2 \cdot 2\text{C}^3\text{H}^5\text{O}^3$, is obtained by adding to a solution of the neutral salt a quantity of lactic acid equal to that which it already contains. It is then deposited in crystals which may be purified by washing with alcohol. It is not altered by exposure to the air or *in vacuo*. It dissolves easily in water. Gives off an aromatic odour at 100°.

LACTATE OF BISMUTH.—Only two basic salts are known: *a*. $2\text{Bi}'''(\text{C}^3\text{H}^5\text{O}^3)^3 \cdot \text{Bi}^2\text{O}^3$. This salt is obtained in needles by treating hydrate or carbonate of bismuth with lactic acid, and evaporating. A better mode of preparing it is to mix the concentrated solutions of nitrate of bismuth and lactate of sodium—the latter in slight excess, whereby a crystalline pulp is precipitated consisting of lactate of bismuth mixed with nitre. On redissolving this in a small quantity of water, and leaving the solution at rest, the lactate of bismuth is deposited in crystalline crusts.

β. $\text{Bi}'''(\text{C}^3\text{H}^5\text{O}^3)^3 \cdot 2\text{Bi}^2\text{O}^3$.—By proceeding in the manner just described, but with boiling solutions, or by adding nitrate of bismuth drop by drop to a solution of lactate of sodium, the salt *β* is precipitated as a powder unalterable in boiling water. It appears also to be produced by the solution of *a*.

LACTATE OF CADMIUM, $\text{Cd}''(\text{C}^3\text{H}^5\text{O}^3)^2$.—Obtained in small needles by dissolving carbonate of cadmium in the acid. When deposited from a boiling solution, it is anhydrous. Insoluble in alcohol.

LACTATES OF CALCIUM.—The *neutral acetate*, $\text{Ca}''(\text{C}^3\text{H}^5\text{O}^3)^2 \cdot 4\text{H}^2\text{O}$ and $\text{Ca}''(\text{C}^3\text{H}^5\text{O}^3)^2 \cdot 5\text{H}^2\text{O}$, is obtained by saturating a boiling solution of lactic acid with carbonate of calcium, and evaporating the filtered liquid. It is also produced abundantly when a solution of sugar mixed with cheese and carbonate of calcium is left to itself for some weeks at a temperature of 20° to 30° C. According to Corriol, the same salt is deposited from an infusion of *nux vomica* which has fermented for a few days. It is deposited from an aqueous or alcoholic solution in small, very white, mammellated crystals. It dissolves in all proportions in water and in alcohol at the boiling heat, but cold water dissolves only traces of it.

The characters of this salt differ somewhat according as it has been prepared with lactic acid *α* extracted from muscular flesh (sarcolactic acid), or from lactic acid *β*, produced by the fermentation of sugar.

The salt of the acid *α*, deposited from an aqueous solution, contains 2 at. water; that of the acid *β* crystallised in the same way contains 5 at. $\text{Ca}''(\text{C}^3\text{H}^5\text{O}^3)^2 \cdot 5\text{H}^2\text{O}$. The lactate *α* retains its water of crystallisation at 100° longer than the salt *β*. Lastly, the salt *α* requires 12·4 pts. of water to dissolve it; whereas the salt *β* dissolves in 9·5 pts. Pure lactate of calcium, dried at 100°, and containing $\text{Ca}''(\text{C}^3\text{H}^5\text{O}^3)^2$, loses water at 280°, and is converted into dialclic dilactate, $\text{C}^3\text{H}^5\text{Ca}''\text{O}^3$ (DILACTIC ACID, p. 461). (Wurtz and Friedel.)

Acid lactate of calcium, $\text{Ca}''(\text{C}^3\text{H}^5\text{O}^3)^2 \cdot 2\text{C}^3\text{H}^5\text{O}^3 \cdot 3\text{H}^2\text{O}$, obtained by mixing a solution of the neutral lactate with as much lactic acid as it already contains, forms crystalline masses resembling wavellite. It dissolves in absolute alcohol, gives off its water of crystallisation at 80°, and rapidly turns brown at a higher temperature.

Lactate of calcium and potassium.—Obtained by incompletely precipitating a solution of lactate of calcium with carbonate of potassium. It forms hard crystals soluble in water.

Lactate with chloride of calcium, $\text{Ca}''(\text{C}^3\text{H}^5\text{O}^3)^2 \cdot \text{Ca}''\text{Cl}_2 \cdot 6\text{H}^2\text{O}$.—Obtained in prisms by mixing the solutions of the two salts, and concentrating the liquid considerably.

LACTATE OF CHROMIUM is an uncrystallisable salt.

LACTATE OF COBALT, $\text{Co}''(\text{C}^3\text{H}^5\text{O}^3)^2 \cdot 6\text{H}^2\text{O}$.—Peach-blossom-coloured needles, nearly insoluble in cold water, moderately soluble in boiling water, insoluble in alcohol. Its solution has a slight acid reaction.

LACTATE OF COPPER, $\text{Cu}''(\text{C}^3\text{H}^5\text{O}^3)^2 \cdot 3\text{H}^2\text{O}$ and $2\text{H}^2\text{O}$, is obtained by precipitating sulphate of copper with lactate of barium, or by boiling carbonate of copper with lactic acid. By the latter method a basic salt is also produced, from which the product must be purified by recrystallisation or by addition of lactic acid.

Lactate of copper *α* (sarcolactate) crystallises in sky-blue nodules containing 3 at. water, which it does not give up at 100° till after a considerable time; whereas *β* forms larger crystals, of a green or very dark blue colour, and containing 2 at. water, which they give off by simple desiccation over sulphuric acid. The salt *α* exposed to a gradually increasing heat does not exhibit any change below 210°; but at that temperature it takes fire and burns, leaving a residue of metallic copper. *β* heated in like

manner decomposes at 140° , leaving a residue of cuprous oxide. Lastly, α dissolves in 1.95 pt. cold water, in 1.24 pt. boiling water, and in a small proportion of alcohol; whereas β requires for solution 6 pts. of cold water, 22 pts. boiling water, 115 pts. cold alcohol, and 26 pts. boiling alcohol.

LACTATES OF IRON.—*Ferrous lactate*, $\text{Fe}''(\text{C}^2\text{H}^3\text{O}^2)^2.3\text{H}^2\text{O}$, may be prepared by decomposing the calcium-salt with ferrous sulphate, or by mixing lactate of ammonium with ferrous chloride in presence of alcohol; also by boiling dilute lactic acid with iron filings. It forms small crystals having a slight greenish tint; their solution oxidises but slowly on exposure to the air. This salt is sometimes used medicinally in the treatment of chlorosis.

Ferric lactate is a brown amorphous mass, deliquescent, and very soluble in water.

LACTATE OF LEAD.—By treating carbonate of lead with boiling lactic acid, a neutral liquid is obtained, which when evaporated deposits a mass of small pellicles, and acquires an acid reaction.

LACTATE OF MAGNESIUM, $\text{Mg}''(\text{C}^2\text{H}^3\text{O}^2)^2.4\text{H}^2\text{O}$ and $3\text{H}^2\text{O}$.—Obtained by dissolving magnesia in lactic acid. Crystallises in prisms permanent in the air, soluble in water, insoluble in alcohol. The salt α (sarcocollate) contains 4 at. water; the salt β contains 3 at. The salt α is also much more soluble in water and alcohol than β .

LACTATE OF MANGANESE, $\text{Mn}''(\text{C}^2\text{H}^3\text{O}^2)^2.3\text{H}^2\text{O}$.—Large, brilliant, amethyst-coloured crystals, moderately soluble in cold water, very soluble in hot water; soluble also in alcohol.

LACTATES OF MERCURY.—*Mercurous lactate*, $(\text{Hg}^2)^2(\text{C}^2\text{H}^3\text{O}^2)^2.2\text{H}^2\text{O}$. Rose-coloured or crimson crystals, obtained by mixing the boiling solutions of lactate of sodium and mercurous nitrate.

Mercuric lactate.—The neutral salt is not known. A basic salt, $\text{Hg}''(\text{C}^2\text{H}^3\text{O}^2)^2.\text{Hg}^2\text{O}$, is obtained by boiling mercuric oxide with dilute lactic acid till the liquid is saturated. The solution yields by evaporation a yellow salt, insoluble in water, and a colourless salt which is very soluble. The latter, which has the composition above given, crystallises in shining prisms which effloresce rapidly in the air, and are very sparingly soluble in alcohol.

LACTATE OF NICKEL, $\text{Ni}''(\text{C}^2\text{H}^3\text{O}^2)^2.3\text{H}^2\text{O}$.—Apple-green needles, very soluble in cold water, more soluble in hot water, insoluble in alcohol. The solution has a slight acid reaction. According to Engelhardt, the salt α gives off the whole of its water at 100° , but β does not part with the third atom before 130° .

LACTATE OF POTASSIUM.—Very soluble, and crystallises with difficulty.

LACTATE OF SILVER, $\text{AgC}^2\text{H}^3\text{O}^2.\text{H}^2\text{O}$.—Obtained by boiling carbonate of silver with lactic acid. It forms silky needles grouped in nodules, neutral to test-paper, blackening quickly by exposure to light, very soluble in warm alcohol, nearly insoluble in cold alcohol. The aqueous solution, when boiled for some time, acquires a fine blue colour, and deposits brown flakes. It may be heated to 80° without decomposing, but blackens and gives off gas at 100° . The air-dried salt contains 2 at. water, which it gives off *in vacuo*.

LACTATES OF SODIUM.—*Monosodic lactate*, $\text{NaC}^2\text{H}^3\text{O}^2$. An amorphous, deliquescent mass, very soluble in water and absolute alcohol; ether precipitates it from its alcoholic solution. Dried at 140° , it possesses the above composition. (Wislicenus.)

Disodic lactate.—Monosodic lactate heated to 130° is acted on by sodium, hydrogen being liberated and a sodium-salt formed, which, together with unaltered monosodic lactate, contains disodic lactate. The product thus obtained is a bright yellow, very hard and brittle mass. It deliquesces quickly in the air. When covered with water, it is decomposed, with very perceptible development of heat, into monosodic lactate and hydrate of sodium. The deliquescent salt absorbs carbonic anhydride from the air; so that when it has been long exposed, absolute alcohol dissolves out monosodic lactate, leaving a residue of carbonate of sodium. Disodic lactate appears to dissolve without alteration in perfectly anhydrous alcohol. With iodide of methyl, it yields iodide of sodium and methyl-lactate of sodium. (Wislicenus, Ann. Ch. Pharm. cxiv. 49.)

LACTATE OF STRONTIUM, $\text{Sr}''(\text{C}^2\text{H}^3\text{O}^2)^2.3\text{H}^2\text{O}$.—Neutral and very soluble.

LACTATE OF TIN. *Stannous lactate*, $\text{Sn}''(\text{C}^2\text{H}^3\text{O}^2)^2.\text{Sn}^2\text{O}$.—This basic salt is obtained by mixing an acid solution of stannous chloride with lactate of sodium. It is a white crystalline powder, insoluble in cold water, very soluble in hydrochloric acid; soluble also in acetic acid after prolonged ebullition.

Stannic chloride mixed with lactate of sodium does not yield crystals, or a precipitate even after concentration to a syrup.

LACTATE OF URANIUM.—Uranic lactate, $(\text{U}^2\text{O})''(\text{C}^2\text{H}^3\text{O}^2)^2$, is obtained in yellow crystalline crusts by evaporating a solution of uranic oxide in lactic acid.

LACTATE OF ZINC, $\text{Zn}''(\text{C}^2\text{H}^3\text{O}^2)^2.3\text{H}^2\text{O}$ and $2\text{H}^2\text{O}$.—Prepared by boiling carbonate of zinc with lactic acid. The salt α (sarcocollate) is deposited, as the solution cools, in very dilute needles, irregularly grouped; on touching the vessel, these groups separate,

and the whole of the liquid solidifies to a pulp. The salt β forms sometimes shining crusts, sometimes large needles irregularly grouped.

The salt α contains 1 at., the salt β $\frac{2}{3}$ at. water, which it gives off quickly at 100° ; whereas α requires heating for several hours to dehydrate it completely. β may be heated without alteration to 210° , whereas α begins to give off empyreumatic vapours between 100° and 150° .

The two salts also differ greatly in solubility. α dissolves in 2.88 pts. of boiling and 5.7 pts. of cold water; in 2.23 pts. of cold alcohol, and in about the same quantity with boiling heat. The salt β requires for solution 6 pts. of boiling water, 5.8 pts. of cold water, and is nearly insoluble in alcohol.

According to Liebig, the neutral salt prepared with lactic acid from sourcroust splits up, when its solution is mixed with alcohol, into a basic and an acid salt. Engelhardt did not observe this decomposition of the zinc-salt prepared with lactic acid obtained by the fermentation of sugar.

Derivatives of Lactic acid.

Acetolactic acid. $C^3H^3O^4 = \begin{matrix} C^3H^3O \\ (C^3H^3O)'' \\ H \end{matrix} \begin{matrix} O \\ O \\ O \end{matrix}$. (Wislicenus, Ann. Ch. Pharm.

cxv. 60.)—Obtained from acetolactate of ethyl (*vid. inf.*) by heating it with water to 150° for two or three hours. It is a thick, syrupy liquid; very easily soluble in water; and has an agreeable, purely acid taste, without any irritating after-taste. It is not volatile without decomposition, but is carried over to a considerable extent by water-vapour; even then, however, it is partially decomposed into acetic and lactic acids. Under all circumstances, indeed, both the acid and its salts readily undergo decomposition into these two acids.

Acetolactate of barium, $Ba''(C^3H^3O^4)^2.4H^2O$.—Acetolactic acid dissolves carbonate of barium, with evolution of carbonic anhydride. The solution is warmed for a very short time with excess of the carbonate, in order to complete the neutralisation (longer heating would cause decomposition into lactate and carbonate); then filtered, and evaporated to a syrup on the water-bath. This syrup becomes a tough mass on cooling, and dries up over sulphuric acid *in vacuo* to a brittle and pulverisable substance resembling gum. It then still retains 4 molecules of water, two of which are given off at 100° , the remainder only at 140° . Acetolactate of barium is very soluble in water, and dissolves also in absolute alcohol. Ether produces in the alcoholic solution a flocculent precipitate, which soon unites into a tough, sticky mass.

Acetolactate of copper.—Obtained as a blue-green, amorphous, gummy mass, by decomposing the barium-salt with sulphate of copper, and evaporating. It dissolves easily in water and alcohol, and becomes moist when exposed to the air.

Acetolactate of zinc, $Zn''(C^3H^3O^4)^2$.—A cold solution of acetolactate of barium is decomposed with an exactly equivalent quantity of sulphate of zinc, and the liquid is evaporated over sulphuric acid without the aid of heat. The gummy mass thus obtained contains imbedded crystals of lactate and acetate of zinc. To separate these, the acetolactate of zinc is dissolved out by a small quantity of absolute alcohol. By evaporating the solution *in vacuo*, the salt is left as a gummy mass, which, when thoroughly dried over sulphuric acid, is not decomposed at 110° . Its solutions, both aqueous and alcoholic, become quickly acid, owing to the extraordinary ease with which the salt decomposes into acetate and lactate of zinc, and acetic and lactic acids.

Acetolactate of ethyl, $C^3H^3O^4 = \begin{matrix} C^3H^3O \\ (C^3H^3O)'' \\ C^2H^5 \end{matrix} \begin{matrix} O \\ O \\ O \end{matrix}$. Formed by the action of chloride of acetyl on monethylic lactate (p. 463). This reaction, which was first mentioned by Porkin (Zeitschr. Chem. Pharm. 1861, p. 166), has been further investigated by Wislicenus (*loc. cit.* p. 58).

Acetolactate of ethyl is a colourless, mobile liquid, of an agreeable, aromatic smell, recalling that of Calville-apples. It is neutral, and insoluble in water, but is gradually decomposed by it into alcohol and acetolactic acid (see above). It dissolves in alcohol and ether in all proportions, and is precipitated by water from its alcoholic solutions. Boiling point 177° , under 733 mm. pressure. Specific gravity, 1.0458 at 17° , water at the same temperature being taken as unity; vapour-density, found 5.70, calculated 5.54.

Benzolactic acid. $C^3H^3O^4$. (See vol. i. p. 561.)

Butyrolactic acid. $C^4H^5O^4 = \begin{matrix} C^4H^5O \\ (C^4H^5O)'' \\ H \end{matrix} \begin{matrix} O \\ O \\ O \end{matrix}$. (See vol. i. p. 697.—To the description there given of butyrolactate of ethyl, we add the following particulars.)

Boiling point, 208° . Vapour-density, found 6.73, calculated 6.51. Heated with caustic potash in a sealed tube, it is decomposed into alcohol, and lactate and butyrate of potassium. (Wurtz, Ann. Ch. Phys. [3] lix. 177.—This mode of decomposition is important, since, were Kolbe's view of the constitution of butyrolactic acid correct, it ought to yield propionate and butylactate (oxybutyrate) of potassium when decomposed by potash. (Compare Ann. Ch. Pharm. cxiii. 234, 235, also vol. ii. p. 701 of this work.)

Dilactie acid. *Anhydrous lactic acid* (Pelouze), *Acide lactidique* (Laurent),

$\text{C}^3\text{H}^4\text{O}^3 = \left\{ \begin{array}{c} \text{C}^3\text{H}^4\text{O}^2 \\ \text{H}^2 \end{array} \right\} \text{O}^2$. This substance remains as a pale-yellow, amorphous,

easily fusible mass, when lactic acid is exposed for some time to a temperature between 130° and 200° . It is converted into lactic acid, slowly by ebullition with water, quickly by the action of aqueous alkalis. By dry distillation, it is converted into lactide (p. 464). With gaseous ammonia it yields the compound $\text{C}^3\text{H}^4\text{N}^1\text{O}^4$, commonly called lactamate of ammonium, but more correctly dilactylamate of ammonium (p. 453).

Dilactate of calcium, $\text{C}^3\text{H}^4\text{Ca}^1\text{O}^4$.—Obtained by heating lactate of calcium, previously dried at 100° , to 280° . It is much less soluble in absolute alcohol than lactate of calc. am. (Wurtz and Friedel.)

Dilactate of ethyl. Monethylic dilactate, $\text{C}^3\text{H}^4\text{O}^3 = \left\{ \begin{array}{c} \text{C}^3\text{H}^4\text{O}^2 \\ \text{C}^2\text{H}^3\text{H} \end{array} \right\} \text{O}^2$, is formed by the action of chloropropionate of ethyl on lactate of potassium:

It is a colourless, oily liquid, of specific gravity 1.134 at 0° ; boiling point about 235° . It is decomposed, when heated with water in sealed tubes, into alcohol and lactic acid. (Wurtz and Friedel, Ann. Ch. Phys. [3] lxxiii. 112.)

Monosulphodilactic acid, $\text{C}^3\text{H}^4\text{O}^3\text{S}$. (Schacht, Ann. Ch. Pharm. cxxix. 4).—This acid was obtained as the product of an operation conducted with a view to the preparation of sulpholactic acid (p. 462). Instead of neutralising the aqueous solution of the crude product containing sulpholactate of potassium (see p. 462) with hydrochloric acid, it was neutralised with dilute sulphuric acid, and a further quantity of sulphuric acid was then added, sufficient to decompose the sulpholactate only. Monosulphodilactic acid then separated at the surface of the concentrated saline solution, and was obtained pure by solution in ether and evaporation under the air-pump.

Monosulphodilactic acid is soluble in water, alcohol, and ether, but does not crystallise. It contains the elements of two molecules of sulpholactic acid *minus* one molecule of sulphydric acid:

By oxidation with dilute nitric acid, it yields dilactylsulphurous acid, $\text{C}^6\text{H}^8\text{O}^6$ (*Dipropionschwefelsäure*, Schacht), the barium-salt of which is a white amorphous powder containing $\text{C}^6\text{H}^8\text{Ba}^1\text{O}^6$.

Ethyl-lactic acid. See LACTIC ETHERS (p. 463).

Lactylsulphurous acid. *Sulphopropionic acid*, $\text{C}^3\text{H}^4\text{SO}^3$.—This acid is formed by the action of fuming sulphuric acid on cyanide of ethyl, or on propionamide, in the process for preparing disulphetholic acid (Buckton and Hofmann, Chem. Soc. Qu. J. ix. 251); also when sulpholactic acid is oxidised with dilute nitric acid. (Schacht.)

Lactylsulphite of Ammonium is exceedingly soluble in water, and uncrystallisable. Absolute alcohol throws it down as a thick treacly mass.

Lactylsulphite of Barium, $\text{C}^3\text{H}^4\text{Ba}^1\text{SO}^3$, crystallises from a saturated boiling solution in fine silky crystals, arranged in spherical groups. It may be dried at 170° without decomposition.

DILACTYLSULPHUROUS ACID. See above.

Lactyl- and dilactylsulphurous acids may be regarded as containing the radicles of lactic and sulphurous acids, and may be represented by the following rational formulae:

Methyl-lactic acid. See LACTIC ETHERS (p. 464).

Succine-lactic acids. The only known representatives of these substances are

diethylic succinylactate, $C^{11}H^{10}O^4$, and diethylic succinodilactate, $C^{14}H^{12}O^6$. Diethylic succinylactate, $\left. \begin{array}{c} (C^2H^3O^2)^2 \\ (C^2H^3O^2)^2 \end{array} \right\} O^2$, is an oily liquid, insoluble in water, boiling at 280° ,

and of specific gravity 1.119 at 0° , formed by the action of chloropropionic ether on succinate of ethyl and potassium in presence of alcohol. It is decomposed, when heated with baryta-water, into alcohol and succinate and lactate of barium.

Diethylic succinodilactate, $\left. \begin{array}{c} C^2H^3O^2 \\ (C^2H^3O^2)^2 \\ (C^2H^3O^2)^2 \end{array} \right\} O^4$, is a liquid boiling between 250° and 270° , produced by the action of chloropropionate of ethyl upon succinate of potassium. (Wurtz and Friedel.)

Sulpholactic acid, $C^3H^4O^3S = \left. \begin{array}{c} (C^3H^4O^2)^2 \\ H^2 \end{array} \right\} S$. (Schacht, Ann. Ch. Pharm. cxxix. 1.)—The potassium-salt of this acid is formed when an intimate mixture of chloropropionate of potassium and sulphhydrate of potassium is heated for four or five hours to a little above 100° :

To prepare the acid, the mixture of chloride, phosphate, and chloropropionate, obtained by neutralising with carbonate of sodium the crude product of the distillation of lactate of calcium with pentachloride of phosphorus, is mixed with sulphhydrate of potassium (1 molecule of the latter for each molecule of lactate used), and the solution is evaporated and the residue heated as above. The product of this operation is dissolved in water, saturated with hydrochloric acid, warmed to expel sulphydric acid, largely diluted, made slightly alkaline with ammonia, and precipitated with acetate of lead. The lead-precipitate is thoroughly washed with cold water, then decomposed with sulphydric acid, and the filtered liquid repeatedly evaporated to a syrup to remove the hydrochloric acid. The residue is dissolved in water and neutralised at the boiling heat with carbonate of barium, which causes a precipitate of phosphate of barium, while sulpholactate of barium remains in the solution. From this solution the acid is again thrown down as lead-salt; the precipitate is decomposed by sulphydric acid; and the resulting solution of the free acid is concentrated by evaporation on the water-bath.

Sulpholactic acid crystallises in broad needles, grouped together in bundles or brushes; it melts without decomposition below 100° , and solidifies in the crystalline form. It dissolves in water, alcohol, and ether, and may be boiled in dilute solution without decomposing. Nitric acid, not in excess, oxidises it to lactylsulphurous acid, $C^3H^4SO^3$ (sulphopropionic acid, Buckton and Hofmann). (*vid. sup.*)

Sulpholactate of barium, $C^{11}H^{10}Ba^2O^3S^2$.—Crystallises in cauliflower-shaped masses; dissolves easily in water, insoluble in alcohol; it is not altered when dried at 100° .

Sulpholactate of lead.—Amorphous, and becomes brown on keeping.

Sulpholactate of potassium is obtained by double decomposition from sulpholactate of barium and sulphate of potassium. The solution evaporated *in vacuo* to a syrup deposits broad plates which are very deliquescent.

Sulpholactate of silver, $C^3H^4AgO^3S$.—A white, amorphous precipitate obtained by adding nitrate of silver to a solution of sulpholactate of barium. It is soluble in nitric acid, and decomposes below 100° .

Trilactic acid. The diethylic ether corresponding to this acid is known. (See LACTIC ETHERS.) H. W. and G. C. F.

LACTIC ANHYDRIDE. Dilactic acid (p. 461) was formerly called anhydrous lactic acid, or lactic anhydride. The true lactic anhydride is LACTIDE (p. 464).

LACTIC ETHERS. Owing to its peculiar constitution as a mono-basic diatomic acid, lactic acid is capable of forming three different ethers containing the same monatomic alcohol-radicle. Thus there are three lactates of ethyl, which may be represented by the following formulæ:

Of these compounds it will be seen that two—namely, ethyl-lactic acid and monethylic lactate—are isomeric, each being represented by the empirical formula $C^2H^4O^3$. The nature of the difference between these bodies will become apparent from the following considerations:—Lactic acid contains one atom of hydrogen, which is readily replaceable by its equivalent of an electro-positive metal by the ordinary processes of saline double decomposition, the result of this replacement being an ordinary metallic lactate: similarly, this atom of hydrogen can be replaced by its equivalent of an alcohol radicle by the ordinary processes of etherification, the result being a neutral ether, which, like compound ethers in general, can be decomposed into alcohol and alkaline lactate by the action of alkalis. But lactic acid contains also another atom of hydrogen, which, by various processes, can be removed, together with an atom of oxygen, the two being replaced by Cl, H²N, or other similar residues, and is therefore spoken of in the language of the theory of types as existing outside the radicle of the acid, although it cannot be replaced by metals or alcohol radicles in the same manner as the saline hydrogen-atom just referred to. The replacement of this second atom of hydrogen can, however, be effected by other means than those usually employed for the production of normal salts or ethers; and when this is done, the resulting products differ essentially from those obtained by effecting a similar substitution in the case of the saline atom of hydrogen. Thus, monethylic lactate results from the substitution of the radicle C^2H^3 for the saline hydrogen-atom of lactic acid, and ethyl-lactic acid from the substitution of the same radicle for the second of the two hydrogen-atoms existing outside the radicle of the acid. The degree of difference in the properties of these two compounds, resulting from the mode of combination of the alcohol- and acid-residues in each, will be seen by the special description of them which follows. (See also GLYCOLLIC ETHERS, ii. 914-916.)

Lactates of ethyl. MONETHYLIC LACTATE. *Lactic Ether.* $C^2H^4O^3 = \begin{matrix} H \\ (C^2H^3O)^- \\ C^2H^3 \end{matrix} \begin{matrix} O \\ \\ O \end{matrix}$

(Strecker, Ann. Ch. Pharm. xci. 352.—Wurtz and Friedel, Ann. Ch. Phys. [3] lxiii. 102.) *Preparation.*—1. One part of lactate of calcium and potassium (p. 458) is distilled with 1·4 pt. ethyl-sulphate of potassium; the thin, faintly-smelling distillate, which passes over between 160° and 180°, is saturated with chloride of calcium, and the syrupy solution is cooled. Crystals are then obtained consisting of $CaCl_2 \cdot 2(C^2H^3O^2)$; and these by distillation yield tolerably pure lactic ether (Strecker).—2. Syrupy lactic acid, heated to 170° with absolute alcohol, yields monethylic lactate very readily. (Wurtz and Friedel.)

Properties.—A colourless liquid of specific gravity 1·0542 at 0°, and 1·042 at 13°. It has a faint smell, and boils at 156° under a barometric pressure of 753 mm. Vapour-density found, 4·14 (Wurtz and Friedel); calculated, 4·07. Soluble in all proportions in water, alcohol, and ether.

Decompositions.—1. Lactic ether soon becomes acid by contact with water, from the formation of alcohol and lactic acids. *Alkalis, alkaline earths, and oxide of zinc* decompose it in the same manner as water.—2. *Potassium* dissolves in lactic ether with evolution of hydrogen, and forms potassio-lactate of ethyl, $C^2H^3KO^2 =$

$\begin{matrix} K \\ (C^2H^3O)^- \\ C^2H^3 \end{matrix} \begin{matrix} O \\ \\ O \end{matrix}$ isomeric with ethyl-lactate of potassium (*vid. infr.*). This substance

forms a viscid mass: treated with iodide of ethyl, it yields iodide of potassium and diethylic lactate (p. 464).—3. Lactic ether, mixed with alcoholic ammonia, and evaporated, yields crystals of lactamide (p. 453).

ETHYL-LACTIC ACID. *Valerolactic acid,* $C^2H^4O^3 = \begin{matrix} C^2H^3 \\ (C^2H^3O)^- \\ H \end{matrix} \begin{matrix} O \\ \\ O \end{matrix}$ (Wurtz, Ann.

Ch. Phys. [3] lix. 171.—Butlerow, Ann. Ch. Pharm. cxiv. 206; cxviii. 325; Bull. Soc. Chim. Paris, 1861, p. 9.) The potassium- and calcium-salts of this acid are obtained as products of the decomposition of diethylic lactate with potash and milk of lime. The acid is also produced (together with iodide of methylene and acrylic acid) by the action of ethylate of sodium on iodoform.

Ethyl-lactic acid is a colourless, somewhat viscid liquid, of a purely sour taste. It boils between 195° and 198°, undergoing partial decomposition at the same time. Water, alcohol, and ether dissolve it in all proportions; but on addition of chloride of calcium or sulphate of sodium to the aqueous solution, it separates as an oil. It becomes more viscid, but does not solidify, in a mixture of salt and snow. Ethyl-lactic acid decomposes the carbonates with effervescence. It cannot be resolved into lactic acid and alcohol by the action of alkalis; but when heated with concentrated hydriodic acid, it yields lactic acid and iodide of ethyl.

The ethyl-lactates are for the most part very soluble, and difficult to obtain in the

crystalline form. The calcium-salt, $C^10H^{12}Ca^2O^8$, crystallises by slow evaporation of its aqueous solution in colourless, prismatic crystals, united into stellate groups. Alcohol dissolves it less readily than water, and deposits it in wart-shaped masses. The silver-salt, $C^8H^8AgO^4$, crystallises from hot water in bunches of needles of a silky lustre: treated with iodide of ethyl, it yields diethylic lactate. The zinc-salt dries up to a gummy mass.

DIETHYLIC LACTATE, *Ethyl-lactate of ethyl*.— $C^8H^{10}O^4 = \left\{ \begin{smallmatrix} C^2H^4 \\ C^2H^4O^2 \end{smallmatrix} \right\} O^2$ (Wurtz,

Ann. Ch. Phys. [3] lix. 169.—Wurtz and Friedel, *ibid.* lxiii. 103.—Butlerow, Ann. Ch. Pharm. cxviii. 328). This substance, which may be regarded as the ether of the acid last described, is produced:—1. By the action of ethylate of sodium on chloropropionate of ethyl (*ether chlorolactique*, Wurtz).—2. By the action of iodide of ethyl on ethyl-lactate of silver.—3. By the action of iodide of ethyl on potassio-lactate of ethyl.

Diethylic lactate is a transparent, mobile liquid, of an agreeable ethereal odour. It boils at 156.5° under a pressure of 757 mm. Its specific gravity at 0° is 0.9203; vapour-density, found, 5.052 (calculated, 5.055).

It is insoluble in water, but soluble in alcohol and ether. By ebullition with alkalis, it is transformed into alcohol and an ethyl-lactate (*vid. supr.*); treatment with ammonia converts it into lactamethane (p. 452); it unites directly with lactide, forming diethylic trilactate.

CHLOROLACTIC ETHER, *Ether chlorolactique*. Syn. with *Chloropropionate of ethyl* (see PROPIONIC ETHERS).

DILACTATE OF ETHYL. See Dilactic acid (p. 461).

DIETHYLIC TRILACTATE, $C^{12}H^{16}O^7 = \left\{ \begin{smallmatrix} C^2H^4O^2 \\ C^2H^4 \end{smallmatrix} \right\} O^4$. A thick, colourless liquid, boiling about 270° , formed by heating diethylic lactate to 170° for several days with lactide. Potash decomposes it into alcohol and lactic acid. A substance which appears to be monethylic trilactate, $C^{11}H^{14}O^7 = \left\{ \begin{smallmatrix} C^2H^4O^2 \\ C^2H^4 \end{smallmatrix} \right\} O^4$, is obtained as a secondary product in the preparation of diethylic trilactate. (Wurtz and Friedel).

Lactates of Methyl. **METHYL-LACTIC ACID**, $C^4H^5O^3 = \left\{ \begin{smallmatrix} CH^3 \\ C^2H^3O^2 \end{smallmatrix} \right\} O$, is the only

compound belonging to this class that has hitherto been described. It is obtained by heating disodic lactate (p. 459) to 110° or 120° with iodide of methyl. *Methyl-lactate of silver*, $C^4H^5AgO^3$, remains as a brittle, amorphous, gummy mass, when its aqueous solution is evaporated *in vacuo*. *Methyl-lactate of zinc* is very soluble in water, and encrystallisable; it dissolves also in absolute alcohol. (Wislicenus, Ann. Ch. Pharm. cxxv. 53. G. C. F.)

LACTIDE. (True) *Lactic anhydride*. $C^4H^4O^3 = C^2H^3O.O$. (J. Gay-Lussac and Pelouze, Ann. Ch. Pharm. vii. 43; Pelouze, *ibid.* liii. 116; Engelhardt, *ibid.* lxx. 243; Wurtz and Friedel, Ann. Ch. Phys. [3] lxiii. 101.)—Produced by the dry distillation of lactic acid. To prepare it, the product obtained by slowly distilling lactic acid is evaporated at 100° , and the residue washed with cold alcohol, and crystallised from boiling alcohol. Lactide crystallises in rhomboidal plates of dazzling whiteness. It is inodorous; melts at 107° , and begins to boil at 250° , giving off white, irritating vapours, which sublime without alteration, and condense in crystals on cold bodies. It is only slightly soluble in hot water, but is gradually converted into lactic acid by ebullition with water, and quickly by the action of bases.

Ammonia converts it into lactamide (p. 453); methylamine, into lactethylamide (p. 453). It unites with diethylic lactate, forming diethylic trilactate (*vid. supr.*).

G. C. F.

LACTIDIC ACID. Laurent's name for DILACTIC ACID (p. 461).

LACTIN and **LACTOSE**. Syn. with SUGAR OF MILK.

LACTONE, $C^4H^4O^3$.—A liquid possessing an aromatic smell, and boiling at about 92° , produced, together with lactide, by the dry distillation of lactic acid. (Pelouze, Ann. Ch. Phys. [3] xiii. 262.)

LACTUCA SATIVA. The common lettuce. This plant yields, according to T. Richardson (Jahresber. 1847–48, No. 134, Table to p. 1074), 0.87 per cent. ash, containing:

K ² O	Na ² O	CaO	MgO	Al ² O ³	SiO ²	P ² O ⁵	Ferric phosphate	NaCl
46.01	5.29	6.05	2.17	8.89	20.23	8.52	trace	7.82 = 99.98

LACTUCARIUM. A brownish viscid substance obtained by evaporating the

juice which exudes, by incision, from the leaves and stems of certain species of *Lactuca*, especially *Lactuca virosa*. It has a peculiar odour resembling that of opium, and acts as a narcotic. German lactucarium contains, according to Ludwig (Arch. Pharm. [2], 7, 129; Jahresber. 1847-8, p. 824), from 44.4 to 53.5 per cent. lactucone; a soft resin; about 4 per cent. of an easy fusible waxy body; lactucin, the chief active principle of the substance; lactic acid; about 1 per cent. of oxalic acid; a non-volatile not bitter acid, which reduces oxide of silver; and a volatile acid smelling like valerianic acid, both in small quantity only; about 7 per cent. of albumin; at least 2 per cent. mannite; a small quantity of a neutral, not bitter, unfermentable substance, crystallising in rhombic pyramids; and from 3 to 6 per cent. ash, containing potash, soda, manganic oxide, ferric oxide, and a small quantity of lime.

LACTUCERIN. A substance, insoluble in water, contained in lactucarium, probably identical with lactucone.

LACTUCIC ACID. This substance is obtained by triturating lactucarium with an equal weight of dilute sulphuric acid, adding 5 pts. of alcohol of 84 per cent., filtering, shaking up the filtrate with slaked lime, decolorising with animal charcoal, evaporating, heating the residue to boiling with a large quantity of water, and evaporating the aqueous solution, after decolorising it with animal charcoal. A mixture of lactic acid and lactucin then remains, and on dissolving this in boiling water, the lactucin crystallises out on cooling, and the remaining liquid yields, by evaporation, impure lactic acid.

Lactic acid thus obtained is a light yellow mass, amorphous at first, but becoming crystalline after a while; its colourless aqueous solution is coloured wine-red by alkalis, and when boiled with cupric sulphate and excess of soda, reduces the cupric to cuprous oxide. (Ludwig, Jahresber. 1847-48, p. 824.) According to Walz (N. Jahrb. Pharm. xv. 118), it is $C^6H^8O^8$.

LACTUCIN. A substance contained in lactucarium, and supposed to be its active principle. It is obtained by treating the extract with alcohol containing 2 per cent. of strong vinegar, diluting the solution with water, precipitating with basic acetate of lead, removing the excess of lead from the filtrate by sulphydric acid, evaporating at a gentle heat, digesting the residue in ether, and leaving the ethereal solution to evaporate. Ludwig and Kromayer (Arch. Pharm. [2] xxi. 1) prepare it by macerating lactucarium in $\frac{1}{2}$ pt. hot water for four days, then pressing the mass, again treating it with a little cold water, boiling it five times with fresh portions of alcohol (which leaves lactucone undissolved), and evaporating the extracts to half the bulk of the material used. The product is then precipitated with basic acetate of lead, and recrystallised from alcohol as above.

Lactucin is yellowish, fusible, bitter, soluble in 80 parts of cold water, moderately soluble in alcohol and in acetic acid, less soluble in ether, which deposits it by evaporation in the crystalline state. According to Kromayer (Arch. Pharm. [2] cv. 3), it crystallises in nacreous scales or rhombic tables, probably containing $C^{12}H^{20}O^7$ or $C^{12}H^{20}O^8$. According to Walz (N. Jahrb. Pharm. xv. 118), it is $C^6H^{10}O^{10}$. Nitric acid, of specific gravity 1.48, converts it into a resinous body quite devoid of taste. Strong sulphuric acid turns lactucin brown. Lactucin heated with potash gives off ammoniacal products (?). Its solutions are not precipitated by any reagent. (Buchner, Rep. Pharm. xliii. 1, Gm. xvi. 276.)

LACTUCONE. $C^6H^{10}O^{11}$ (?).—A crystalline substance extracted from lactucarium by boiling alcohol. It forms mammillated crystals, which, after purification by recrystallisation and treatment with animal charcoal, are colourless, insipid, melt between 150° and 160° , are insoluble in water, but dissolve very easily in alcohol, ether, and oils, both fixed and volatile. It yields acetic acid in large quantity by distillation. It may, however, be partly volatilised without decomposition in a stream of carbonic acid gas. It yields by analysis 80.66—81.25 per cent. carbon, and 10.91—11.33 hydrogen, numbers which agree nearly with the formula $C^6H^{10}O^8$. It is an indifferent substance, and is not affected by potash or by chlorine. Its alcoholic solution does not precipitate metallic salts dissolved in alcohol. (Lenoir, Ann. Ch. Pharm. lix. 83.)

LACTUCOPICRIN. An uncrystallisable substance, which remains in the mother-liquors of the preparation of lactucin by Ludwig and Kromayer's process (*vid. sup.*), after the greater part of that substance has been precipitated by basic acetate of lead. When freed from admixed lactucin and lactucone by ether, it forms a brown, amorphous, very bitter mass, having a faint acid reaction, soluble in water and alcohol. It contains 52.6 per cent. carbon, 6.8 hydrogen, and 36.6 oxygen, agreeing nearly with the formula $C^6H^{12}O^{10.4}$, and is therefore produced from lactucin by assumption of water and oxygen. (Kromayer, Die Bitterstoffe, Erlangen, 1861, p. 79.)

LACTYL, CHLORIDE OF. *Chloride of chloropropionyl.* $\text{C}^{\text{H}}\text{C}^{\text{H}}\text{O}^{\text{C}}\text{Cl} = \text{C}^{\text{H}}\text{C}^{\text{H}}\text{O}.\text{Cl}$ (Wurtz, Ann. Ch. Phys. [3] lix. 183.—Ulrich, Chem. Soc. Qu. J. xii. 23.)—Obtained, together with oxychloride of phosphorus, by gently heating a mixture of well-dried lactate of calcium with twice its weight of pentachloride of phosphorus. It is difficult to separate the whole of the oxychloride of phosphorus, but the chloride of lactyl may be obtained nearly pure by distilling the liquid, which passes over during the reaction in small quantities at a time, and collecting separately the portion which distils above 140° . Chloride of lactyl is also formed by the direct combination of ethylene and oxychloride of carbon. (Lippmann.)

When freshly prepared, chloride of lactyl is a colourless liquid, but it soon becomes dark coloured, giving off hydrochloric acid. Its boiling point seems to be above 140° , but it is partially decomposed when distilled, the thermometer rising to 180° or 190° .

It sinks to the bottom of water and gradually dissolves, forming hydrochloric and chloropropionic acids (PROPIONIC ACID, DERIVATIVES OF) (Ulrich). With absolute alcohol, it reacts very energetically, forming hydrochloric acid, chloride of ethyl, and chloropropionate of ethyl. (Wurtz's *Éther chlorolactique*.) G. C. F.

LAGONITE. A ferric borate, $\text{Fe}^{\text{O}}\text{B}^{\text{O}}\text{O}^{\text{O}}\text{H}^{\text{O}}$, occurring as an incrustation in the Tuscan lagoons. (Bechi, Sill. Am. J. [2] xvii. 129.)

LAKE. This term is used to denote a species of pigment formed by precipitating colouring matters with some earth or metallic oxide. The principal red lakes are the *Carmine*, *Florence*, and *Madder lakes*.

For the preparation of carmine-lake, four ounces of finely pulverised cochineal are poured into 4 or 6 quarts of rain or distilled water (which has been previously boiled in a pewter kettle), and boiled with it for six minutes longer (it is sometimes recommended to add, during the boiling, two drachms of pulverised cream of tartar). Eight scruples of Roman alum in powder are then added, and the whole is kept upon the fire for one minute longer. As soon as the coarse powder has subsided, and the decoction has become clear, the latter is carefully decanted into large cylindrical vessels, covered over and kept undisturbed, till a fine powder settles to the bottom. From the decanted liquor, which is still much coloured, the rest of the colouring matter may be separated by means of tin-solution: it then yields a carmine-lake but little inferior to the other.

For the preparation of Florentine lake, the sediment of cochineal remaining on the kettle after the preparation just described may be boiled with the requisite quantity of water, the red liquor which remains after the preparation of the carmine likewise mixed with it, and the whole precipitated with the solution of tin. The red precipitate must be frequently washed with water. Exclusively of this, two ounces of fresh cochineal, and one of crystals of tartar, are to be boiled with a sufficient quantity of water, poured off clear, and precipitated with the solution of tin, and the precipitate washed. At the same time, two pounds of alum are also to be dissolved in water, precipitated by caustic potash, and the white earth repeatedly washed with boiling water. Finally, both precipitates are to be mixed together in the liquid state, put upon a filter, and dried. For the preparation of a cheaper sort, one pound of Brazil wood may be employed in the preceding manner, instead of cochineal.

For the following process for making a lake from madder, the Society of Arts voted their gold medal to Sir H. C. Englefield. Enclose two ounces troy of the finest Dutch crop madder in a bag of fine and strong calico, large enough to hold three or four times as much. Put it into a large marble or porcelain mortar, and pour on it a pint of clear soft water, cold. Press the bag in every direction, and pound and rub it about with a pestle, as much as can be done without tearing it, and when the water is loaded with colour, pour it off. Repeat this process till the water comes off but slightly tinged, for which about five pints will be sufficient. Heat all the liquor in an earthen or silver vessel, till it is near boiling, and then pour it into a large basin, into which a troy ounce of alum dissolved in a pint of boiling soft water has been previously put. Stir the mixture together, and while stirring, pour in gently about an ounce and half of a saturated solution of carbonate of potassium. Let it stand till cold to settle; pour off the clear yellow liquor; add to the precipitate a quart of boiling soft water, stirring it well; and when cold, separate by filtration the lake, which should weigh half an ounce. If less alum be employed, the colour will be somewhat deeper; with less than three-fourths of an ounce, the whole of the colouring matter will not unite with the alumina. Fresh madder root is equal, if not superior, to the dry.

Almost all vegetable colouring matters may be precipitated into lakes, more or less beautiful, by means of alum or oxide of tin. U.

Yellow lakes are prepared chiefly with decoctions of the berries of various species of *Rhamnus*, also of fustic, weld, quercitron, &c.; the decoctions, mixed with carbonate of potassium in greater or smaller quantity as the colour is to be lighter or darker, being poured into a hot solution of alum quite free from iron. The colour

may be heightened by treating the still moist precipitate with tin-solution.—As many of the preceding solutions contain a large quantity of tannin, it is usual, in order to obtain a fine yellow-lake from them, to mix them, in the first instance, with a considerable quantity of sour milk, which precipitates the tannin.

An orange-yellow lake is obtained in like manner by precipitating turmeric or annatto, dissolved in potash with alum. A common kind of yellow-lake is obtained by mixing yellow-lake, prepared as above, with clay, marl, or chalk; better, however, by boiling 5 pts. of crushed yellow berries with 25 to 30 pts. water containing 1 pt. of alum, pouring the clear liquid on 3 or 4 pts. of pounded chalk, and leaving it for several days, stirring frequently, then decanting the liquid, and washing and drying the precipitate. If a greenish tint is desired, a small quantity of burnt or slaked lime may be added.

Blue lakes are but seldom prepared, since Prussian-blue, ultramarine, cobalt-blue, &c., and indigo-carmin answer every purpose for which they could be required. If indigo-carmin be prepared by saturating the solution of sulphindigotic acid with magnesia or its carbonate, instead of potash, it is obtained of a still finer colour. Sometimes a dilute solution of sulphindigotic acid is mixed with alum-solution, and the mixture is precipitated with carbonate of potassium, whereby a peculiar blue lake is obtained. A solution of logwood mixed with alum yields a violet, and, on addition of sulphate of copper, a blue-lake, if the solutions are precipitated in the cold with carbonate of potassium.

Green lakes are usually prepared by mixing blue and yellow lakes. A very good green lake is obtained directly by exhausting 1 lb. of bruised coffee-berries with 10 lbs. of water, and dissolving in the liquid from 2; to 3 lbs. of sulphate of copper. The clear liquid is precipitated with caustic potash, the coffee-extract being kept in excess to prevent the precipitation of free cupric oxide. The precipitate, which weighs about as much as the coffee-berries used, is moistened with a small quantity of vinegar, and left for some time exposed to the air, whereby its colour is heightened.

LAMINARIA. See SEAWEED.

LAMPADITE. Syn. with WAD.

LAMP-BLACK. Finely-divided carbon, obtained by collecting the smoke of an oil-lamp, or that of burning-pitch or resin. (See CARBON, i. 760.)

LAVA PHILOSOPHICA. An old name for the snowy flakes of white oxide which rise and float in the air when zinc is burned.

LANARKITE. A sulphato-carbonate of lead, $\text{PbSO}_4 \cdot \text{PbCO}_3$, or $\left. \begin{matrix} (\text{SO}_3)^{''} \\ \text{Pb}^{\text{a}} \end{matrix} \right\} \text{O}^{\text{a}}$.

occurring sometimes in monoclinic crystals, cleavable in two directions, sometimes massive or in flexible laminae, at Leadhills, Scotland, at Tanné in the Hartz, and at Biberweiler, Tyrol. Hardness = 2 to 2.0. Specific gravity = 6.3 to 7. Lustre of cleavage-faces, pearly; of others, adamantine, inclining to resinous. Streak white. Colour, greenish-white, pale-yellow, or grey. Transparent or translucent. Contains, according to Brooke's analysis (Ed. Phil. J. iii. 17), 53.5 per cent. sulphate, and 46.85 carbonate of lead, which is very near the calculated composition. Before the blowpipe it melts to a globule, which becomes white on cooling. Dissolves in nitric acid without perceptible effervescence.

LANCASTERITE. A mineral consisting of a mixture of brucite and hydromagnesite, found near Texas, Lancaster County, Pennsylvania (Dana, ii. 467).

LANTANURIC ACID. (Lantalic acid, Laurent.) A product, according to Schlieper (Ann. Ch. Pharm. lvii. 216), of the oxidation of uric acid, by a mixture of ferricyanide of potassium and potash. The result of the process, which is somewhat complicated, is impure lantanurate of potassium, which is dissolved in water, mixed with acetate of lead, and filtered from the precipitated oxalate of lead; the lantanurate of lead then precipitated from the filtrate by ammonia, washed, suspended in water, and decomposed by sulphuretted hydrogen. The filtrate, on evaporation, yields lantanuric acid as a gummy mass, easily soluble in water, insoluble in alcohol: its solution reddens litmus. It appears to be a dibasic acid. It forms a normal- and an acid potassium-salt, the former of which is syrupy, the latter crystallisable. The solution of either of these salts gives, with ammoniacal acetate of lead, a white precipitate, insoluble in cold water and alcohol, soluble in acetic acid or basic acetate of lead.—With ammoniacal nitrate of silver, the acid potassium-salt gives a white precipitate, containing 62.93 per cent. silver.

Schlieper states the formula of the lead-salt to be $\text{C}^{\text{a}}\text{H}^{\text{a}}\text{PL}^{\text{a}}\text{N}^{\text{a}}\text{O}^{\text{a}}$, whence that of the acid is $\text{C}^{\text{a}}\text{H}^{\text{a}}\text{N}^{\text{a}}\text{O}^{\text{a}}$. Laurent proposes to double the formula. According to Gerhardt (Traité, i. 528), lantanuric acid is probably identical with allanturic acid. F. T. C.

LANTHANITE. Native carbonate of lanthanum (and didymium) (La ; D'f $\text{CO}_3 \cdot 3\text{H}_2\text{O}$, formerly called carbonate of cerium. (See CARBONATES, i. 785.)

LANTHANUM. Atomic weight, 92.8; *Symbol*, La. This metal appears to be constantly associated with cerium and didymium. Mosander showed in 1839 (Pogg. Ann. xvi. 648; xlvii. 207) that the red-brown oxide obtained from cerite in the manner described under Cerium (i. 831), and originally regarded as the oxide of a single metal, contained the oxide of another metal which he called lanthanum (from *λανθάνειν*, because it had previously been concealed in the oxide of cerium); and subsequently, in 1841 (Pogg. Ann. lvi. 504), he discovered that this supposed oxide of a single metal, lanthanum, was really a mixture of the oxides of two distinct metals, for one of which the name lanthanum was retained, while the other was called didymium (*δίδυμοι*, twins).

The separation of lanthanum and didymium from cerium may be effected by either of the methods described under cerium (i. 831, 832). The second and third are easier and more expeditious than the first. If the solution obtained by treating the crude red-brown oxide with dilute nitric acid be evaporated to dryness, and the residue treated with nitric acid diluted with at least 200 pts. of water, a solution will be obtained quite free from cerium (Marignac). Boiling the red-brown oxide with chloride of ammonium also yields a solution of lanthanum and didymium free from cerium. In both cases, however, it is best to test a portion of the solution for cerium by precipitating with excess of caustic potash, and passing chlorine through the solution. The presence of cerium, even in a very small quantity, will be indicated by the formation of a yellow precipitate, after the liquid, supersaturated with chlorine, has been left in a close vessel for several hours.

Holzmann, (J. pr. Chem. lxxv. 321; Rép. Chim. pure, i. 241), prepares pure lanthanum-salts from the liquid which remains after the precipitation of basic ceric sulphate in Bunsen's process for the separation of cerium (i. 832). This liquid, which contains both lanthanum and didymium, is evaporated (during which process a large additional quantity of cerium separates as basic sulphate) and heated till the greater part of the free acid is expelled. The sulphates of lanthanum and didymium, which then separate out, are dissolved in water containing a little nitric acid, and the solution, together with the mother-liquor, is precipitated with oxalic acid; the precipitate, mixed with an equal weight of *magnesia alba*, is heated for some time to low redness; the resulting dark brown oxide is digested with small quantities of dilute nitric acid, which dissolves scarcely anything but the oxides of lanthanum, didymium and magnesium; and the filtrate is boiled for some time with magnesia to separate the last traces of cerium. The liquid is then again precipitated with oxalic acid; the dried and ignited precipitate dissolved in dilute nitric acid; the solution precipitated by sulphate of potassium; the precipitated lanthano- and didymio-potassic sulphates digested with dilute carbonate of sodium, and the resulting carbonates dissolved in dilute sulphuric acid.

A solution free from cerium having been obtained, the separation of the lanthanum and didymium is effected by the different solubilities of their sulphates. To convert them into sulphates, if not already in that form, the solution is treated with excess of a caustic alkali, and the washed precipitate dissolved in dilute sulphuric acid. The mode of proceeding varies according as the lanthanum or the didymium is in excess.

1. When the lanthanum is in excess, in which case the solution has but a faint amethyst tinge, the liquid is evaporated to dryness, and the residue heated in a platinum dish to a temperature just below redness, to drive off the excess of acid, and render the sulphates perfectly anhydrous. The residue is then dissolved in rather less than six times its weight of water, at about 2° or 3° C. (36° F.), the salt being reduced to powder and added in successive small portions, and the vessel containing the liquid being immersed in ice-cold water. Without these precautions, the temperature of the liquid may be raised several degrees, in consequence of the heat evolved by the combination of the anhydrous sulphates with water; and in that case, crystallisation will commence, and rapidly extend through the whole mass of liquid, as these sulphates are much less soluble in warm than in cold water; but if the liquid be properly cooled, the whole dissolves completely. The solution is next to be heated in the water-bath to about 40° C. (104° F.); the sulphate of lanthanum then crystallises out, accompanied by only a small quantity of sulphate of didymium. To purify it completely, it is again rendered anhydrous, re-dissolved in ice-cold water, &c., and the entire process repeated ten or twelve times. The test of purity is perfect whiteness, the smallest quantity of didymium imparting an amethyst tinge (Mosander). This process succeeds best when a considerable quantity of the mixed sulphates is operated on.

2. When the didymium-salt is in excess, in which case the liquid has a decided rose-colour, separation may be effected by leaving the solution containing excess of acid, in a warm place for a day or two. The sulphate of didymium then separates in large rhombohedral crystals modified with numerous secondary faces; and, at the same time, slender, needle-shaped, violet-coloured crystals are formed, containing the two sulphates mixed. The rhombohedral crystals, which are nearly free from lanthanum, are

removed, and the needles, together with the mother-liquid, treated as in the first method, to obtain sulphate of lanthanum. (Mosander.)

In both cases, the separation may be greatly facilitated by first dissolving the mixed oxides of the two metals in a large excess of nitric acid, and precipitating in successive portions by oxalic acid; the first precipitates thus formed have a much deeper rose-colour, and are much richer in didymium than the latter. The separation thus effected is very imperfect in itself, but it greatly facilitates the subsequent separation of the sulphates, which is much more rapid when one of the sulphates is in great excess with regard to the other. (Marignac.)

Metallic lanthanum is obtained by decomposing the anhydrous chloride with sodium, and dissolving out the chloride of sodium with alcohol of specific gravity 0.833. It is a dark, lead-grey powder, soft to the touch, and adhering when pressed.

Lanthanum appears to form only one series of compounds, in which it is diatomic, e.g. the chloride LaCl_3 ; the protoxide LaO .

LANTHANUM, CHLORIDE OF. LaCl_3 , is obtained in the anhydrous state by igniting the oxide in a current of hydrochloric acid gas (Mosander), or by dissolving the oxide in hydrochloric acid, evaporating the solution, mixed with sal-ammoniac, to dryness, and heating the residue till the sal-ammoniac is expelled. It then remains as a radio-crystalline mass, which deliquesces in moist air, and dissolves easily in alcohol. (R. Hermann, J. pr. Chem. lxxxii. 385.)

A *hydrated chloride*, $\text{LaCl}_2 \cdot 4\text{H}_2\text{O}$, is obtained as a radio-crystalline mass, by evaporating a solution of the oxide to a syrup, and leaving it over oil of vitriol. When heated in moist air, it gives off water and hydrochloric acid, leaving a mixture of chloride of lanthanum and an oxychloride containing $3\text{LaO} \cdot \text{LaCl}_3$.

Chloromercurate of Lanthanum, $\text{LaCl}_2 \cdot 3\text{HgCl}_2 \cdot 8\text{H}_2\text{O}$, is obtained by evaporating a solution of the component chlorides, in colourless cubes, easily soluble in water, but not deliquescent. (Marignac, Ann. Min. [5] xv. 272.)

LANTHANUM, DETECTION AND ESTIMATION OF. 1. *Reactions.* Pure lanthanum-compounds fused with borax before the blowpipe, form a perfectly colourless bead; the slightest tinge of amethyst is an indication of the presence of didymium.

Lanthanum-salts in solution are colourless, and have an astringent taste. With caustic *potash* or *soda*, they yield a white bulky gelatinous precipitate of the hydrated oxide, which is insoluble in excess of the alkali, but dissolves completely in chlorine-water, without forming any yellow deposit. *Ammonia* throws down a basic salt. *Oxalic acid* or *oxalate of ammonium* forms a white flocculent precipitate, which does not become crystalline. In other respects the solutions resemble those of cerous salts (i. 833), especially in forming with sulphate of potassium a white crystalline precipitate quite insoluble in excess of the reagent.

2. *Estimation and Separation.*—Lanthanum is best precipitated from its solutions by oxalate of ammonium. The precipitated oxalate, ignited in a covered platinum crucible, is converted into the anhydrous oxide, La_2O_3 , containing 85.4 per cent. of the metal.

The methods of separating lanthanum from most other metals are the same as those adopted for cerium and didymium. The separation of lanthanum from cerium itself may be effected by precipitation with an alkaline hypochlorite, or by boiling the mixed oxides in a solution of sal-ammoniac (i. 832). No method of separating lanthanum from didymium, sufficiently exact for quantitative analysis, has yet been discovered.

3. *Atomic Weight of Lanthanum.*—Mosander, by the analysis of sulphate of lanthanum, estimated the atomic weight of the metal (diatomic) at 92.8. Marignac (Ann. Ch. Phys. [3] xxvii. 209), by a similar method, obtained a somewhat higher number, viz. 94.08. Holzmänn (J. pr. Chem. lxxv. 321), from the mean of his analyses of the sulphate and of the iodate, obtained the number 92.8; and R. Hermann (*ibid.* lxxxii. 385), from his analyses of the carbonate, sulphate, and chloride, obtained 92.88. Mosander's determination may, therefore, be regarded as fully confirmed.

LANTHANUM, FLUORIDE OF. Sulphate of lanthanum forms, with fluoride of sodium, a white flocculent precipitate, sparingly soluble in hydrochloric acid. (Hermann.)

LANTHANUM, OXIDES OF. Lanthanum forms two oxides, viz. a *protoxide*, LaO , and a *peroxide*, the composition of which has not perhaps been exactly ascertained.

The protoxide is obtained by igniting the hydrate, carbonate, or oxalate, first in contact with the air, afterwards in contact with the reducing gases of the flame. It then forms white lumps having the same texture as the peroxide, and a specific gravity of 5.94. When exposed to the air, it takes up water and carbonic acid, and in contact

LANTHANUM. Atomic weight, 92.8; Symbol, La. This metal appears to be constantly associated with cerium and didymium. Mosander showed in 1839 (Pogg. Ann. xvi. 648; xlvii. 207) that the red-brown oxide obtained from cerite in the manner described under Cerium (i. 831), and originally regarded as the oxide of a single metal, contained the oxide of another metal which he called lanthanum (from *λανθάνει*, because it had previously been concealed in the oxide of cerium); and subsequently, in 1841 (Pogg. 470 LANTHANUM: OXYCHLORIDE—LAPIS LAZULI.

with water is converted into the hydrate, $\text{LaH}^{\circ}\text{O}^2$, which is a soft white powder resembling slaked lime. By precipitating a salt of lanthanum with potash or soda, the hydrate is obtained as a bulky, translucent precipitate, which rapidly absorbs carbonic acid. Both the hydrate and the anhydrous protoxide dissolve easily in acids, without evolution of gas.

The peroxide, said to have the composition $\text{La}^{\circ}\text{O}^3$ or $64\text{LaO}\cdot\text{O}$, is obtained by igniting the carbonate, oxalate, or nitrate, in contact with the air. It is a light brown or brownish-grey substance, which dissolves in sulphuric, nitric, or acetic acid, with evolution of oxygen, and in hydrochloric acid with evolution of chlorine.

LANTHANUM, OXYCHLORIDE OF, $\text{La}^{\circ}\text{Cl}^2\text{O}^2 = \text{LaCl}^2\cdot 3\text{LaO}$, remains on heating the hydrated chloride (p. 469), and after washing with water, forms a white powder, insoluble in water, but dissolving slowly in hydrochloric or nitric acid.

LANTHANUM, OXYGEN-SALTS OF. The solutions obtained by dissolving either of the oxides of lanthanum in acids, are colourless and have an astringent taste. Most salts of lanthanum are soluble in water; but the carbonate, borate, and phosphate are insoluble. Lanthanum has a great tendency to form basic salts, by precipitation with ammonia for example. Many of these salts, the basic nitrate and chloride (oxychloride) for instance, run through the filter as milky liquids during washing. If the precipitate be boiled, the whole runs immediately through the filter; but if it be left in the moist state for a few days, it is converted into a neutral salt, which dissolves in water, while carbonate of lanthanum remains on the filter. Sulphate of lanthanum resembles the corresponding salts of cerium and didymium, in forming with sulphate of potassium a crystalline double salt, sparingly soluble in pure water, and quite insoluble in water saturated with sulphate of potassium.

LANTHANUM, SULPHIDE OF, LaS , is obtained by igniting the metal in vapour of sulphide of carbon, as a yellow powder, which is decomposed by water, with evolution of sulphydric acid, and formation of the white hydrate of lanthanum. The sulphide may also be obtained by igniting the oxide in vapour of sulphide of carbon, or by fusing it with sulphide of sodium; but it is then of a fiery yellow colour, and when examined by the microscope, is seen to be made up of fine crystals. (Mosander.)

LAPATEIN. The name given by Buchner and Herberger (Rep. Pharm. xxxviii. 337), to a substance which they obtained in a very impure state from the root of *Rumex obtusifolius* (the official *Radix lapathi acuti*): it has since been shown to be identical with chrysophanic acid (i. 958).

LAPIS LAZULI. *Ultramarine*. *Lasurstein*.—A silicate of sodium, calcium, and aluminium mixed with a sulphur-compound of sodium. It occurs sometimes in rhombic dodecahedrons, with imperfect dodecahedral cleavage, but more commonly massive and compact. Hardness = 5.5. Specific gravity = 2.38 to 2.45. Lustre vitreous. Colour rich Berlin or azure blue. Translucent to opaque. Fracture uneven. Before the blowpipe it fuses to a white glass, and if calcined and reduced to powder, loses its colour, and gelatinises in hydrochloric acid. With borax, it effervesces and forms a colourless glass.

Analyses.—1. From the East: *a*. Klaproth (*Beitrag*, i. 189); *b*. L. Gmelin (Schw. J. xiv. 329); *c*. Varrentrapp (Pogg. Ann. xlix. 515); *d*. Köhler (*Ram-melsberg's Mineralchemie*, p. 710); *e*. Schultz (*ibid.*).—2. From Vesuvius: L. Gmelin (*loc. cit.*).—3. From the Andes: *a*. Field (Chem. Soc. Qu. J. iv. 331); *b*. Schultz (*loc. cit.*):—

These analyses show that lapis lazuli is not a mineral of definite constitution, but a mixture, a result which is corroborated by its appearance and physical structure. It

is, therefore, useless to attempt the calculation of a formula from the analyses. On examining thin slices of the mineral under the microscope, the blue colouring matter is seen to be distributed amidst a white ground. The composition of artificial ultramarine renders it probable that the colouring matter of the natural mineral is either a polysulphide of sodium, or a compound of the protosulphide with a polythionate of sodium.

Lapis lazuli is usually found in granite or in crystalline lime-stones. It is brought chiefly from China, Siberia, and Bucharia; the specimens often contain scales of mica and pyrites. On the banks of the Indus, it occurs disseminated in a greyish limestone.

The richly coloured varieties are highly esteemed for making costly vases and ornamental furniture; it is also employed in the manufacture of mosaics, and when powdered constitutes the rich and durable pigment called ultramarine (*q.v.*)

LAPIS OLLARIS or *Polstone* is a coarse granular dark-coloured variety of steatite.

LARCH. See **LARIX**.

LARDERELLITE. A borate of ammonium occurring at the lagoons of Tuscany, as a white efflorescence composed of microscopic crystals. It contains, according to Bechi (Sill. Am. J. [2] xvii. 130), 68.55 per cent. boric anhydride, 11.73 oxide of ammonium, and 18.32 water, agreeing nearly with the formula $(\text{NH})^2\text{O} \cdot 4\text{B}^2\text{O}_3 \cdot 4\text{H}^2\text{O}$. It is soluble in water, and the hot solution yields another salt, composed of $(\text{NH})^2\text{O} \cdot 6\text{B}^2\text{O}_3 \cdot 9\text{H}^2\text{O}$.

LARDITE. A variety of talc (*q.v.*); also syn. with **AGALMATOLITE**.

LARIX EUROPEA or *Pinus Larix*. The Larch tree. The young branches of this tree exude a kind of manna, from which Berthelot has obtained a fermentable sugar called melezitose (*q.v.*) The bark contains a peculiar acid, to be described in the next article.

LARIXINIC ACID. $\text{C}^{10}\text{H}^{16}\text{O}_2$. (Stenhouse, Phil. Trans., 1863, p. 53; Proc. Roy. Soc. xi. 405.)—A volatile crystallisable acid contained in the bark of the larch-tree, most abundantly in that of the smaller branches of trees from 20 to 30 years old. It is obtained by exhausting the bark with water at 80° , evaporating the extract to a syrup and distilling in vessels of glass, porcelain, or silver. The acid which passes over crystallises, partly on the inner surface of the receiver, but the greater part is obtained in the crystalline form on evaporating the distillate. The brown-yellow crystals thus obtained are purified by recrystallisation and sublimation.

Sublimed larixinic acid forms crystals resembling those of benzoic acid, often an inch long, and having a brilliant silvery lustre; they are monoclinic and usually occur in twins. The crystals deposited from water are also monoclinic. The acid sublimes at 93° , melts at 153° , often volatilises with vapour of water, has a slightly bitter-astringent taste, and smells like camphor or naphthalene. The crystals catch fire readily, and burn with a bright flame, leaving no residue. The acid reddens litmus slightly, dissolves in 87.9 pts. water at 60° , more easily in boiling water and in alcohol, sparingly in ether. Nitric acid converts it into oxalic acid. When treated with hydrochloric acid and chlorate of potassium it does not yield chloranil.

The aqueous solution of larixinic acid is precipitated by baryta-water, forming an easily decomposable precipitate which contains 34.9 per cent. baryta. The acid is not precipitated by lime-water or sugar-lime, or by lead-, or silver-salts; neither does it reduce the metal from the latter on boiling. Ferric salts produce, even in dilute solution of larixinic acid, a characteristic purple-red colour.

Larixinate of potassium forms flat red-brown crystals which become darker on recrystallisation, and are decomposed, even by carbonic acid.

Larixinic acid is not found in the bark of *Alnus excelsior*, or *Pinus sylvestris*.

LASIONITE. Syn. with **WAVELLITE**.

LASURITE. Blue carbonate of copper (i. 783).

LASYLIC ACID. $\text{C}^8\text{H}^8\text{O}_2$. An acid whose phenyl-ether, $\text{C}^{12}\text{H}^8\text{O}_2 = \text{C}^8\text{H}^8(\text{C}_6\text{H}_5)_2\text{O}_2$, is produced, together with hydrochloric acid, by the action of oxychloride of phosphorus in excess on salicylate of sodium. When the temperature rises high, the acid liquid passes over, which, on standing, deposits tabular crystals of the phenyl-ether, leaving a mother-liquor which smells of hydrate of phenyl. (Kolbe and Baute-mann, Ann. Ch. Pharm. cxv. 157.)

LATERITE (from *later*, a brick) is a name applied by Indian geologists to a formation common in Ceylon and India, and consisting of reddish clay, more or less hardened, and enclosing nodules of quartz: the Cingalese call it *cabook*. True laterite is a hard, dense, almost jasper-like, reddish or brick-red rock, consisting of hardened

clay enclosing quartz-crystals. A second variety, which is most common in Ceylon, is softer, may be cut with the knife, but hardens on exposure to the air. A third kind is sedimentary or breccia-like, consisting of quartz-nodules loosely embedded in clay, and has been produced by disintegration of true laterite, which appears to be itself a product of the decomposition of granite or gneiss containing hornblende. (Jahresber. 1853, p. 392.)

LATEX. A juice which circulates through plants by means of a set of vessels called the laticiferous tissue or cinenchyma, and coagulates into a gelatinous substance called cambium, which precedes the formation of cells. The descending juice is, according to Frémy, a mixture of several liquids, some of which contain vegetable secretions, while others serve for the development of vegetable organs. In those parts of the vegetable organism which are in process of development, there exists a kind of juice called by Frémy, the *albuminiferous latex*, which closely resembles the young organs in chemical composition, and forms the material for the production of the cambium. Under favourable circumstances, this juice may be obtained tolerably pure by making a slight incision into the growing tissues just below the epidermis. This juice—which is obtained with essentially the same properties from the leaf-stalks of *Colocasia odora*, and the banana tree, the stems of *Stephanotis* and *Tanghinia*, the roots of the arum, and the parenchyma of the gourd—coagulates completely when heated, or on addition of a trace of nitric or tannic acid. It usually exhibits the alkalinity of serum or of egg-albumin; leaves, when dried up, a residue consisting almost wholly of albumin (in fact it is as rich in albumin as blood-serum or milk), and yields ash consisting mainly of alkaline chlorides and carbonates. (Frémy, Compt. rend. li. 647.)

LATHYRUS ANGUSTIFOLIUS. In the seed of this plant, Reinsch found an uncrystallisable bitter substance, vegetable fibre, starch, legumin, vegetable albumin, gum, salts, a fixed oil, a resinous and a waxy substance.

LATROBITE. Syn. with ANORTHITE.

LAUMONTITE. *Laumontite, Lomonite, Efflorescing zeolite.*—A hydrated silicate of calcium and aluminium, occurring in monoclinic crystals, in which the principal axis, orthodiagonal and clinodiagonal are to one another as 0.516 : 1 : 0.8727, and the inclined axes make an angle of $68^{\circ} 40'$. Angle $\infty P : \infty P = 86^{\circ} 16'$; $\infty P : (P) = 151^{\circ} 9'$. Observed planes $\infty P : \infty P : (\infty P\infty) : P : -P : -2P\infty$. Cleavage perfect parallel to $\infty P\infty$, also to ∞P . The mineral occurs also in columnar, radiating, or divergent forms. Hardness = 3.5 to 4. Specific gravity = 2.29 to 2.36. Lustre vitreous, inclining to pearly on the cleavage-faces. Colour white, passing into yellow or grey, sometimes red. Streak uncoloured. Transparent or translucent; becomes opaque, and usually pulverulent on exposure. Fracture scarcely observable, uneven. Not very brittle. Before the blowpipe it intumesces and melts to a frothy mass; forms a transparent bead with borax. It gelatinises with nitric or hydrochloric acid, but is not affected by sulphuric acid.

Analyses: a. From Phippsburg, State of Maine (Dufrénoy, Ann. Min. [3] viii. 303.—b. From Courmayeur, Savoy (Dufrénoy, *ibid.*).—c. From Skye (Connel, Edinb. J. of Sc. 1829, p. 252).—d. From Huelgoet, Bretagne (Malaguti and Durocher, Ann. Min. [4] ix. 325).—e. Red variety from Upsala (Berlin, Pogg. Ann. lxxviii. 415).—f. From Port George, Nova Scotia (How, Sill. Am. J. [2] xxvi. 30).

	SiO ₂	Al ₂ O ₃	Fe ₂ O ₃	CaO	H ₂ O
a.	51.98	21.12	. .	11.71	15.05 = 99.86
b.	50.38	21.43	. .	11.14	16.15 = 99.10
c.	52.04	21.14	. .	11.62	14.92 = 98.72
d.	52.47	22.56	. .	8.41	15.56 = 100
e.	51.61	19.06	2.96	12.53	14.02 = 100.18
f.	50.43	21.64	. .	12.07	15.26 = 100.40

These analyses lead to the formula $\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot 4\text{SiO}_2 + 4\text{H}_2\text{O}$ (requiring 51.68 SiO₂, 21.51 Al₂O₃, 11.78 CaO, 15.08 H₂O), or $\text{Ca}^{+}(\text{Al}^{+})_2\text{Si}_4\text{O}_{12} \cdot 4\text{H}_2\text{O}$, which is reducible to that of a hydrated metasilicate, $\text{R}_2\text{SiO}_3 \cdot \text{H}_2\text{O}$.

Laumontite occurs in the cavities of amygdaloid, also in porphyry and syenite, and occasionally with calcspar, in veins traversing clay-slate. Its principal localities are in the Faroe Islands, at Disko in Greenland; at Eule in Bohemia, in clay-slate on the St. Gothard, and in large masses in the Fassa valley; at Hartfield Moss in Renfrewshire, accompanying analcime; in the amygdaloid rocks of the Kilpatrick Hills near Glasgow; and in several trap-rocks of the Hebrides and the north of Ireland. Fine specimens are found at Peter's Point, Nova Scotia; it is also abundant in many places in the copper-veins of Lake Superior, and in several other localities of North America.

Laumontite is remarkable for the facility with which it gives up its combined water, in consequence of which it is often found opaque and friable. This change may be prevented in cabinet specimens by dipping them in a thin solution of gum-arabic. According to Malaguti and Durocher, it loses 2.26 per cent. water when kept for a month in a vacuum, and 3.65 in the exsiccator over sulphuric acid. In damp air it does not effloresce; and the effloresced mineral, when exposed to such an atmosphere, recovers the water which it has lost.

Sometimes the alteration of laumontite by natural processes goes a step further, and carbonate of calcium is formed. A laumontite from Oberscheid, near Dillenburg, thus altered, contains (dried at 100°), according to Wildenstein (Jahresber. 1850, p. 734),

SiO ₂	AlPO ₃	Fe ² O ₃	CaO	H ₂ O	CO ₂	
39.12	13.43	2.60	25.18	6.22	13.45	= 100

or, deducting carbonate of calcium:

66.33	19.34	3.73	11.64	8.96	. . .	= 100
-------	-------	------	-------	------	-------	-------

It has therefore been converted into a mixture of laumontite containing only half of the original quantity of water, with carbonate of calcium and a small quantity of free silica.

Laumontite likewise occurs more or less altered to orthoclase (C. Bischof, *Rammsberg's Mineralchemie*, p. 631; Lewinstein, *ibid.* p. 997; Jahresber. 1860, p. 771).

Caporicianite (i. 741) is perhaps an altered laumontite.—*Schneiderite*, a zeolite from the gabbro of Tuscany, and containing, according to Bechi (Sill. Am. J. [2] xiv. 64), 47.79 per cent. silver, 19.98 alumina, 16.76 lime, 11.04 magnesia, 1.62 alkali, and 3.41 water, is, according to Breithaupt, a decomposed laumontite. Berlin regards *adiforsite* (ii. 361), and similar minerals from Fahlun and Martenberg in Sweden, as decomposed laumontites.

LAURELIC ACID. An acid obtained, according to Grosourdi (Jahresber. 1851, p. 562), from the berries of *Laurus nobilis* (p. 477).

LAURIC ACID. $C^{12}H^{24}O^2 = \begin{matrix} C^{12}H^{24}O \\ II \end{matrix} \left. \begin{matrix} \end{matrix} \right\} O$. *Laurostearic acid*. *Pichuric acid*. (MARSSON, Ann. Ch. Pharm. xli. 33.—Sthamer, *ibid.* liii. 393.—Görgey, *ibid.* lvi. 303.—Heintz, Pogg. Ann. xcii. 429 and 583; J. pr. Chem. lxvi. 1.—A. C. Oudemans, Jun., J. pr. Chem. lxxxi. 356.—Gm. xv. 43.)—This acid, belonging to the series $C^mH^{2m}O^2$, occurs in the fat of the bay-tree, *Laurus nobilis* (MARSSON); in the fat of pichurim-beans (Sthamer); also in the volatile oil of these beans (A. Müller, J. pr. Chem. lviii. 469); in small quantity, together with many other acids, in sperm-ceti (Heintz); in croton-oil (Schlippe, Ann. Ch. Pharm. cv. 14); in the fruit of *Cyclocodaphne sebifera* (Gorkom, Tydschrift af Neerl. Indie, lxxi. 410); in the so-called Dika bread, the fruit of *Mangifera gabonensis*, together with myristic acid, but unaccompanied by any other acids (Oudemans); in the age or axin of the Mexicans, a salve-like fat obtained from *Coccus Azia* (Hoppe, J. pr. Chem. lxxx. 102); and in cocoa-nut oil (Görgey and Oudemans). It may be formed artificially by heating ethal (cetylic alcohol) with potash-lime to 275°—280° (Heintz, Scharling). According to Heintz, it is produced only from mixed (crude) ethal, inasmuch as this substance contains lethal:

But, according to Scharling, it is obtained from the ethal itself, $C^{12}H^{24}O$, which, according to him, is decomposed by heating with potash-lime, in such a manner as to yield stearic, palmitic, myristic, lauric, and butyric acids. (Scharling, Ann. Ch. Pharm. xvi. 236; Heintz, Ann. Ch. Pharm. xvii. 271.)

Preparation.—1. *From Bay-fat.*—Laurostearin from commercial oil of bay (p. 476), is saponified with potash-ley; the soap is separated by common salt, and its hot aqueous solution is decomposed with tartaric acid. The lauric acid then rises to the surface in the form of an oil which solidifies on cooling, and is freed from adhering tartaric acid by repeated fusion with water. (MARSSON.)

2. *From Pichurim beans.*—Laurostearin from *Faba pichurim maj.* is saponified with potash-ley till a clear soap-jelly is formed; common salt is added, and the white, brittle soda-soap thus produced is dissolved in boiling water, and supersaturated at the boiling heat with hydrochloric acid; lauric acid then rises to the surface as a colourless oil, which on cooling solidifies to a white crystalline mass. It is freed from hydrochloric acid by repeated washing with water, and purified by repeated crystallisation from weak alcohol. (Sthamer.)

3. *From Cocoa-nut oil.*—The oil is saponified with weak potash-ley; the soap

decomposed by dilute sulphuric acid, and the mixture distilled as long as fatty acids pass over, the water being repeatedly poured back. The distillate neutralised with potash, solidifies on evaporation to a gelatinous soap, which is separated by common salt, repeatedly dissolved in potash and again separated with salt, to free it from the fatty acids which can be thus removed, and again decomposed with dilute sulphuric acid. It is then neutralised with ammonia; the solution precipitated by chloride of barium; the liquid strained off; and the barium-salts which remain repeatedly boiled with water. The resulting solutions, as they run from the funnel, immediately deposit those flocks of laurate of barium, and the liquid, as it cools down, becomes turbid and deposits pulverulent caprate of barium. (Görgey; see also *Prep.* 5.)

4. *From Spermaceti.*—The saponification of this substance yields, besides ethal, considerable quantities of stearic, palmitic, and myristic acids, and smaller quantities of lauric acid.—The solution of 10 lbs. of purified spermaceti in 30 lbs. alcohol is boiled for some time with $\frac{1}{2}$ lbs. caustic potash previously dissolved in alcohol; the solution precipitated with aqueous chloride of barium, and strained while hot; the still warm residue pressed as strongly as possible in a warmed press, then well moistened with alcohol and again pressed; the alcohol distilled off from the solutions; the residue freed from the whole of the soluble matter by repeated treatment with ether; and the portion insoluble in ether added to the barium-salts previously obtained. In this manner are obtained, on the one hand, crude ethal; on the other, the barium-salts of the fatty acids of spermaceti.

The barium-salts suspended in water are boiled with very dilute hydrochloric acid, till the supernatant oily layer appears perfectly clear; the fatty acids thus obtained are dissolved in alcohol; the solution is left to cool; and the crystals which separate are pressed, first alone, then several times after being moistened with alcohol; whereby a mixture of palmitic and stearic acids is separated, while a portion of these two acids, and the whole of the myristic and lauric acids, remain in solution.

The whole of the mixed alcoholic solutions are heated; a concentrated aqueous solution of acetate of magnesium is added, so as to precipitate about $\frac{1}{20}$ of the quantity of fatty acids present; the precipitate which forms on cooling is separated by filtration; acetate of magnesium added to the filtrate in about the same quantity as before, and the same treatment repeated (the liberated acetic acid being neutralised towards the end with ammonia), till acetate of magnesium no longer forms any precipitate even in presence of excess of ammonia. In this manner a number of magnesium-salts (19) are obtained, from which stearic, palmitic, and myristic acids may be separated by processes to be hereafter described in connection with these acids.

The alcoholic solution, from which everything precipitable by acetate of magnesium in presence of excess of ammonia has been thus removed, still retains lauric acid, together with myristic and oleic acids. It is precipitated with acetate of lead; the precipitate is washed with dilute alcohol, dried, and freed from a small quantity of oleate of lead, by treatment with ether; and the undissolved portion is decomposed by prolonged and repeated boiling with very dilute hydrochloric acid, whereby a mixture of acids melting at 39.7° is separated. By repeatedly crystallising this mixture from alcohol, as long as the separated acid exhibits a rise of melting point, lauric acid is ultimately obtained, melting at 43.6° , and not capable of further decomposition by partial precipitation with acetate of barium, while myristic acid remains in solution. (Heintz.)

5. *From spermaceti or other fats containing lauric acid*, provided they are free from oleic acid, or this acid has been removed by the process to be described below.—The fat is saponified with alcoholic potash; the fatty acids are separated from the ethal or the glycerin, as above described, and dissolved in 10 pts. of hot alcohol; the solution is left to cool slowly in a cellar; and the fatty acids which crystallise out are separated by filtration and pressure. The mother-liquor is diluted with an equal quantity of boiling alcohol and supersaturated with ammonia; acetate of magnesium is added in excess to remove a certain portion of the fatty acids; the alcohol distilled off from the filtrate; the remaining salts decomposed by boiling with dilute hydrochloric acid; the separated acids re-dissolved in a quantity of hot alcohol sufficient to retain them in solution after cooling; and a concentrated solution of acetate of barium equal to about $\frac{1}{4}$ of the weight of the fatty acids, is repeatedly added, as long as a precipitate is thereby formed on cooling. The precipitates last obtained, which contain chiefly lauric acid, are separately decomposed by boiling dilute hydrochloric acid, and each portion of acid thereby liberated, whose melting point lies above 43.6° is separately and repeatedly crystallised from dilute alcohol, till its melting point has risen to 43.6° . (Heintz.)

If the fat contains oleic acid, it is saponified, the fatty acid is separated and mixed with a small quantity of hot alcohol, and the solid portions are removed by submitting the cooled mass to pressure. The mother-liquor (together with the alcohol used for washing the separated acids) is precipitated with ammonia and neutral acetate of lead; the washed and dried lead-salts are completely freed from oleate of lead by means of ether; the undissolved portion is decomposed by boiling hydrochloric acid; and the separated fatty acids are treated as above (Heintz). In this manner, pure lauric acid is easily obtained from cocoa-nut oil (which, according to Oudemans, does not contain oleic acid). If the acids dissolved in alcohol be precipitated in small portions with acetate of barium, the first portions contain palmitic and myristic acids; and from the remaining liquid, lauric acid may be obtained by repeated fractional precipitation, or by crystallisation in the cold. (Oudemans.)

Properties.—Lauric acid solidifies after fusion to a sealy crystalline mass, exhibiting a laminated texture on the fractured surface; from alcohol, in white, silky needles, united in tufts, or in prickly glandular scales. It melts to a colourless oil at 43.5° (Heintz), 42° – 43° (Marsson, Görgey), 43° (Sthamer), 45° (Müller), 43.5° (Schlippe), 43.5 (Oudemans). The alcoholic solution has a slight acid reaction. Specific gravity 0.883 at 20° (Görgey). When boiled with water it volatilises with the vapour. (Görgey, Oudemans.)

It is insoluble in water, but dissolves easily in alcohol and in ether.

By the distillation of its calcium-salt, lauric acid is resolved into laurostearous and carbonate of calcium. (Overbeck):

Laurates. Lauric acid is monobasic, the general formula of its salts being $M^{11}H^{20}O^2$, and $M^{11}(C^{11}H^{20}O^2)^2$.

The **barium-salt**, $Ba^{11}(C^{11}H^{20}O^2)^2$, is prepared as above described (p. 474), and crystallises on cooling from a boiling saturated aqueous solution in snow-white flakes. The saturated alcoholic solution becomes filled, on cooling, with delicate crystalline spangles, which, after drying at 100° , resemble caprate of barium (Görgey). It is wetted by alcohol and ether, but not by water (Görgey). Dissolves in 10,864 pts. of water at 17.5° , in 1,982 pts. boiling water, in 1,468 pts. cold and 211 pts. hot alcohol (Görgey). Decomposes before melting. (Heintz.)

The **calcium-salt** is a white precipitate, obtained by mixing the solutions of laurate of sodium and chloride of calcium.

The **lead-salt**, $Pb^{11}(C^{11}H^{20}O^2)^2$, forms a snow-white, loose, amorphous powder (Heintz); amine, having a beautiful nacreous lustre (Müller). It melts between 110° and 120° , and solidifies to a dull, amorphous mass (Heintz); melts below 100° to a colourless liquid, which solidifies in the crystalline form on cooling (Müller). It is insoluble in water; insoluble in cold, sparingly soluble in boiling alcohol. (Müller.)

The **copper-salt**, $Cu^{11}(C^{11}H^{20}O^2)^2$, is obtained by precipitating the hot alcoholic solution of the aqueous sodium-salt with aqueous sulphate of copper.

The **silver-salt**, $AgC^{11}H^{20}O^2$, obtained by precipitating the solution of the sodium-salt in weak alcohol with nitrate of silver, is a white powder, consisting of slender microscopic needles (Heintz). It dissolves easily in ammonia, and crystallises from the hot concentrated solution in very small needles (Marsson). It is scarcely or not at all altered by light, but decomposes before fusion when heated. (Heintz.)

The **sodium-salt**, $NaC^{11}H^{20}O^2$, prepared by nearly saturating a boiling solution of pure carbonate of sodium with lauric acid, evaporating over the water-bath, dissolving the remaining soap in alcohol, and evaporating the filtrate to dryness, forms a white powder, whose alcoholic solution solidifies on cooling to a white opaque jelly. The aqueous solution becomes turbid when largely diluted with water.

LAURIC ETHERS. *Laurate of Ethyl*, $C^{11}H^{20}O^2.C^2H^5$, is prepared by passing hydrochloric acid gas into an alcoholic solution of lauric acid, adding water, which separates the ether, washing first with alkaline, then with pure water, and drying over chloride of calcium. It is a colourless oil, having a fruity odour and sickly taste. Specific gravity 0.86 at 20° (Görgey). Crystallises at 10° . Boils at 269° , when the barometer stands at 760 mm. (Delffs); at 264° , with partial decomposition. (Görgey.)

Vapour-density by experiment 8.4; by calculation (2 vol.) = 7.9.

Laurate of Glycerol, or *Laurostearin*, $C^2H^5O^2\{C^{11}H^{20}O^2\}_2$ [or rather, perhaps, $C^2H^5O^2\{C^{11}H^{20}O^2\}_2$].—This fatty body is found in the berries of the sweet bay-tree (*Laurus nobilis*) (Marsson); also in cocoa-nut oil (Görgey), and in pichurim beans. (Sthamer.)

Preparation.—1. *From the berries of the Bay-tree.*—These berries are treated with

boiling alcohol; the solution is filtered hot; the crystals of impure laurostearin which separate on cooling are melted over the water-bath; the liquid thus obtained is filtered to separate a resinous substance which accompanies it; and the remaining laurostearin is purified by repeated crystallisation from alcohol. It is thus obtained perfectly pure.

3. *From Commercial Oil of Bay.*—The oil is exposed to sunshine on porcelain plates covered with glass shades, whereupon the green colour soon disappears, and brown hard lumps of laurostearin separate from the mass of fat melted by the sun's heat; these are separated by filtration, dissolved in alcohol, and obtained of a pure white by evaporation or by precipitation with water. (Bolley.)

4. *From Pichurim beans (Faba pichurim major).*—The beans are exhausted with cold alcohol (which extracts volatile oil, pichurim-camphor, resin, a buttery fat, and a brown coloring matter); and the exhausted beans are boiled with alcohol of 81 per cent., and pressed between hot plates. The expressed liquid, as it cools, deposits pale yellow laurostearin, only a small quantity of that substance remaining dissolved in the alcohol. It is purified by washing with cold alcohol, pressure, and recrystallisation from ether-alcohol. (Sthamer.)

Laurostearin forms white needles having a silky lustre, melting at about 44° , sparingly soluble in cold alcohol, moderately soluble in boiling alcohol, very soluble in ether. By dry distillation, it yields acrolein. When treated with alkalis, it is resolved into glycerin and lauric acid.

Laurostearin gives by analysis 73.19 to 73.53 per cent. carbon, and 11.45 to 11.68 hydrogen, agreeing nearly with the formula $C^{27}H^{52}O^1$ (calc. 73.97 C, 11.41 H, and 14.62 O), according to which, laurostearin contains the elements of 2 at. lauric acid + 1 at. glycerin - 3 at. water:

This, however, does not agree with the constitution of the normal glycerides (ii. 878). Perhaps, therefore, the true formula may be $C^{27}H^{52}O^3 = 2C^{12}H^{24}O^2 + C^3H^6O^3 - 2H^2O = \left. \begin{matrix} (C^3H^6) \\ C^{12}H^{24}O^2 \end{matrix} \right\} O^3$.

LAURIN. *Bay-berry Camphor.*—A substance discovered by Bonastre (J. Pharm. x. 32) in the berries of the bay-tree, and further examined by Marsson (Ann. Ch. Pharm. xli. 329) and Delffs (*ibid.* lxxxviii. 354). It is prepared by boiling the skinned and pounded berries with alcohol of 85 to 90 per cent., filtering at the boiling heat, and leaving the liquid to itself for several days. Laurostearin is then first deposited; and on filtering again and leaving the liquid to evaporate, laurin is deposited in crystals contaminated with a viscid oil, from which they may be freed by pressure between paper and recrystallisation.

Laurin forms crystals belonging to the dimetric system, destitute of taste and smell, insoluble in water, very soluble in alcohol, even in the cold—also in ether. The solutions are neutral to test-papers. Laurin does not dissolve in alkalis.

According to the analysis by Delffs, laurin contains 76.5–77.1 per cent. carbon, and 86.92 hydrogen, numbers agreeing approximately with the formula $C^{22}H^{40}O^3$.

Laurin cannot be distilled without decomposition. Its alcoholic solution is not precipitated by acetate of lead or nitrate of silver.

LAURONE. $C^{12}H^{16}O = C^{12}H^{20}O.C^4H^8?$ *Laurostearone.*—A substance produced by the dry distillation of laurate of calcium. It crystallises from alcohol in shining plates, which melt at 66° . It becomes electric by friction. Gives by analysis 81.42 and 81.04 per cent. C, and 13.82–14.10 H, agreeing nearly with the preceding formula (81.65 C, 13.61 H, and 4.74 O), which is that of the acetone of lauric acid. (Overbeck, Pogg. Ann. lxxvi. 591.)

LAUROSTEARIN. See LAURATE OF GLYCERYL (p. 475).

LAURUS CAMPHORA, OIL OF. See i. 729.

LAURUS NOBILIS. The *Sweet Bay-tree*.—The fruit of this tree has been analysed by Grosourdi (J. Chim. méd. [3] vii. 257, 321, 385; Jahresber. 1851, p. 562). He finds that, in the fresh berries, the pericarp constitutes nearly a third of the entire weight; the kernels, freed from epispem, make up more than half the weight of the seed; and the epispem amounts to rather more than $\frac{1}{11}$ th of the weight of the fresh seed.

100 pts. of the dried berries yielded 0.86 silica, 0.12 carbonate of calcium, 0.12 oxides of iron and manganese, 0.53 carbonate of potassium, 0.07 sulphate of potassium, 0.16 chloride potassium: in all, = 1.75 per cent. ash.

The composition of the entire fresh fruit, pericarp and kernel (cotyledon), is given in the following table:—

Composition of Bay-berries.

	Pericarp.	Kernel.	Entire Seed
Water	47.417	39.539	42.214
Starch		37.827	21.929
Lignin	32.850	7.785	20.526
Oil of kernels		5.975	3.377
Oil from pericarp	4.724		1.560
Stearolaurin	0.210		0.068
Stearolauritin		0.180	0.068
Pectin or Pectic acid	2.772		0.855
Resin	2.054		0.655
Phæosin or Phæosic acid	3.318	5.685	5.347
Laurin		1.428	0.855
Uncrystallisable sugar	4.301	1.003	2.080
Lauretin		0.120	0.009
Lauretic acid	0.650	0.360	0.403
Albuminous matter	0.200	0.110	0.320
Colouring matter	1.619		0.488
Volatile oil	0.005	trace	trace
	100.120	100.010	100.729

Laurelic acid was obtained by treating the pericarp with water, precipitating the pectin with alcohol, evaporating the alcoholic liquid, dissolving the residue in water, precipitating the aqueous solution with nitrate of lead, and decomposing the precipitate with sulphydric acid.

Stearolaurin (? identical with laurostearin) is the solid fat which gradually separates at 10° from the warm-pressed oil of the pericarp.—*Phæosin* or *Phæosic acid* is a brown substance extracted by carbonate of sodium from the pericarp, exhausted successively with water, alcohol, and ether.

LAVA. See VOLCANIC PRODUCTS.

LAVENDER, OIL OF. Lavender (*Lavandula Spica*, L.) yields a yellowish volatile oil, having a strong but agreeable odour, and an acrid aromatic taste. It reddens litmus, and contains, in variable proportions, a crystalline substance having the composition of common camphor (Dumas). The liquid portion of the oil appears to be mainly composed of two substances, one of which has the composition of oil of turpentine. (Gerhardt, *Traité*, iv. 336.)

LAVENDULAN. An amorphous mineral from Annaberg in Saxony, which appears to be an arsenate of cobalt, mixed with the arsenates of nickel and copper. It has a greasy lustre, inclining to vitreous. Hardness = 2.5 to 3. Specific gravity = 3.014. Colour lavender-blue. Streak paler blue. Translucent. Fracture conchoidal. Melts easily before the blowpipe, colouring the flame blue, and becoming crystalline on cooling. (Breithaupt, *J. pr. Chem.* x. 565.)

LAZULITE. *Azurite. Azure-stone. Blue Spar. Varavilite. Klaprothin.*—A hydrated phosphate of aluminium, magnesium, and iron, occurring in monoclinic pyramids, with truncated summits and several secondary faces. The inclined axes make an angle of 88° 15'; and the principal axes, orthodiagonal and clinodiagonal, are to one another as 0.86904 : 1 : 1.0260. Angle $\infty P : \infty P = 91^{\circ} 30'$; $\infty P : P\infty = 139^{\circ} 45'$. Observed faces, +2P ∞ , -2P ∞ , ∞P , +2P, -P, and others. Twin-crystals also occur with face of composition $\infty P\infty$. Cleavage lateral, indistinct. The mineral also occurs massive.

Hardness = 5 to 6. Specific gravity = 3.057 (Fuchs); 3.067 to 3.121 (Prüfer); 3.122 (Smith and Brush). Lustre vitreous. Colour azure-blue, commonly of a fine deep blue when viewed along one axis, and a pale greenish-blue along another.

When heated in a tube, it gives off water and turns white. Before the blowpipe, it colours the flame faint green, swells up, becomes tumid, but does not melt; gives a fine blue colour with cobalt solution.

Analyses.—a. Light blue from Krieglach in Styria: mean of two analyses (Rammelsberg, *Mineralchemie*, p. 340).—b. Light blue from near Werfen in Salzburg (Fuchs, *Schw. J.* xxiv. 373).—c. Dark blue from the Fischbach Alp in Styria: mean of two analyses (Rammelsberg, *loc. cit.*).—d. Dark blue from Sinclair County, North Carolina (Smith and Brush, *Sill. Am. J.* [2] xvi. 365).

	P ∞ O ∞	AlP ∞	MgO	FeO	CaO	H ∞ O	
a.	44.16	33.14	12.52	1.77	1.53	6.88	= 100
b.	42.70	36.60	9.54	2.70		6.19	= 97.68
c.	42.58	32.89	9.27	2.11	1.11	6.04	= 100
d.	48.76	31.70	12.04	2.77		6.69	= 99.26

From these numbers Hammarley deduced the formula, $[3(\text{Mg}:\text{Fe})^{\circ}\text{O}:\text{Pb}^{\circ}]\cdot 11\text{O}^{\circ}:\text{P}^{\circ}\text{O}^{\circ} + 3\text{H}^{\circ}\text{O}$. The darker varieties contain a larger proportion of iron than the lighter varieties.

Lazulite occurs in narrow veins in gray-slate, in the torrent beds of Chladning and Rädelsgraben, near Völs in Salzburg, and the other localities above mentioned; also at Tijoco in Minas Geraes, Brazil. It is abundant at Crowder's mount, Lincoln County, North Carolina. (Dana, li. 405.)

LEAD. Synonyms: *Blei*; *Plomb*; *Plumbum*; *Saturnum*. Symbol, Pb. Atomic weight, 207.

This metal does not often occur in nature in the metallic state; but of all the instances in which it is recorded to have been found native, the most trustworthy are those in which it was discovered among volcanic products.

The colour of lead is bluish-grey; and when it is cut, the fresh surface has considerable lustre; but this brilliancy disappears in a short time, in consequence of the formation of a thin crust of suboxide.

The lead of commerce is nearly pure, as shown by the analyses given at p. 504; the impurities, often present in very small quantities, are silver, copper, antimony, and sometimes iron and manganese.

Lead is very soft, is easily cut by a knife, and may be scratched by the nail. It readily receives impressions, and leaves a streak on white paper. It is very malleable and ductile, and is capable of being rolled into thin sheets or drawn into wire. It occupies the sixth rank among metals as to malleability, and the eighth rank as to ductility. Rolled lead is more ductile than cast lead, in the proportion of 7 to 5. Its malleability and ductility are much affected by the presence of impurities, especially by the oxide of lead, which it dissolves in small quantities in the melted state.

It is very deficient in tenacity; a wire $\frac{1}{16}$ of an inch in diameter does not support 2 lbs. In this respect, rolled and cast lead are precisely alike; but with the latter, fracture takes place at once, and the ends are clean and granular.

Lead begins to melt at 325°C ., and is completely fused at 335°C . (635°F .); at a higher temperature, it gives off vapours. At a temperature of 50°P ., it loses .005 of its weight in a charcoal-lined crucible, which increases to .09 as the heat rises to 150°P ., and the galena loses 3.71 per cent.

Lead crystallises in regular octahedrons. Mongez obtained it in four-sided pyramids on cooling; and Marx procured it in fern-like forms, similar to those in which ammoniac crystallises, by allowing a considerable quantity of melted lead to cool until half had solidified, then piercing the crust and running off the fluid portion. By the electro-chemical action of zinc in a solution of acetate of lead, it is deposited in an arborescent form, known under the name of *Saturn's Tree*. Landrin states that, in 1828, he noticed, in a deep mine in Cornwall, cubical crystals of lead which had been deposited on the miner's tools, and had been entirely oxidised. The presence of silver interferes with the crystallisation.

Lead emits a dull sound when struck with a hammer; but when cast in the form of a mushroom, it becomes sonorous.

The specific gravity of lead is, according to Kupffer, 11.3305; Brisson and Herapath, 11.852; Morveau, 11.358; Karsten, 11.3888; according to Berzelius, when in a state of purity, 11.445.

Its specific heat, according to Cooke, is 0.031400. It is an inferior conductor of heat and electricity.

Lead is pyrophoric in a state of fine division. It is usually obtained in this state by heating tartrate of lead in a glass tube as long as any fumes are evolved, when the tube is sealed by a blowpipe. On breaking the tube after cooling, and scattering the powder in the air, it will burn with a red flash.

When lead is melted in contact with the air, its surface is rapidly coated with an iridescent pellicle, which then passes into a yellow oxide. When the temperature is high enough to melt the oxide, it is absorbed by the lead, which loses its lustre and ductility: it becomes brittle, and all the faces of the fracture are dull. It recovers all its original properties by refusion with charcoal.

The action of air and water on lead has been carefully studied by Prof. Miller, from whose account of their combined action we give the following particulars:—This metal undergoes no change in a perfectly dry atmosphere, nor when sealed up in contact with pure water from which the air has been expelled by boiling. It is, however, subject to a powerful corrosion when exposed to the combined action of air and pure water. The surface of the lead then becomes oxidised, the water dissolves the oxide, and this solution absorbs carbonic acid, when a film of hydrated carbonate of lead, $2\text{PbHO}.\text{Pb}^{\circ}\text{CO}^{\circ}$, is deposited in silky scales. Another portion of oxide is formed, which is dissolved by the water, and thus a rapid corrosion of the metal ensues. This action is materially modified when various salts exist in the water, even when their quantity does not

exceed 3 or 4 grains in the gallon. Its solubility is increased by the presence of chlorides and nitrates, but diminished by phosphates, and carbonates, the oxide of lead being scarcely soluble in water. These salts in solution. Acid carbonate of lime is remarkable for its powerful influence; and in consequence of the presence of this salt in most spring waters, they do not act on lead to any serious extent, a film of carbonate of lead being deposited on the surface of the metal, and protecting it from further action.

The action of water on lead is very important in a sanitary point of view, as this metal is so constantly employed in making cisterns, pipes, &c. for domestic purposes. Rain-water from the roofs of houses, especially in towns, is sufficiently impure to prevent its action on the metal. The most insoluble salt of lead is the hydrated oxycarbonate (p. 478) which is only soluble to the extent of about 1 pt. in 4 millions or one-sixtieth of a grain per gallon of water. When a solution of lead is exposed to the air, silky crystals of this hydrated oxycarbonate are formed, and in a few hours the water does not contain more than $\frac{1}{4,000,000}$ of lead in solution. Water, however, which contains much carbonic acid in solution, is very dangerous, as it dissolves the carbonate of lead. When such water is boiled, the carbonic acid escapes, and the carbonate is deposited. Water has generally so much action on lead, that slate cisterns are much safer than those made with lead.

The *non-oxidising acids* do not act upon lead, except when in contact with the air, as already explained in the case of carbonic acid. *Nitric acid* easily acts on lead, even in the cold, forming protoxide, which is then dissolved. Strong *sulphuric acid* converts the lead into sulphate, when the acid is heated to the boiling point. *Hydrochloric acid* has little or no action, but aqua regia converts the lead into chloride. When *arsenic* or *arsenious acid* is heated with lead, arsenite and arsenide of the metal are formed.

Lead is readily oxidised by *cupric oxide*, which is at the same time reduced to the state of cuprous oxide; it also partially reduces the cuprous oxide, but the oxide of lead which is formed retains a portion of the oxide of copper in combination and prevents any further action on the metallic lead.

Nitre acts rapidly on lead at a high temperature, forming a fusible compound, protoxide of lead and potash. The *acid sulphates* also oxidise this metal; but neutral sulphates and the alkaline carbonates have no action.

Sulphur, selenium, phosphorus, and arsenic combine directly with lead.

Lead also alloys with most of the *metals*; but only imperfectly with copper, tin, uranium, cerium, cobalt, nickel, and iron.

EXTRACTION OF LEAD.

Historical Notices. The most abundant and valuable ores of lead possess so many properties likely to attract the attention of uncivilised nations, that it is not surprising to find early mention of this metal. Some authorities think that allusion is made to its metallurgy in the Hebrew word *opher*, in reference to the powder produced by the formation of the oxide on molten lead. The earliest mention of lead is in the well-known passage in the Book of Job; and it is again named as one of the spoils taken from the Midianites in the Book of Numbers. It is also probable that galena was used as a glaze for earthenware in the time of Solomon, from the notice in Proverbs xxvi. It was also one of the articles in which the Phœnicians traded, and which they may have obtained, in part at least, from this country. It was used in the hanging gardens of Babylon, the level of each terrace being covered with sheets of solid lead.

The Romans also worked the ores of this metal both in Spain and in this country. In the former country, the extent of the Carthaginian mining and smelting operations excite our surprise in the present day, and the slags left by them have been re-smelted on a large scale within the last twenty years, while lead cast in Roman moulds—*pign*, in fact, of the age of Hadrian and other emperors—have been found in Flintshire, Yorkshire, and other localities.

The methods of obtaining the lead from its ores have not undergone any great change, the smelters having adopted the reverberatory or blast furnace as they found the one or the other more suited to the character of the ores of each locality. The one great improvement in the metallurgic treatment of this metal is Pattinson's desilverising plan, which has been followed by the softening process for the hard leads of commerce, especially those of Spain; and we may remark that the only other addition to the ancient methods has been the condensation of the lead fume.

The Ores of Lead. Lead is seldom found native, but there are upwards of twenty ores of this metal known to the mineralogist. Those of practical importance, however, are very few in number, and all the lead of commerce may be said to be

procured from five minerals, viz. the carbonate, sulphate, phosphate, arsenate, and the sulphide, the latter ore furnishing more of this metal than all the others.

Sulphide of Lead, or *Galena*, is found in the older and more recent strata, and more or less, in every country of the globe. It occurs in veins in the killas of Cornwall, and in the mountain limestones of Derbyshire and the northern counties. In Cardiganshire and Montgomeryshire, it occurs in the strata of the lower Silurian rocks; and the chief deposits of the United States are found in the rocks of the same geological age. It fills veins in gneiss in Saxony; at Sala in Sweden, it is found in granular limestone.

Sulphide of lead occurs also, in combination with the sulphides of antimony and copper, in the minerals *Geocronite*, *Boulangerite*, *Jamesonite*, *Bournonite*.

Carbonate of Lead, or *Cerussite*, occurs in crystals, and in fibrous, compact, and earthy masses. It is frequently found in lodes, and sometimes in beds in sedimentary limestone, generally associated with galena. It is worked in quantity near Aix-la-Chapelle, and in the neighbourhood of Santander in Spain. It is also found in the mines of Cornwall and Devonshire, in Yorkshire, at Leadhills in Anglesey, and at Seven-Churches in Wicklow.

Carbonate of lead is also found, with other salts of lead and copper, in the minerals *Cromfordite*, *Susannite*, *Lavarkite*, *Calcedonite*.

Sulphate of Lead, or *Anglesite*, is found in cavities, but more generally in lodes associated with galena and carbonate of lead. It occurs at Leadhills in Scotland; in Cornwall and Derbyshire; in the Channel Islands; in Spain, Germany, France, and America.

The composition of this mineral is given in the following analyses:

Locality .	Anglesey.	Wanlockhead, Lead Hills.	Zellerfeld, Harts.

	98.8	98.50	99.21

Sulphate of lead also occurs combined with other salts, in the form of *Linarite*, *Calc. donite*, *Leadhillite*.

Phosphate of Lead, or *Pyromorphite*, occurs generally at the upper parts of lodes, less frequently in layers, and also usually associated with other ores of lead. There are three classes of this ore, viz. such as contain only phosphoric acid; secondly, those containing both phosphoric and arsenic acids; and lastly, those containing lime and fluorine.

The composition of some of the ores of the first class, is given in the following Table:

Locality .	Leadhills.	Poullusouen.	Kransberg.	Becresoo.

Oxides of iron and chromium	0.59
	100.00	100.00	99.63	99.71

This ore is found at Leadhills, and in Cornwall; at Wicklow in Ireland; at Phoenixville, in the United States; and many other localities.

Arsenate of Lead or *Mimetesite* is met with in large quantities at Drygill, in Cumberland, and has been used in the manufacture of flint glass, to which it imparts great brilliancy. It is found at Redruth and other Cornish mines; at Beeralston in Devonshire, and in America, Siberia, &c. generally occurring near the outcrop of the veins. There are three classes of it, similar to those of the previous ore. The following is the composition of a specimen of the ore which contains arsenic acid, analysed by Bergemann:

	From Blanca, Mexico.
Oxide of lead	74.96
Arsenic acid	23.06
Chlorine	2.44
	100.46

The other ores of lead will be found described in these volumes under their respective mineralogical designations.

Metallurgical Treatment of the Ores of Lead. The differences in the nature of the ores of lead, the peculiarities of the localities as to labour, fuel, &c., and the application of the lead afterwards, have all tended to modify the metallurgy of this valuable metal. It would have been more satisfactory to have described all the different plans in detail; but as this would be inconsistent with the limited space which can be devoted to a metallurgical subject in these volumes, we must confine this article to an account of some of the methods adopted for extracting lead from its ores. Various arrangements might also be pursued in this account of the smelting of lead ores, but we prefer the following, in which we will describe—I. Reduction of the Ores, II. Refining of the Lead. III. Softening of Hard Lead. IV. Smelting of the Slags and other Products. V. Condensation of the Lead Fume.

I. Reduction of Lead Ores.

All the ores of lead may be arranged in two classes in respect to their metallurgical treatment, viz. the sulphur and oxygen compounds of lead, and again as to the form of furnaces employed in their reduction, viz. the reverberatory and the blast furnace.

1. THE REDUCTION OF SULPHUR ORES IN REVERBERATORY FURNACES.

The sulphur ores of lead are treated after two different systems in the reverberatory furnace, which have been distinguished by Phillips as the *method of double decomposition* and the *process by affinity*, and these again differ in the details as practised in this country, in France, and in Germany.

The first plan depends upon the reaction between sulphide of lead and oxide of lead, as shown in the following equation:

or upon the double decomposition when sulphide and sulphate of lead are the constituents of the mixture, thus:

This process consists in roasting the galena in a reverberatory furnace, until a portion of the ore has been converted into oxide and sulphate of lead; it may be performed either in a distinct furnace, or in the smelting furnace where the subsequent fusion is effected. The following table of analyses of roasted ores, from different localities, illustrates the above remarks.

Analyses of Roasted Galena.

Locality	Pexey.	Holzapfel.		Pontgibaud.		
Oxide of lead	18	35	31.0	52.6	16.9	62.9
Sulphate of lead	86	19	8.0	8.0	12.1	
Sulphide of lead	10	4	11.8			
Oxide of iron	..	6	9.0	13.0	21.3	4.9
„ zinc	..	27	30.2	9.0	21.6	3.7
„ manganese	..	2				
„ antimony	..					
„ copper	..					
Arsenic acid	0.4	1.0	
Sulphate of baryta	14.0	19.8	0.7
Silica	..	7	10.0	3.0	6.2	23.9
Lime, &c.	3.1
	114	100	100.0	100.0	98.9	99.2

When the roasted ore has been thoroughly mixed, the doors are closed and the fires are set away. The reactions above explained then take place, when the lead is separated.

This process is applicable to the ores which are comparatively free from silica and earthy impurities, and is generally adopted in England.

The process by affinity consists in fusing the ore with iron in some form or other, when, the iron combining with the sulphur, the lead is eliminated: thus,

and this plan is better suited to the impure ores of lead.

a. Method by double Decomposition.

ENGLISH PROCESS.—The Reverberatory Furnace consists, as usual, of three essential parts, the fireplace, hearth and chimney. The position and relative proportions of each

Fig. 589.

part are shown in *figs. 589 and 590*, where *a* represents the grate; *b*, the door of the fireplace; *c*, the fire-bridge; *d*, the arched roof; *e*, the hearth; *ff*, the working doors; *gg*, flues running into one main flue leading to a condensing-chamber and chimney.

The hearth is hollow or funnel-shaped, to facilitate the descent of the lead to the lowest point in the bed of the furnace. The bottom of these furnaces, or hearth, as it is called, is built of bricks, which are covered with a layer of slags. These slags are run into a semi-fluid condition by a heavy fire, and then worked into the proper shape by means of paddles and rakes. The hearth slopes more rapidly from the fire-bridge than from the flue, to prevent the lead being exposed too long to the action of the heated air.

There are three working doors on each side of the furnace, attended by two men, who assist each other in manipulating the charge. The lead collects at the lowest part of the hearth, covered by the slags, and is drawn off by a tap-hole into the metal pot, *i*, in front of the furnace.

The arch falls rather rapidly towards the flues, *gg*, to give more effect to the heat, and the draught is capable of regulation by means of dampers.

The usual charge of ore in these furnaces at Holywell weighs 20 cwt., which is introduced through a hopper, *h*, in the arch of the furnace. This charge is then spread evenly over the surface of the earth, and gently heated for two hours, the doors being closed and the damper lowered.

The two front doors, farthest from the fire, being opened, the smelter throws in the slags swimming on the surface of the lead in the pot, *i*, from the previous operation. The tap-hole is opened in a little time to allow the metallic lead to run off from the slags, and at the same time, an assistant turns over the ore, through the back doors, by means of a paddle. These doors are now closed, while the front ones are open, through which some small coal is thrown in upon the lead-bath, and the whole is worked up together, the ore being turned over with a paddle. The smelter, in about three-quarters of an hour from the commencement, throws back upon the sole of the hearth, the fresh slags, which then float upon the bath, and are mixed with the coppy matter. These slags and the ore are then turned over with the paddle, and all the doors are closed.

The ore is turned over again through the back doors, and the first lead appears, obtained from the slag last remelted. This lead is run off by the tap, and both workmen then turn over the ore, through all the doors. The smelter now closes all the front doors except that next the fire-bridge, and lifts off the fresh slags from the lead pot, drains them, and throws them back into the furnace. The interior of the furnace, at this period, has a dull red heat.

The lead begins to separate from the ore in about $1\frac{1}{2}$ hour from the charging of the furnace, and the two workmen again turn over the ore from each side of the furnace. Some coal is thrown on the grates, slightly to raise the heat, the ore is turned over, and all the doors are closed.

The *first fire* or *roasting* lasts about two hours, and the damper is then raised a little; coal is thrown on the grates to give the *second fire*, which lasts 25 minutes. The heat of the furnace has now become bright red, and the lead flows from all sides to the bath. The smelter then pushes the slags back towards the upper part of the hearth, while the assistant spreads them over its surface, through the back doors. The smelter now throws in a few shovelfuls of quicklime upon the lead-bath, through the middle door. The assistant works the ore and slags through the three back doors, spreading them out, while the smelter again pushes the slags from the inner bath to the upper part of the sole. The doors are left open for a short time, and the lead flows down into the basin from the slags with which it was mixed as they were pushed back.

The workmen in a short time again turn over the ore and slags, and in three hours from the commencement, a little more fuel is thrown on the grate. In ten minutes, fresh fuel is added for the *third fire*, the damper is fully raised, all the doors are again closed, and the furnace is left in this state for three-quarters of an hour. At the expiration of about four hours, all the doors being opened, the assistant levels the surface to facilitate the separation of any lead, and then spreads the slags which are pushed back towards him by the smelter, who now throws in more lime to render the slags less fluid and to cover the lead-bath.

The smelter adds a fresh charge of fuel in about ten minutes after the completion of the third fire, and closes the doors to give the *fourth fire*. This fire is finished in four hours and forty minutes, when the doors are opened, the tap-hole is pierced to allow the lead to flow into the pot outside, and some lime is thrown upon the slags in the inner bath. The smelter then pushes these *dried* slags towards the upper part of the hearth, whence the assistant rakes them out of the furnace through the back doors.

We have given this detailed account of the working of a charge from Mr. Phillips' excellent description of the process followed in Wales, as an illustration of the nature of these operations, and to avoid the necessity of similar minute details in other analogous processes.

Fig. 590.

The weight of a charge varies in different localities, 12 to 14 cwt. being that used in the north of England; 21 cwt. in Bristol, and 30 cwt. in Cornwall, while the time extends from 6 to 24 hours, according to the weight and nature of the ore.

The cost of smelting an average parcel of galena in the reverberatory furnace is:

	s.	d.	
Labour	9	7.2	per ton of ore.
Coals 19.9 cwt.	3	3.8	"
Lime 0.9	0	4.9	"
Repairs	0	4.0	"
	13	7.9	

In some smelting works, the roasting process is conducted in a distinct furnace, and in other mills, the two furnaces are combined in the manner shown in *fig. 591*, which

Fig. 591.

represents the front or tapping side of the furnace. It is unnecessary to give any details of this form, after the description of the previous furnace.

When the process of roasting is conducted in a separate furnace, as a distinct operation, the cost per ton, from an average of upwards of 700 tons, is as follows:

	s.	d.
Labour	3	2.5
Coals 5.6 cwt.	0	11.2
Repairs	0	1.8
	4	3.5

This is probably the most suitable place to notice the results of some experiments made by Plattner and other chemists, on the loss of silver which occurs during the roasting of ores containing this metal, and which we can confirm from our own experience.

1. The loss of silver arises from chemical reactions.

2. The volatilisation of the silver appears to take place at the moment when it passes into the metallic state from its combination with sulphur, or when the sulphate of silver is decomposed.

3. The loss of this metal increases with the duration of the roasting, and the rise in the temperature.

4. The loss also increases when the oxides of iron or copper are present to decompose the sulphate of silver.

5. The loss is not so great with the silver-compounds of arsenic and antimonie acids, obviously because these salts are not so soon decomposed as the sulphate of silver.

We may also here notice the proposal of Fallizé, to tap the lead at different periods, instead of doing so at the end of the operation. He founds his proposal on the fact, that the lead which is first reduced, is the richest in silver; and by keeping the different products distinct, the subsequent operation of desilverising would be to some extent anticipated as well as facilitated, by providing leads varying in their richness in silver.

REDUCTION IN REVERBERATORY FURNACES. 485

We believe this suggestion to be well worthy of adoption, as we have found the lead obtained in smelting rich ores to fall from 74 oz. to 44 oz. silver per ton, according to the period when the lead was collected.

Another proposal for treating galena containing silver has also been made. The galena is to be mixed with 1 per cent. of chloride of lead, and 10 per cent. of common salt, and the mixture fused, when it is said the galena will be desilverised, and the chloride of silver will float on the surface with the common salt. The mixture of the latter salts is then to be reduced, with any chloride of lead that may be present. We have great doubts as to the economical results of this process, having found the loss of lead to be most serious, whenever any chloride of lead was present.

CARINTHIA PROCESS.—The furnace employed in this process differs from the English, as indicated by *figs. 562, 563.*

Fig. 592 represents a front elevation, and *fig. 593* a horizontal section. Two furnaces are built side by side, and work into one chimney. The hearth of these furnaces is

Fig. 592.

Fig. 593.

narrow, sloping regularly from the fire-bridge to the flue; and is so arranged that the fluid contents will flow to the metal pot *a*, outside the furnace. The hearth is formed of two concentric beds, the lower one of beaten clay, and the upper of fused slags. The arch is curved like the sole, but in an opposite direction, and at its highest point, is 23 inches above the hearth. The fireplace is shown by the dotted lines *ppp*, and the products of combustion, passing over the hearth, escape to the chimney *k*, through a flue over the working door. In recent furnaces of this form, the hearths are constructed one above the other, the operation being completed in the lower hearth.

The fuel employed consists of the wood of the spruce and pine, and the charge of ore weighs about 420 lbs. The working lasts 23 hours, and the produce is very large. The slags, when rich in lead, are washed and treated again. The lead flows into the outer pot, is purified by a second fusion, and then cast into pigs.

Kerl has given the following explanation of the reactions on which this Carinthia process is founded.

When galena is roasted at a low but gradually increasing heat, a portion of the sulphide is converted into sulphate of lead, along with some oxide of lead, while part of the sulphide remains unchanged.

When the temperature is raised, during the vigorous stirring of the ore, a quantity of lead is liberated, as already explained. Some subsulphide of lead is, however, also formed, which likewise reacts with the sulphate of lead, producing metallic lead; thus,

During this first period of the operation, lead is continuously liberated, and runs down to the bath in the hearth. The progress of the roasting converts more and more of the sulphide into sulphate of lead, diminishing the liberation of lead until a point is reached, when oxide of lead is the only product of the reaction; thus,

The second stage of the operation is then in progress, when, by the addition of red-hot charcoal and an increased temperature, the litharge is reduced and another portion of lead is obtained.

FRENCH PROCESS.—When galena is exposed to a continuous and slowly increasing temperature, a large proportion is converted into sulphate of lead, and a smaller portion into oxide of lead. If the roasting is interrupted at this point and the heat raised, but not so high as to induce fusion, these compounds react upon each other, producing oxide of lead, which furnishes metallic lead by the reducing action of coal; thus,

The coal also reduces the sulphate of lead ultimately into metallic lead and sulphurous acid. At a low heat, only half of the sulphate is converted into sulphide of lead; thus,

And as the temperature is raised, the same reaction occurs, as explained in the Carinthia process.

Fig. 594.

REDUCTION IN REVERBERATORY FURNACES. 487

There are three doors close together on the same side, and in front of the middle door the lead pot *i* is built. The firebridge *A* is 23 inches wide, and the hearth *g*, 11 feet by 6½ feet. The hearth is made with a tenacious clay resting upon an arch of granite.

A charge of ore weighs 2600lbs.; it is heated so gradually that at the end of five hours a dark red heat is reached. The doors are closed, and the heat raised till the ore commences to soften. The smelter now vigorously works the ore, when the reactions above explained take place, and the lead runs into the metal pot *i*. A second roasting for two hours follows, and then another turning over of the contents of the furnace. This alternate roasting and working is repeated several times, and at the end of 13 hours, some coal and wood are thrown into the furnace, to reduce the oxide of lead. A last roasting and stirring are then given, and the slags withdrawn from the furnace.

Fig. 596.

The composition of the slags obtained in the preceding processes is given in the following table:

Analyses of Lead-slags from Reverberatory Furnaces.

	Perey.	Holz- apfel.	Poullaouen.			Bir- ming- ham.	Katz- enthal.	Graw- sling- ton.	Lea, near Matlock.

The lead is purified by stirring it with beams of wood and repeated skimmings, after which it is refined.

ACTION OF THE GANGUE.—All the ores of lead contain more or less of other earthy and metallic compounds, which exercise a considerable influence on the chemical reactions which the smelter aims at accomplishing. When these foreign bodies are present in a large proportion, the processes just described are not adapted for the treatment of such ores, which are smelted by other methods to be hereafter explained. It will, however, be useful to take a rapid survey of the influence which these gangues exert on these processes.

Carbonate of Calcium.—When this substance is present in small quantities, it facilitates the chemical action, by contributing to the decomposition of the sulphide of lead, with formation of sulphate of calcium, and by preventing the materials becoming too fluid at the moment when the most important reactions are taking place. It has been found that 10 to 12 per cent. of this substance may be present in the ore without being prejudicial.

Sulphate of Barium.—This substance remains perfectly inert during the whole operation of smelting, and is objectionable therefore only as a mechanical hindrance, by diminishing the contact of the compounds of lead which are to act on each other in the furnace. Galenas which contain 16 per cent. of this gangue are, on this account, unfitted for treatment in the reverberatory furnace.

Fluor Spar.—This mineral is very similar in its action to the carbonate of calcium, but it is very beneficial when present with sulphate of barium, towards which substance it acts the part of a flux.

Quartz, Clay, and Silicates.—These gangues, when present only to the extent of 5 or 6 per cent., are very injurious, and it is impossible to obtain any lead in the reverberatory furnace, when they amount to 12 per cent. During the roasting they are inert, but when the heat reaches a dark red, and before the sulphide and oxide of lead react on each other, the silica unites with the latter, forming very fusible basic silicates, rendering the whole charge fluid, and preventing any further action.

Blende.—This ore may be present to the extent of 10 or even 15 per cent. without much prejudice to the working in the reverberatory furnace. It does not complicate the treatment, and is objectionable only by its conversion into oxide and sulphate of zinc, which are inert, and prevent the intimate mixture of the lead-compounds. The small portion of blende which escapes oxidation during the roasting, reacts afterwards on the oxide of lead, producing sulphurous acid, oxide of zinc, and metallic lead. When coal is introduced in the subsequent operations, the oxide of zinc is reduced at the same time as the oxide of lead, and the zinc, being very volatile, carries off a considerable portion of lead.

Iron Pyrites.—The presence of a small quantity of this mineral does not seriously interfere with the smelting operations. During the roasting, the pyrites is more rapidly oxidised than the galena, and what escapes, afterwards assists in reducing the oxide of lead. In the concluding operations, the oxide of iron is disseminated through the mass, and retards the fusion of the lead-compounds. A large proportion of pyrites is, however, very prejudicial, as that portion which is unoxidised, forms a very fusible matt with the sulphide of lead, which escapes the reduction.

When the pyrites is arsenical, the lead is always rendered more or less impure by the presence of arsenic, which increases the loss of both lead and silver in the subsequent cupellation.

Sulphide of Antimony.—This ore is always very injurious, even when present only to the extent of 2 or 3 per cent. It gives rise to the same reactions as galena; and, a portion of the antimony being brought to the metallic state, combines with the lead, rendering the latter hard, and occasioning a loss of both lead and silver when submitted to cupellation. The compounds of antimony also form very fusible compounds with those of lead, which cannot then be brought to the metallic state. The great volatility of antimony, its oxide and sulphide, also increases the loss of lead and silver.

Copper Pyrites.—This mineral renders the ores unfit for treatment in the reverberatory furnace. Even when it is present in such small quantities as not to interfere with the reactions, the lead always retains a portion of the copper, which diminishes its commercial value.

Carbonate of Iron.—This substance acts only as a mechanical hindrance in the furnace, where it is gradually converted into oxide of iron. During the later period of the operations, it retards the fusion of the slags, and postpones the reactions until nearly all the sulphide of lead is oxidised. This gangue therefore, when present in small quantities, is favourable rather than otherwise in the reverberatory furnace.

b. Process by Affinity.

This plan was used in France for treating a Spanish galena which contained a large proportion of quartz, and is founded on the reactions already explained.

The furnace employed is shown in *fig. 597*, and is charged with about 800 lbs. of

Fig. 597.

ore through a side door. This charge is mixed with 200 to 240 lbs. of iron, which ought to be in the form of scrap iron, as cast iron, mill cinder, and iron ores are not found to answer equally well with malleable iron. The mixed charge is then rapidly heated until the galena begins to soften, when the temperature is kept stationary to permit the reactions to take place. The lead, as it is reduced, flows to the lower part of the furnace at *p*, while the matt swims on the surface, and this again is covered by the slag. The contents are then drawn off through the tap-hole *b*, into the metal pot.

A modification of this plan has been proposed by Phillips and Rivot, who employ a furnace with a hearth slightly inclined towards a basin at the side, placed before one of the two side doors.

The furnace is to be charged with 1600 lbs. of ore, which must be carefully spread

over the hearth, and roasted for 12 hours at a moderate heat. At this point, if the ore does not contain sufficient silica, 12 per cent of sand and $1\frac{1}{2}$ per cent. of charcoal are added. The heat is rapidly brought up to a cherry-red, when the charcoal reduces the oxide of lead, and facilitates the action of the sand, which decomposes the sulphate, forming silicate of lead. The charge passes through a process of boiling, and when this subsides, a quantity of iron is thrown in while the charge is being well worked; the iron decomposes the silicate of lead, producing metallic lead and silicate of iron. When the slags are properly impoverished, the contents of the furnace are tapped into the pot, where the lead remains, and the slags flow off at one side.

Mr. W. J. Cookson has introduced another modification of this principle. He mixes the lead ore and iron together, and adds a small quantity of alkali and carbonaceous matter. This mixture is exposed to heat in large crucibles, when a very pure lead is obtained. The matt falls to powder, which is afterwards mixed with a little water, made into bricks, and burnt in kilns, as a substitute for sulphur ores, in the manufacture of sulphuric acid.

The Reduction of Oxygen-ores of Lead.

Carbonate of Lead.—When this ore of lead contains a large proportion of galena, it is treated by one of the plans already described, but when tolerably pure, it is submitted to special operations.

The furnace is of the ordinary reverberatory character, in which the hearth has only a slight inclination towards the tap-hole at one of the sides. The ore, in the form of a fine sand, is mixed with some reducing agent, such as coal, and some flux adapted to the nature of the gangue. This charge is then spread upon the hearth, the doors are closed, and the heat is gradually raised, during which the mixture is often turned over. The temperature is kept as low as possible, and the lead, gradually reduced, falls down to the tap-hole, through which it is drawn off from time to time.

When the lead has ceased to appear, the spongy mass on the hearth, is heated until it fuses, when the whole is drawn out and smelted in a blast furnace.

Sulphate of Lead.—This salt of lead is found native, and large quantities are also produced in various chemical and other manufactories. In the latter case, it is often mixed with an excess of sulphuric acid, which must be expelled in a reverberatory or other furnace.

The only mode of treating this compound of lead is that proposed by Phillips and Rivot, to which we must refer the reader.

Spanish Air-furnace, or Horno de gran tiro.

This furnace, shown in *figs.* 598—600, does not differ from the blast furnace in its form, but as the draught depends entirely upon the chimney, it may be said, in this respect, to resemble the reverberatory furnace, and finds its appropriate position in this part of the article.

Its height is 8 feet, and the diameter varies from $3\frac{1}{2}$ feet to 4 feet. The charging

Fig. 598.

door, D, is placed a little above the spring of the arch, S. The sole of the furnace, P, is formed of a very refractory material called *Laguena*, a species of decomposed argillaceous slate, which is found in great abundance near Cartagena. It is ground to fine powder, and mixed with coke also in powder, in the proportion of 3 to 1. This mixture is moistened with water, and carefully beaten with rammers. The walls, R, are also

built of the slate in its undecomposed state, called *Laja*. The hearth or crucible is then cut out to the shape shown in *fig. 598*. Six openings (*figs. 599, 600*) G G, are left in the walls for the admission of the air, and for drawing off the slags. The flue, C, connecting the furnace and chimney, is carried by an arch, K, and is built so as to be

Fig. 599.

independent of the furnace. The chimney, A, is about 44 feet high, has a large area, and works two furnaces. The air-holes are 15 inches by 12 inches at the outside, and taper to 9 inches by 4 inches next the interior. They are formed by working some clay

Fig. 600.

upon a wooden mandril, and placed to point towards the centre of the furnace. There are also other holes (register), F, above the air-holes, but temporarily built up, so as to be easily opened when required. An inclined plane, H, is built to draw away the slag, as in an iron blast furnace, and it is kept cool by an air-channel below. The lead is collected in a small pot, T, through an opening cut through the sole to the hearth.

The ore smelted in these furnaces contains carbonate of lead and galena, mixed with oxide and carbonate of iron, oxide of antimony, carbonate of lime, clay and sands. This ore is used raw, mixed with lead-slugs, and coke is the fuel employed.

The furnace having been annealed for some hours, 3 or 4 pigs of lead are placed in the hearth to form a bed for the slags, and the furnace is charged with coke. In 5 or 6 hours, a few baskets of slags are thrown in with a little granulated iron. After a little time, the slags begin to run down the incline, when the regular charge of ore is added. The air-holes are regularly watched to keep them all at the same degree of heat, as any neglect is apt to allow the materials to harden, when these air-tuyeres become choked. It is in fact the duty of one man to remove all the *niggers* or hard black lumps, which tend to form in and near them. The furnace is charged only once every hour, as the opening of the charging door, D, injures the draught.

The charge consists of:

40 baskets of ore, or about 5 cwt.	
8 to 10 " old Slag.	
4 to 5 " coke, with some dry wood.	

The latter assists in diffusing the air uniformly through the materials. The quantities used in 24 hours are:

Ore cwt. 134	Coke cwt. 20
Slag " 44	Wood " 2

As the air has a tendency to ascend round the sides of the furnace, the smelter throws his charges against the walls, and keeps the air-channels as far as possible open to the centre of the furnace. When the furnace becomes *gobbed* in any part, one or more of the register-holes are opened to enable the smelter to remove the obstruction.

The lead is tapped every six hours, and the matt is returned to the furnace. The produce varies from 6 to 7 cwt. of lead upwards, according to the richness of the ore.

We have described this furnace at some length, as it is cheaply built, lasts about 6 to 8 weeks, and can be used in localities where more perfect plans would be impracticable.

2. THE REDUCTION OF LEAD ORES IN BLAST FURNACES.

The ores generally smelted in blast furnaces are such as, from the proportion of their impurities, are not adapted to the reverberatory furnace; but this remark does not apply to the peculiar form of blast furnace known under the name of the *ore-hearth*, as used in America and this country (p. 497).

a. The Cupola or Blast Furnace.

This form of furnace is very generally adopted on the Continent, and exhibits at different works a great variety of form and dimensions. The great difference in the ores, the fluxes available and the nature of the fuel, are all so many conditions which require special modifications to overcome the difficulties peculiar to each locality.

We will select, as illustrations of this mode of smelting, three of the modifications in which the ore is used in the raw and roasted form, and in both states.

Silesian Furnace.—The form and construction of this furnace are represented in fig. 601. The walls, *a a*, are vertical from the tuyere upward; for a distance of 10 feet 4 inches to 6 feet, the section of the furnace is rectangular, while above this point it takes a circular form. The exterior wall, *c c*, is built of common bricks, and the lining or *shirt*, *a*, is constructed of fire-bricks. The charge of raw ore and flux is mixed on the floor, *E*, and thrown into the furnace through the opening *f*. The blast enters at *t*, and fusion takes place, during which the hearth, *h*, is gradually filled with the lead produced. The slag floats on the surface of the lead, and is drawn off at *e*, while the lead is occasionally tapped through a canal which passes to the bottom of the hearth. The fume is carried away from the top of the furnace through a series of condensing chambers. These furnaces can only be worked for about eight days, when the operation is stopped to repair the lining.

The *lit de fusion* consists of:

Galena in small pieces	. . . 100 parts.
Cast iron	. . . 12 "
Slag from iron forge	. . . 14 "

Each ton of this charge requires a ton of coal, which is thrown against the front, and the ore, &c. against the back of the furnace.

When the slag contains 7 or 8 per cent. of lead it is resmelted. The matt or regulus, consisting of sulphide of iron and lead, with a little silver, is roasted and smelted in the same furnace.

Hartz Furnace.—This plan is adopted in the Hartz, France, and Belgium, more or less modified according to the circumstances of the locality. The ore is always submitted to previous roasting; and when this operation is performed in a reverberatory furnace, the heat is gradually raised, until the oxidation is sufficiently advanced, when the doors are closed. The fire is then urged to melt the mass of materials, which is then drawn, allowed to cool, and broken up into pieces fit for charging the blast furnace.

The following tables contain numerous analyses of the matt and slags which are obtained from the blast furnaces of France and Germany.

The ore is sometimes roasted in the open air, as at Rammelsberg, on the Hartz, and Fahlun in Sweden. The ore at the former place, consisting of an intimate mixture of the sulphides of lead, copper, iron and zinc, is formed into heaps, as seen in *fig. 602*.

Fig. 602.

A thick layer of pine wood, *a a a*, is laid down for a foundation, upon which the ore, *b b*, is placed in pieces decreasing in size towards the top. The whole is covered with a layer of roasted ore in powder, which shuts off the access of an excess of air. These heaps contain about 160 tons of ore, and after they are ignited, the combustion is supported by the sulphides, through a period varying from 18 to 24 weeks.

At the top of the pile are a number of cavities, *s s s*, formed in the porous covering, in which a portion of sulphur collects, as it is sublimed from below, and from which it is ladled at times. A ton of sulphur is usually obtained from a heap, and it is said nearly to pay the cost of roasting. The metallic products are afterwards roasted in a second and third heap.

This roasted ore is smelted in a furnace constructed as shown in *fig. 603*. The charge is prepared on the floor, *g*, and thrown into the furnace, *s*, through the opening *c*, along with the fuel. A strong blast is driven in through the tuyere, *t*.

Fig. 603.

The charge consists of

Roasted ore	35 cwt.
Highly siliceous slags	10 "
Oxide of lead and pieces old cupels	$\frac{1}{2}$ "

The matt is repeatedly roasted and resmelted to obtain any copper, lead and silver, it may contain.

Spanish Economic Furnace. The discovery of enormous deposits of slags left by the Romans, near Cartagena and other places in Spain, together with the mining of a poor lead ore in these districts, has led, within the last 15 or 20 years, to a very great development of lead smelting on this coast. Furnaces of different descriptions were tried, one after another, but they have all given place to what is known under the above name.

This furnace, as improved by the writer, is represented in *figs. 604, 605, 606*, in elevation, section and plan. The blast enters through three water-tuyeres, *a a a*, and the materials are maintained up to the level of the charging door, *b*. The upper layers are kept cool by a fine rain of water from a rose, *c*, and the steam which is formed assists in condensing the fumes which escape into the flue, through an opening, *d*, in the back side of the top of the furnace. The upper part of the furnace rests upon four metal pillars, *ffff*, so that when the body of the furnace requires to be renewed, this part remains untouched. The lead accumulates in the hearth, *g*, whence it is tapped, from time to time, into the pot, *h*, to be ladled into moulds. The slag runs continuously into a tank, *i*, which is kept supplied with a stream of water. The slag in this case falls into a coarse sand, which is easily carted away, but it is sometimes run into small waggons, forming large blocks on cooling.

The furnace is circular, with a diameter of from $2\frac{1}{2}$ to $2\frac{3}{4}$ feet, and built of fire-bricks moulded to suit the form of the furnace. The body of the furnace is only one brick thick, and when any portion of the wall gives way, the hole is filled with clay, which is driven into the interior, while the smelter lays fresh bricks to rebuild the wall.

The bottom of the furnace is formed in Spain of a kind of clay which is found to answer remarkably well, but in this country a mixture of pure ground coke and fire-

clay is employed. This mixture, made into a paste, is very carefully beaten down, and then the hearth is cut out, as shown in the figure (605). The formation of this bottom

Fig. 604.

Fig. 605.

Fig. 606.

requires the greatest care, as the duration of the furnace depends more upon its stability than upon the continuance of the walls, which, as already explained, can be repaired from the outside.

The breast of the furnace is made of a semi-circular plate of cast iron, with a lip to carry off the slag, and a slit through which the taphole is drilled. Above the breast-pan is an arch about 18 inches wide and 24 in height.

The materials are charged, layer upon layer, of ore and flux and coke. The ore may be either raw or roasted, and the nature of the flux depends upon the character of the gangue. In Spain the ore is sometimes roasted in kilns, consisting of large chambers, something like our fire-brick kilns. The ores or materials containing lead to be smelted in this furnace should not hold more than 20 or 30 per cent. of lead.

When this form of furnace was introduced into this country, the writer made a great number of experiments as to the ores and fluxes which could be most profitably smelted by it; but it would be impossible to give the details in so limited an article as the present. It may, however, possess some interest to give the materials smelted and the cost of one of the first campaigns, which term is employed to designate the time the furnace works without being rebuilt. This campaign lasted 15 weeks, working night and day, and the following weights of ores were smelted:

Spanish ore	3249.50 cwt.	English lead ore slags	1521.25 cwt.
English lead ores	8634.60 "	Litharge	30.50 "
American silver ores	86.75 "	Litharge cinders	973.75 "
			14496.35

There was a gain of silver on the assays, but a loss of lead of about one-tenth on the

assays, which, however, it is proper to say, were made most carefully by the best methods. The cost was as follows:

								per ton.
1. Wages connected with the furnace					£124	1	9	—

								10 3.6

The following statement contains the cost of smelting the Roman slags near Cartagena, in Spain, calculated on the produce of lead:

Cost of 20 cwt. of Lead.

360 quintals at 8 per cent. lead, washed up to 24 per cent.	
= 120 quintals for smelting	360 reals
30 „ of coal for engine, at 6 reals	180 „
50 „ of coke for smelting, at 11 reals	550 „
2 smelters, at 8 reals	16 „
4 labourers, at 6 reals	24 „
Wear and tear	50 „
Management, &c. &c.	100 „
	1280 reals

and this expense, at 92 reals per £ sterling, brings the cost of a ton of lead up to £13 6s. 8d. per ton, where the Roman slags are obtained free of charge.

We believe this form of furnace is admirably adapted for many of our poorer ores and materials containing lead, and that it well deserves the attention of our smelters.

b. The Ore-hearth.

This method of reducing can only be applied to the purest description of ores, and the advantage which it possesses over the reverberatory furnace, consists chiefly in the greater purity of the lead which is produced. This, however, is of great commercial importance, as such lead is suitable for conversion into the best white and red leads, and in consequence brings £1 per ton more in the market than ordinary soft lead. The ore-hearth is also worked with less consumption of fuel and a smaller outlay in labour. The cost of the furnace is much less and the working may be discontinued and resumed at any time without repairs being required.

The first construction to be noticed is that of

The Backwoods Hearth.

This form of furnace is of the most primitive character, and yet the practice of the Western backwoodsman is still more simple; if he wants shot or bullets, he kindles a fire in a hollow tree, or an old stump of a tree, places some galena on the charred wood, and melts it down, when after cooling, he finds the metal at the bottom of the hollow.

In Missouri, the ore was reduced in square furnaces, constructed of logs or stones, as shown in fig. 607.

Vol. III.

K K

The air is admitted through the arch in the fore-side, and the lead is collected in the basin in front. The management consists in placing a layer of heavy logs at the bottom; then billets of split wood are set upright, on which the galena is thrown, the top of the ore being covered with small wood. A fire is kindled in the front arch, which chars the lower portion of the wood, and the process of reduction commences. The lead runs into the basin, and the operation lasts 24 hours. The ashes are collected after the furnace cools, and they are smelted in what is called an *ash-furnace*.

This plan is now superseded by constructions of a modern type.

The American Hearth.

This furnace (*fig. 608*) is sometimes made of cast iron, and so arranged that a hollow case surrounds the hearth, H, through which the air passes on its way to the tuyere, by which contrivance the blast is raised to a high temperature. The air enters through the pipe, C, and, following the course of the arrows, is driven through the tuyere into the hearth.

Fig. 608.

As the ore is reduced, the lead flows down the channel, *b*, into the pot, B. The force of the blast can be regulated by the valve, V.

The hearth is first carefully warmed by a wood fire, when the reservoir in the hearth, H, is filled with lead, which soon melts, and upon which the charge floats during the operation. The smelter places several pieces of wood before the blast, and then charges with raw galena. The whole soon becomes heated, the reduction follows, and the lead flows off into B. The first charge is followed by another, and thus the process is continued as long as the smelter wishes.

At Rossie, in New York, 75 cwt. of lead is obtained in 24 hours, and the cost of working is about seven shillings per ton.

The Scotch Hearth

is in use in the northern counties of this country, and Mr. Phillips' account of the mode of working it, is so admirable that we cannot do better than quote it.

Fig. 609.

This furnace (*fig. 609*) is from 22 to 24 inches in height, and 12 to 18 inches area inside, but its horizontal section, always rectangular, varies much in its dimensions at different levels.

The ore can be worked either in a raw or roasted state, but the latter is now generally used, as it yields a better produce, and works dry, allowing the blast to diffuse itself more perfectly through the mass.

In proceeding to smelt by means of an ore-hearth, two workmen are required to be in attendance from the beginning to the end of each smelting shift, the duration of which is from 12 to 15 hours. The first step in commencing a smelting shift is to fill up the hearth-bottom and

space below the workstone with peats, placing one already kindled before the nozzle of the bellows. The powerful blast very soon sets the whole in a blaze, and by the addition of small quantities of coal at intervals, a body of fire is obtained, filling the hearth. Roasted ore is now put upon the surface of the fire, between the forestone and pipestone, which immediately becomes red-hot and reduced, the lead from it sinking down and collecting in the hearth-bottom. Other portions of ore, of from 10 or 12 lbs. each, are introduced from time to time, and the contents of the hearth are stirred and kept open, being occasionally drawn out and examined upon the workstone, until the hearth-bottom becomes full of lead. The hearth may now be considered in its regular working state, having a mass of heated fuel, mixed with partly fused and semi-reduced ore, called *browse*, floating upon a stratum of melted lead. The smelting shift is then regularly proceeded with by the two workmen, as follows:—The fire being made up, a stratum of ore is spread upon the horizontal surface of the browse, and the whole suffered to remain exposed to the blast for about five minutes. At the end of that time, one man plunges a poker into the fluid lead in the hearth-bottom below the browse, and raises the whole up at different places, so as to loosen and open the browse, and in doing so, to pull a part of it forwards upon the workstone, allowing the recently added ore to sink down into the body of the hearth. The poker is now exchanged for a shovel, with a head 6 inches square, with which the browse is examined upon the workstone, and any lumps that may have been too much fused, are broken to pieces; those which are so far agglutinated by the heat as to be quite hard, and further known by their brightness, are picked out, and thrown aside, to be afterwards smelted in the slag hearth. They are called "grey slags." A little slaked lime in powder is then spread upon the browse, which has been drawn forward upon the workstone, if it exhibit a pasty appearance; and a portion of coal is added to the hearth, if necessary, which the workman knows by experience. In the meantime, his fellow-workman, or shoulder-fellow, clears the opening through which the blast passes into the hearth, with a shovel, and places a peat immediately above it, which he holds in its proper situation, until it is fixed, by the return of all the browse from the workstone into the hearth. The fire is made up again into the shape before described; a stratum of fresh ore spread upon the peat; and the operation of stirring, breaking the lumps upon the workstone, and picking out the hard slags, repeated, after the expiration of a few minutes, exactly in the same manner. At every stirring a fresh peat is put above the nozzle of the bellows, which divides the blast and causes it to be distributed all over the hearth; and as it burns away into light ashes, an opening is left for the blast to issue freely into the body of the browse. The soft and porous nature of dried peat renders it very suitable for this purpose; but in some instances, where a deficiency of peats has occurred, blocks of wood of the same size have been used with little disadvantage. As the smelting proceeds, the reduced lead, filtering down through all parts of the browse into the hearth-bottom, flows through the channel, out of which it is laded into the pig-moulds.

The principal particulars to be attended to in managing an ore-hearth properly during the smelting shift are these: First:—it is very important to employ a proper blast, which should be carefully regulated, so as to be neither too weak nor too powerful. Too weak a blast would not excite the requisite heat to reduce the ore, and one too powerful has the effect of fusing the contents of the hearth into slags. In this particular, no certain rules can be given; for the same blast is not suitable for every variety of ore. Soft, free-grained galena, of great specific gravity, being very fusible, and easily reduced, requires a moderate blast; while the harder and lighter varieties, many of which contain more or less iron, and are often found rich in silver, require a blast considerably stronger. In all cases, it is most essential that the blast should be no more than sufficient to reduce the ore, after every other necessary precaution is taken in working the hearth. Secondly:—The blast should be as much divided as possible, and made to pass through every part of the browse. Thirdly:—The hearth should be vigorously stirred at due intervals, and part of its contents exposed upon the workstone, when the partially fused lumps should be well broken to pieces, and those which are farther vitrified, so as to form slags, carefully picked out. This breaking to pieces, and exposure of the hottest part of the browse upon the workstone, has a most beneficial effect in promoting its reduction into lead; for the atmospheric air immediately acts upon it, and in that heated state, the sulphur is readily consumed, or converted into sulphurous acid, leaving the lead in its metallic state; hence it is that the reduced lead always flows most abundantly out of the hearth immediately after the return of the browse which has been spread out and exposed to the atmosphere. Fourthly:—The quantity of lime used, should be no more than is just necessary to thicken the browse sufficiently, as it does not in the least contribute to reduce the ore by any chemical reaction; its use is merely to render the browse less pasty, if, from the heat being too great, or from the nature of the ore, it has a disposition to become very soft. Fifthly:—

Coal should be also supplied judiciously, too much unnecessarily increasing the bulk of the browse and causing the hearth to get quite full.

When the ore is of a description to smelt readily, and the hearth is well managed in every particular, it works with but a small quantity of browse, which feels dry when stirred, and is easily kept open and permeable to the blast. The reduction proceeds rapidly with a moderate degree of heat, and the slags produced are inconsiderable; but, if in this state, the stirring of the browse and exposure upon the workstone are discontinued, or practised at longer intervals, the hearth quickly gets too hot, and immediately begins to agglutinate together, rendering evident the necessity of these operations to the successful management of the process. It is not difficult to understand why these effects take place, when it is considered, that in smelting by means of the ore-hearth, it is the oxygen of the blast and of the atmosphere which principally accomplishes the reduction; and the point to be chiefly attended to, consists in exposing the ore to its action, at the proper temperature, and under the most favourable circumstances. The importance of having the ore free from impurities is also evident, for the stony or earthy matter it contains impedes the smelting process, and increases the quantity of slag. A very slight difference of composition of perfectly dressed ore may be readily understood to affect its reducibility; and hence it is that ore from different veins, or the same vein in different strata, as before observed, is frequently found to work very differently when smelted singly in the hearth. It happens, therefore, that with the best workmen, some varieties of ore require more coal and lime, and a greater degree of heat, than others; and it is for this reason, that the forestone is made movable, so as either to answer for ore which works with a large or a small quantity of browse.

It has been stated that the duration of a smelting shift is from 12 to 15 hours, at the end of which time, with every precaution, the hearth is apt to become too hot, and it is necessary to stop for some time, in order that it may cool. At mills where the smelting shift is 12 hours, the hearths usually go on 12 hours, and are suspended 5; four and a half or five bings* of ore (36 to 40 cwt.) are smelted during a shift, and the two men who manage the hearth, work each four shifts per week, terminating their week's work at 3 o'clock on Wednesday afternoon. They are succeeded by two other workmen, who also work four 12-hour shifts, the last of which they finish at 4 o'clock on Saturday. In these 8 shifts, from 36 to 40 bings of ore are smelted, which, when of good quality, produce from 9 to 10 foddors of lead. At other mills, where the shift is 14 or 15 hours, the furnace is kindled at 4 o'clock in the morning, and worked until 6 or 7 in the evening each day, six days in the week; during this shift, 5 or 5½ bings of ore are smelted, and two men at one hearth, in the early part of each week, work three such shifts, producing about 4 foddors of lead; two other men work each 3 shifts in the latter part of the week, making the total quantity smelted per week in one hearth from 30 to 33 bings.

Hearth-ends and Smelter's fume.—In the operation of smelting, as already described, it happens that particles of unreduced and semi-reduced ore are continually expelled from the hearth, partly by the force of the blast, but principally by the decrepitation of the ore on the application of heat. This ore is mixed with a portion of the fuel and lime made use of in smelting, all of which are deposited upon the top of the smelting hearth, and are called hearth-ends. It is customary to remove the hearth-ends from time to time and deposit them in a convenient place, until the end of the year, or some shorter period, when they are washed to get rid of the earthy matter they may contain, and the metallic portion is roasted at a strong heat, until it begins to soften and cohere into lumps, and afterwards smelted in the ore-hearth, exactly in the same way as ore undergoing that operation for the first time, as already described.

It is difficult to state what quantity of hearth-ends are produced by the smelting of a given quantity of ore, but in one instance, the hearth-ends produced in smelting 9751 bings, on being roasted and reduced in the ore-hearth, yielded of common lead 315 cwt., and the grey slags separated in this process gave, by treatment in the slag-hearth, 74 cwt. of slag lead, making the total quantity of lead 362 cwt., which is at the rate of 3 cwt. 2 qrs. 23 lbs. from the smelting of 100 bings of ore.

The cost of smelting well-dressed galena at the ore-hearth is as follows:

	s.	d.
Labour	6	1 9

The ore-hearth, as usually constructed, often allows the fumes to fill the mill, whenever the draught is defective, and thus proves injurious to the health of the work people. Under all circumstances, a large volume of air passes into the flue, and so far diminishes the condensation of the lead-fume.

In order to diminish the objection, the writer introduced the following modifications, shown in *fig. 610*.

Fig. 610.

The hearth is covered with a hood of brick-work, *a*, at the back of which there is an opening into the flue. This opening can be enlarged or diminished by means of a damper, worked from the outside at *b*. The opening in front can also be regulated by means of a movable iron plate, *c*, which can be raised or lowered according to circumstances. The hood is firmly bound by iron straps, *d d*, which are maintained in position by screw-bolts above and below the hearth. The opening *e*, under the arch *f*, allows the workman to regulate the blast, which is admitted at the back through the ordinary tuyere.

The ore is charged through the opening *g*, in the side of the hood, and the furnace is worked from the front, in the manner just described.

We have now finished our account of the reduction of lead ores, and regret that we are compelled to omit many details relating to the various modifications adopted in Germany and elsewhere, which are treated at great length in Kerl's valuable *Handbuch der Metallurgischen Hüttenkunde*, to which we beg to refer the reader for further information.

Chemical Reactions in the Blast Furnace.

The substances which compose the charge in blast furnaces, are generally either in the form of powder more or less fine, or in masses more or less fused.

The fume is in the form of powder, and consists chiefly of carbonate and sulphate of lead. The dross and lead skimmings are in coarse powder, and contain oxide of lead, and some metallic lead mixed with the ashes of the fuel and other earthy matters. The furnace-waste contains quartz, clay, and silicate of lead; while the test-bottoms consist either of silicates of lead, &c., or of phosphate of calcium and oxide of lead. The ores and the grey slags are very varied in their composition, containing sulphide and oxide of lead, sulphates and silicates of lead, calcium, barium, &c., and differ as much in their mechanical condition.

The chemical reactions resulting from the fusion of so varied a mixture of compounds, are necessarily of a very complex character, and change even in the different parts of the furnace; thus in the

Upper Zone.—The uncombined oxide of lead, which happens to be present in the furnace in the form of powder, or as a porous mass, is reduced, and as this lead trickles down to the hearth, a considerable portion is volatilised. It is necessary, therefore, in roasting ores, &c., to raise the temperature high enough to fuse them into masses, which are only acted upon, on the surface, by the reducing gases in the upper part of the furnace.

The sulphide of lead is not easily decomposed by the aqueous vapour, and reaches the lower zone almost unaffected. The sulphate of lead stands in the same relation.

The compounds of iron, on the contrary, undergo a striking change, and in fact, play the part of reactives in the lower zone, in consequence of their reduction in this part of the furnace. A high furnace is necessary to complete this reduction, but such a furnace would be unsuitable for lead for the reasons previously given. The size of the pieces of these iron compounds, must therefore be regulated by the height of the furnace, being smaller as the furnace is lower.

Lower Zone.—The matters thus prepared in the upper zone, soften, and gradually enter into fusion as they descend, undergoing very complicated chemical changes which are difficult to regulate, and in which the reducing gases exercise little action, but where the solid fuel comes into operation.

The favourable working of the furnace is also assisted, inasmuch as the materials are not all equally fusible, and do not all soften at the same time. The matters containing the oxide of lead and the slags, melting first, gradually absorb the gangues and produce silicates rich in lead. The sulphates are rapidly decomposed by the melted silicates, and they produce very little sulphides under the reducing action of the solid fuel. Any sulphide of lead present, mixes with the metallic silicates, the reduction of the lead-compounds commencing only after the formation of the silicates. The reducing action is due chiefly to the metallic iron and solid fuel, the sulphides of barium and calcium also assisting in the production of the metallic lead.

Action of the Iron.—This metal decomposes part of the oxide and sulphide of lead, forming sulphide of iron and oxide of iron, which combines with the silicates. The sulphide of iron acts energetically on the silicate of lead, producing sulphurous acid, protoxide of iron, and metallic lead. When the roasting has been complete, there is little or no matt formed, and when a sufficient supply of iron has been produced in the upper zone, the lead is all precipitated and the slags then contain no oxide of lead.

The solid fuel assists the action of the iron, but its contact is of course much less intimate than that of the metal, which ought therefore to be always present in the proportion of an equivalent for every equivalent of lead. Under such circumstances, the slag is very fusible, and does not contain particles of lead, which being reduced in the lower zone the loss by volatilisation is as small as the volatile nature of this metal permits.

The important point consists in the reduction of sufficient iron in the upper zone, without necessitating the employment of a very high furnace. In a *lit de fusion* containing 40 per cent. of lead, there ought to be 9 per cent. of iron in the metallic state or an equivalent quantity of iron ore.

Iron borings, cast iron, &c. have been used, but the proportion of this metal must still be in equivalent quantities to the lead, and they do not act so well as iron finely divided, produced by the reduction of the iron ores.

Action of the Coke.—The reducing action of the solid fuel may be made to take the place of the iron, but unless the gangues and other substances contain sufficient oxide of iron to produce a fusible slag, the latter will consist only of earthy bases, requiring a high temperature for fusion, and thus increasing the loss of lead by volatilisation.

Coke has no action on the sulphide of lead, and as the fuel is charged in large pieces, its reducing action is limited to surface contact. The fuel should therefore be reduced to powder, and intimately mixed with the *lit de fusion*, while the roasting of the lead-compounds should be as complete as possible. This latter operation would, however, require a long time, and its expense would prove a great objection. We made some experiments on this subject, and found that it required upwards of thirty hours' roasting to bring the sulphur, in pure galena, down to 4½ per cent.

The employment of the fuel in powder, is also attended with the inconvenience of a great heat at the furnace-mouth, and the reduction takes place high above the tuyere, which causes a great loss of lead and silver by volatilisation. It is necessary therefore to employ very low furnaces, and to conduct the fusion very slowly; but without the aid of the iron there is always an increased loss of lead, when the reduction depends upon the fuel, and with such furnaces, the iron-compounds act simply as fluxes. On the contrary, in a furnace of suitable height, the intimate mixture of the iron ores and the fuel, is very effective, the whole of the metal acting as a reducing agent.

The reducing action of the fuel is attended with another difficulty, as it facilitates the conversion of the sulphates into sulphides, which then go to form more or less matt. In the case of the sulphates of baryta and lime, the reducing action of the fuel is however, to some extent, beneficial, as these substances assist in decomposing the oxide of lead.

When the matts are poor in lead and silver and not in large quantity, their presence is not very objectionable. We have often worked a furnace where the matt contained only 1·1 per cent. of lead, and 10 dwt. 10 grs. silver per ton. They indicate, when rich,

either imperfect roasting in the lead-compounds, or a deficiency of the reducing agents, sulphides of iron, barium, or calcium.

Iron Pyrites as Reducing Agent.—This mineral should be previously roasted to expel a portion of the sulphur, when it is to be used in the blast-furnace, but its employment has a tendency to increase the formation of matt. The same effect is produced, to a greater extent, when the galena employed is loaded with pyrites, since these two sulphides enter into combination in the upper zone of the furnace, and the matt produced does not act so vigorously upon the silicates as the sulphide of iron alone. The matt therefore partly escapes decomposition, and the quantity is accordingly increased.

Fume.—This substance, being in the form of powder, ought not to be charged direct, but it should undergo a preliminary treatment in a reverberatory furnace. It is advisable to mix it with some lead-compounds and a quantity of sand, varying from 15 to 20 per cent., according to its contents in lead. The charge is rapidly heated to the point of fusion, and about 8 per cent. of fuel, in small pieces, added. The whole is then well worked, to mix the fuel as intimately as possible, which promotes the separation of the lead obtained by the reduction of the silicate of lead.

ACTION OF THE GANGUES. Carbonate of iron.—This substance is converted, more or less, into sesquioxide of iron during the roasting process, and only interferes with the oxidation of the galena when present in large quantities. It acts in the furnace in the manner already explained, and must be regarded as a useful impurity; but when present in larger quantities and intimately mixed with the lead ores, it prevents the agglomeration of the powder, even when sand is added. Under such circumstances, the reducing action must be moderated in the upper zone of the furnace, and the union of the oxides of iron and lead with some fusible siliceous slags, must be promoted. The furnace ought to be low, and driven with a gentle blast; but with all precautions, there is a tendency to gob the furnace.

Iron pyrites.—When this mineral is present, the roasting requires a longer time, and it is difficult to prevent the agglomeration of the ores, with an undue formation of sulphates. Towards the end, the heat must be raised, and the presence of an excess of sand is necessary. The loss of lead and silver by volatilisation in such ores is less, however, probably, from the rapid formation of sulphuric acid by the oxidation of the pyrites, and the conversion of the lead and silver into sulphates.

When the roasting is complete, the only reducing agent necessary in the blast-furnace is coke, the action of which has been previously explained.

The arsenical pyrites is always injurious; the formation of arsenious acid during the roasting, increases the volatilisation of the silver, but the greater part of the arsenic remains behind in the form of arsenates. In the blast-furnace, some more arsenic is volatilised in the upper zone, and part remains combined with the lead and in the matt in the form of arsenuret of iron.

Sulphide of antimony.—During the roasting, the volatility of the antimony increases the loss of lead and silver, and towards the end of this operation, it is impossible to decompose the antimonates, even with an excess of gangues and fusible silicates.

In the blast-furnace, the antimonates are gradually reduced by the gases, the iron, and the solid fuel, with the same facility as the compounds of lead. A part of the antimony is volatilised, by which the loss of lead and silver is increased, and another portion passes into the lead and matt. The presence of this substance necessitates the use of an increased proportion of iron and coke. The antimony also accompanies the lead in all the subsequent operations, although the greater portion can be removed in the calcining process.

Copper pyrites.—In the blast-furnace, the copper is nearly all reduced at the same time as the lead, and when a matt is formed, a portion of the copper is always present. The lead, however, always carries away some copper, which reappears in all the subsequent operations, after giving a characteristic appearance both to lead and litharge.

Blende.—During the roasting, the blende is more rapidly oxidised than the galena, being converted into oxide and sulphate of zinc, which is decomposed with difficulty in the second period, while the infusibility of the oxide impedes the melting of the other materials. It is, therefore, necessary to add some argillaceous compounds to such galenas, and prolong the roasting process. These compounds of zinc are not volatile, but, being infusible, are more liable to be carried off with the current of fume, of which they always form a large proportion; these fumes are richer in silver than those formed in treating similar galenas free from blende. It is not known in what state of chemical combination the silver exists in fume, but from the facts observed in treating ores with different gangues, it would appear that the presence of silver in the fumes is due more to mechanical than to chemical causes.

In the upper zone of the blast-furnace, the oxide of zinc is partially reduced, and as

the metal descends, it is volatilised, when it acquires a dark red heat, and burns at the mouth of the furnace, spreading its oxide on all sides. This metal has therefore no beneficial action on the reduction of the lead.

In the lower zone, the oxide of zinc combines with the silica and retards the fusion, while the iron does not easily reduce it, and the metal, once formed, is volatilised without any appreciable action on the silicates with which it comes in contact.

The slags contain some oxide of zinc, which render them of a refractory character. The lead produced, does not contain much zinc, as the temperature is too high to favour the combination of the two metals.

When the roasting has been imperfect, the sulphide of zinc is partially oxidised by the aqueous vapour in the upper zone of the furnace, but the greater portion unites with the sulphide of lead, and forms matt. The greater porosity of these roasted materials, from the presence of the infusible zinc-compounds, increases the reducing action of the gases in the upper zone, and this again adds to the quantity of matt which is formed. This zinc-matt is, however, not so fusible as the others, and consequently remains longer in contact with the silicate of lead, on which it exerts a reducing action, the only benefit derived from the presence of blende.

The volatility of the zinc increases the loss of lead and silver in various ways, by its direct action, as well as by its rendering the roasted materials more porous, in consequence of the infusibility of its compounds in all the operations of roasting, smelting, and treatment of the fume.

The great object therefore in treating such ores is to diminish the chances of volatilisation, by perfect roasting, and the addition of fusible slags in sufficient quantity to overcome the infusibility of the zinc compounds. The beneficial action of iron pyrites in such ores, is due to the facility with which it melts, thus counteracting the opposite tendency of the blende; but the quantity necessary to accomplish this effect may, if the percentage of blende is great, prove so large as to render the ore too poor for any kind of metallurgical treatment.

II. The Refining of the Lead.

All lead ores contain more or less silver, and as the latter metal is reduced along with the lead, its separation becomes an object of commercial importance. The cost of separating silver by the old plan of cupellation, renders it impossible to refine lead with less than eight ounces of silver per ton, and the world is indebted to the late Mr. Pattinson for the discovery of a beautiful process, by which lead with no more than $\frac{1}{2}$ oz. will now pay for its extraction.

The separation of silver, therefore, now involves three operations, viz. desilverisation, cupellation, and the reduction of the pot-dross and litharge.

1. DESILVERISATION.—Pattinson's Process.

This process, known among the workmen as the *separating* process, and called in France, *Pattinsonage*, consists in slowly cooling the melted lead in iron pots, during which a portion of the contents assume a crystalline form, and sink to the bottom. These crystals contain less silver than the portion which remains in a liquid state.

The composition of this desilverised lead, from different localities, is given in the table below.

Analyses of Desilverised Lead.

Locality .	Altenau.	Stolberg.	Billach.	Eschweiler.	Pirach and Jung.	English.

The pots are large metal pans, and are generally set in a row of 10 or more, those to the left being called the *working* pots, and that to the right, which is smaller, the *market* pot, from the circumstance, that the *poor* lead is ladled from it into the pig moulds, ready for market.

The mode of setting a range of these pots is so clearly shown in *fig. 611*, as to supersede the necessity of any description.

Fig. 611.

Fig. 612.

The operation is conducted in the following manner:—One of the pots about the middle of the range is filled with pigs of lead, which are melted. The dross which forms on the surface is skimmed off by a small perforated ladle, when the fire is withdrawn from the grates below this pot. The lead, as it cools, is constantly stirred, and any portion which solidifies round the edges, is removed by an iron paddle or *slice*, and mixed with the molten lead. In a short time, the crystals, above mentioned, make their appearance, and continue to increase in quantity as the cooling progresses. The workman then dips a large perforated ladle, represented in *fig. 612*, into the mass of liquid lead and crystals, and withdrawing it, allows the liquid portion to drain away, which he hastens by an occasional shake of the ladle. He then attaches to the shank of the ladle, a hook, which is suspended at the end of a chain hanging upon the joists of the roof, and holding on by the handle, swings the ladle full of crystals over the next pot to his right, into which he empties the crystals. He continues this operation until the necessary quantity of lead has been crystallised out, when the liquid portion is ladled into the adjoining pot on his left. The same operation is repeated with all the intermediate pots, until the desilverised lead arrives at the market-pot, and the enriched lead reaches the rich pot, whence the lead is taken for cupellation.

The proportion of lead crystallised out in each pot varies very much with the richness of the lead at the command of the refiner, and especially if he has *original* leads of different values, by which he can keep up a continuous supply of lead to each pot. When the original lead is poor, then what is known as the *low system*, is adopted, where as much as seven-eighths of the lead is separated; but with richer lead, the *high system* is followed, and as little as two-thirds is removed as crystallised lead.

During the operation, the large ladle is liable to cool by its repeated exposure to the air, and in consequence the perforations become closed by the adhesion of the lead. This difficulty is overcome by occasionally dipping the ladle into the small intermediate pots on the one side, which are kept full of lead, maintained at a higher temperature by a small fire beneath them, as shown in *fig. 611*.

The shaking or jerking of the large ladle by the workmen when draining the crystals, would ultimately injure the pot, to protect which, a pig of lead with a bar of iron cast

Fig. 613.

in its upper surface, is laid on the broad rim of the pot, and this serves at the same time as a fulcrum on which the shank of the ladle rests.

These pots often require to be renewed, and as a large weight of metal in the rims

is rendered useless in each renewal, the upper portion of the brickwork is covered in some works with a circular metal slab, on which the narrow rim of the pot rests, by which a saving of expense in the repairs is effected.

This process is also accompanied by another advantage in purifying the lead. Each time the lead is melted, the surface becomes covered with a scum, which contains more or less impurity along with the oxide of lead, and this dross being always skimmed off, the quality of the lead is continuously improved as it approaches the market-pot. This circumstance is so well recognised, that leads containing only one ounce silver per ton, and even less, are regularly treated by this process, especially when the lead is to be used in the manufacture of white lead.

An average cost, founded on the crystallisation of 1,917 tons of lead containing 24 ounces of silver per ton, was found to be as follows:

	s.	d.
Labour	9	7-6
Coals, 6-2 cwt.	1	0-4
Repairs	0	2-9
	10	10-9

Stagg's apparatus.—The expense of labour is an important item in Pattinson's process, and none but powerful men are capable of managing the crystallising ladle. This objection attracted the attention of the late Mr. I. D. Stagg, who succeeded in constructing an apparatus for obviating this difficulty. This arrangement, known as *Stagg's apparatus*, is represented in *fig. 613*; it consists of a crane and windlass, *a b*; a chain attached to the end of the shank of the ladle is wound up by the windlass, and draws up the ladle, filled with crystals, out of the pot. A workman guides the handle of the ladle, which is afterwards placed under a catch, *c*, of the crane. While the crystals are draining, the ladle is occasionally shaken by the workmen, and by moving the crane, the ladle is easily carried over the adjoining pot, into which the crystals are emptied.

Worsley's apparatus.—This gentleman has also patented arrangements by which the labour is economised. He fixes an upright shaft in the centre of the pans, with a bearing at top and bottom, while arms radiate from the shaft to the sides of the pans; with this apparatus he obviates the use of the slice.

The other plan consists in drilling a $\frac{1}{4}$ to $\frac{1}{2}$ inch hole horizontally through the side of the pan, about two inches above the bottom. The opening inside the pan is covered with a sheet-iron strainer screwed down to the pan, and a spout is set in an opening made through the side wall of the fire-hole of the pan, to carry off the liquid lead into a pot placed outside. The hole in the pan is made tight by a slightly tapering *tapping bar*. The crystals remain behind for further treatment.

Parques' Process.

This process depends upon the superior attraction of silver for zinc over lead, and is applied by Mr. Parkes in the following manner:

The silver-lead is melted in one of the large pans already described, and raised to the temperature of melted zinc. The zinc being melted, is then added, and the fluid metals are stirred for a period of one to two hours. The fire is now lowered and the metals allowed to cool down until the lead is about to set. The zinc and silver rise to the surface during the interval, and are removed by means of a perforated ladle.

This alloy is afterwards heated in a sloping iron retort to remove a portion of the lead, which contains 1,000 ounces of silver per ton, and is ready for cupellation. The portion left in the retort, is heated in clay pots to distil off the zinc. The residue contains silver mixed with the impurities of the original lead and zinc. It is melted with lead and cupelled to obtain the silver.

Mr. Parkes also proposed to roast the alloy in close retorts or muffles, by which it was reduced to a fine powder, which was then to be treated with dilute sulphuric acid. The foreign oxides dissolved in the acid, leaving the silver, which was treated in the usual way.

The quantity of zinc required to desilverise the lead, depended upon the proportion of silver and other metals present in the lead, and he gave the following statement in his specification—viz. for 20 cwt. of lead containing

14 oz. of silver per ton	22-4 lbs. of zinc.
21 " " " " " " " " " " " "	33-6 "
28 " " " " " " " " " " " "	44-8 "

The loss of lead in this process is said to be about 1 per cent., but on account of

the difficulty in treating the alloy of zinc and silver, Messrs. Neville are understood to have abandoned the plan.

Separation of Copper in Crystallisation.

Mr. Baker has published the following results of an inquiry to ascertain how far the impurities of lead, viz. silver, copper and iron, are removed in this process of crystallisation.

The original lead contained :

	1	2
Silver . . .	0.0046	0.0052
Copper . . .	0.0066	0.0164
Iron . . .	0.0065	0.0068
Sulphur . . .	trace.	

The various products of the process contained :

	Silver.	Copper.	Iron.
Rich Pot:—			
Before crystallising . . .	0.0108	0.0344	0.0312
Crystals, 25 pts. . . .	0.0052	0.0152	0.0086
Fluid lead, 85 pts. . . .	0.0140	0.0476	0.0122
Second Pot:—			
Before crystallising . . .	0.0052	0.0154	0.0068
Crystals, 95 pts. . . .	0.0020	0.0066	0.0118
Fluid lead, 25 pts. . . .	0.0126	0.0286	0.0146
Third Pot:—			
Before crystallising . . .	0.0020	0.0102	0.0118
Crystals, 70 pts. . . .	0.0010	0.0038	0.0198
Fluid lead, 25 pts. . . .	0.0100	0.0240	0.0082
Fourth Pot:—			
Refined lead	0.0014	0.0054	0.0112

From this Mr. Baker very naturally draws the conclusion that there is an alloy of copper-lead which remains fluid when crystals of lead are formed, and that when the former metal is present in moderate proportions, it may be separated from the latter by a process similar to that of Pattinson.

This statement has been disputed by Reich and Streng, who deduce from their experiments the conclusion, that the copper is not separated; but the writer, without having analysed the different leads, inclines to believe in the correctness of Mr. Baker's conclusions.

2. CUPELLATION OR REFINING OF THE RICH LEAD.

Although it may be difficult to assign a correct interpretation to Hebrew terms of art, yet we think it is clear that the use of lead in purifying other metals was known in very ancient times. Jeremiah would seem to allude to this fact in the passage in ch. vi. ver. 29, and similar reference is made in Ezekiel xxii. 18–22, Malachi iii. 2, 3. The first notice of the process of cupellation among the ancients, appears in the works of Dioscorides; and Pliny and Geber describe an operation which is a true cupellation by means of lead. In 1343, Philippe le Bel issued an ordinance prescribing the use of cupels for testing the precious metals. In 1556, Agricola in his work, *De re Metallica*, fully describes the whole process, with instructions how to make the tests; this was followed by the work of Barba, *Arte de los Metales*, in 1640, where the construction of the refining furnaces is minutely explained.

The chief object is generally to separate the silver from the lead, but when an oxide of lead in the form of litharge is wanted, then the former becomes a secondary operation.

There are many modifications as to the form of furnace, mode of refining, &c., but only what may be called two distinct methods of cupellation—viz. the English and German.

The English System.

The peculiarities of this system consist in the cupel being movable, and the lead being fed at intervals.

The furnace, which is termed a *Refinery*, is represented in *figs.* 614, 615, where two cupels can be worked at the same time when necessary; *a a* are the positions of the cupels or tests, one of which is shown resting on an iron waggon, *b*; *c c*, the pots containing the rich lead in a melted state, which is ladled into an iron gutter, *d d*, to supply the test; *e e*, the point where the blast enters, and *f f* the opening or *gate*, through which the litharge is blown over into a pot below; *g g*, the fire grates, and *h h* the ash pits; *i i*, the flues, and *k k* the chimneys.

Fig. 614.

Fig. 615.

The bottom or sole of this reverberatory furnace is formed of bone-ash, finely ground, which is prepared by moistening it with a very weak solution of pearl-ashes. This mixture is placed within an oval iron frame-work, formed of an iron ring *a a*, (fig. 616) about four inches deep, called the *test-ring*, and iron bars cross the bottom *b b*. The bone-ash mixture is then carefully and firmly beaten down with iron rammers. The centre of this mass is then scooped out by means of a small trowel, as seen at *c*, and the portion round the sides and ends, *d d d*, left as walls to retain the melted metals.

As the success of the cupellation depends in a great measure on the careful preparation of the cupel, an apparatus has been contrived to give a proper consistence to the bone-

Fig. 616.

Fig. 617.

ash. A longitudinal section of this apparatus is shown in fig. 617 in such detail as to render any description unnecessary. It is worked by hydraulic pressure.

The test is allowed to dry in the air for some time, and then placed on the waggon, which is run into position. The test is then wedged tight up against an iron ring built firmly in the masonry. The fire is now lighted and the test carefully annealed, otherwise it is liable to crack. When perfectly dry, it is heated to a dull redness, and then filled with the melted rich lead.

This lead soon becomes coated with a greyish dross, but as the heat increases, the surface of the lead appears, and the formation of litharge commences. The blast is now turned on, and while supplying the oxygen necessary for the oxidation of the lead, it drives the litharge to the mouth of the refinery, where it flows in a continuous stream over the gate into a little iron pot placed on wheels for the convenience of removal.

When there is only enough rich lead to yield a small cake of silver, the refining is completed in the same test, and in that case, the workman cuts down the opening in the bone-ash at this end of the test, which is called the gate, to the level of the melted lead, until the *fining* of the silver commences.

When there is a stock of rich lead, the concentration of the silver is confined to the first test, which is called the *lead-test*. As soon as the silver amounts to about 8 per cent. of the contents of the test, a small hole is carefully drilled in the bottom, and the rich alloy is run into moulds. The hole is then closed by a pellet of bone-ash, and another cupellation commenced. The rich alloy is afterwards refined in the same manner in another test, hence called the *silver-test*.

When the lead has been nearly all oxidised, the film of silver becomes thinner and thinner; it then exhibits a succession of the beautiful iridescent tints of Newton's rings, and at length the film of oxide disappears, revealing the brilliant surface of silver beneath. Such is Dr. Miller's admirable description of this beautiful phenomenon, known as the *fulguration* of the metal, or as the men call it, the *brightening of the plate*.

At this point the blast is turned off, the fire withdrawn, and the silver allowed to cool. When the silver has *set* and begun to harden, the wedges are removed, and the test with its cake of silver falls on the iron waggon. When cold, it is removed, the impurities adhering to its under surface are chipped off, and the silver is ready for fusing into ingots.

During the cupellation, the silver absorbs oxygen, which is evolved as the metal cools, forming crater-like eruptions on the surface, and the extent of these protuberances is a very good indication of the purity of the silver.

There is not much silver lost in the refinery by volatilisation, but a comparatively large absorption takes place in the test. We have assayed several test-bottoms, and have found the contents in silver to vary from 74 oz. to 115 oz. per ton of test.

Chambers' Steam Blast.—The blast employed in refining must be soft, and is best supplied by means of a fan, but a very excellent plan of Mr. Chambers was tried by the writer, and furnished very good results. It consisted in substituting a steam jet for the blast of air, and as the steam passed through a wide nozzle, it carried sufficient air along with it to oxidise the lead, while mixing a body of steam with the lead fume, which was thus more completely recovered in the long flues by the condensation of the steam.

A more simple and compact form of refinery is shown in *figs.* 618, 619, where the steam blast-pipe is represented entering the furnace at *a*. This refinery is also fitted with an iron hood, *b*, placed in front of the working door, where occasional puffs of fume are blown over the workman. This fume is carried off by an iron pipe, *c*, into the chimney, and this protects the men from the injurious consequences of inhaling the lead smoke.

The following statement as to the cost of refining is founded on the cupellation of rich lead, which produced upwards of 60,000 oz. of fine silver:

	<i>s.</i>	<i>d.</i>
Labour	3	10 3
Coals 4·7 cwt.	0	9 4
Pearl-ashes 0·6 lbs.	0	4 0
Bone-ashes 18·7 „	3	3 8
Repairs	0	2 0
Engine Power: Coals cwt. 5·2 = 0 10 4	}	1 10 7
Wages 1 0 3		

Per ton of lead 10 4 2

or 3*s.* 1·1*d.* per 100 oz. of silver.

When the silver has been removed, the test is broken up, those portions of the bone-ash which are free from lead, being removed for subsequent use, and the rest is generally

carried to the slag-hearth or blast-furnace, where the bone-ash of course is lost. Mr. Johnson recovers this bone-ash as follows:—

Johnson's Process.—He reduces the cupel to a powder, and mixes it with acetic acid of 1.030 to 1.048 specific gravity, in sufficient quantity to render the mixture of a thin

Fig. 618.

Fig. 619.

consistence to admit of its being well agitated in a dolly tub. The greater part of the lead dissolves, and by renewing the acid, a further quantity is removed, so that, on working the residue to separate all the solution, the bone-ash is sufficiently pure to be employed again in making tests. The solutions yield the lead, in the form of sugar of lead, by concentration.

The German System

differs from the English in forming the hearth of marl instead of bone-ash; and in making it of large dimensions, and charging all the lead at one time.

The form and construction of this furnace is shown in fig. 620, which is taken from an excellent treatise on the Metallurgy of Lead by Dr. Lamborn. The corner on the

Fig. 620.

right is removed, to show the interior. The circular portion contains the hearth and a rectangular fireplace. The foundations, F F, are built of stone, cramped with iron rods, and pierced with openings to carry off the moisture. A, represents the fireplace, in which either wood or coal can be burnt. The hearth is formed of bricks set on edge on a bed of scoræ which has been well beaten down. A layer of marl, also carefully beaten with iron rammers, is formed on the bricks, and this bed is generally renewed at each cupellation. A wall, K K, surrounds the hearth, and serves to support a movable cap, C, which is formed of sheet iron, strengthened by bars on its upper side, and lined with clay secured by numerous iron straps. The cap is suspended by chains from the crane, R, and supported by a lever, L, so that it can be raised or removed on one side, when necessary. The opening, G, opposite the fire-bridge, B, serves to introduce the materials of which the hearth is constructed, as well as the lead to be refined, and acts as a chimney to carry off the products of combustion. The workman watches the operation through an opening in the corner, which is removed in the wood-cut, through which the vapours pass away. The blast enters at T, through two tuyeres, whose nozzles are frequently covered by two small valves, called *butterflies*, to diffuse the blast over all the surface of the bath.

When all is ready for work, a thin bed of straw is laid upon the hearth, on which the pigs of rich lead are piled. The cap, C, is then lowered on the walls, and fluted with clay all round the edges. The fire is then lighted, and soon after the lead is melted, its surface is covered with a dark crust called *abeugs*, consisting of the oxides of the foreign metals, and other impurities from the lead. This crust is drawn off through the working door, opposite T. The fire is kept up to maintain the lead at a dark-red heat, while the impurities, termed *abstrichs*, continue to separate. The table which follows, contains the analysis of some of these products. The next product which appears, is known under the name of *cupreous* or *wild Litharge*, and at the end of some hours, the formation of the true litharge commences. The heat is now maintained between a cherry and a bright red, until the operation is complete.

There are two varieties of litharge obtained, distinguished by their colour, *yellow* and *red*, the former being in fused pieces, while the latter is in flakes. The difference arises from their mechanical condition, which results from a difference in the cooling.

The period when the operation approaches a termination is marked by the brightening of the melted mass, when some hot water is thrown over its surface, and as soon as the silver begins to solidify, cold water is used to harden the cake. This silver contains 2 or 3 per cent. of lead, and is refined by another process.

Separation of Lead from Bismuth.

This process of cupellation has been employed by Paters to separate the two metals, lead and bismuth. At Joachimsthal in Bohemia, the small quantity of bismuth in the ore gradually accumulates in the rich lead, and when the latter is submitted to cupellation, a green litharge makes its appearance towards the end of the operation. This substance, called "Black Litharge," is reduced and refined in the usual way. The lead is first oxidised, and leaves the bismuth, nearly pure, on the test. This impure metal is refined in a second cupellation, and the bismuth so obtained is very pure, as indicated by the following analysis:

Bismuth . . .	99.58
Silver . . .	0.42
Lead . . .	trace
Iron . . .	trace
	100.00

The original alloy obtained by reducing the black litharge, consists of:

Bismuth . . .	34.5
Lead . . .	65.5
	100.0

The progress of the cupellation is carefully watched, and samples of both the litharge and the metal on the test are analysed from time to time. The mixed metals are dissolved in nitric acid, and an excess of hydrochloric acid is added to convert the metals into chlorides. Strong alcohol is added, which precipitates the chlorides of silver and lead, and the bismuth is thrown down from the solution by carbonate of ammonia, then filtered, and weighed.

Manufacture of Litharge.

An oxide of lead is in demand for the preparation of acetate of lead and other purposes, and this substance is produced in two forms, as *Flake* and *Levigated* litharge.

Flake Litharge.—When litharge is manufactured for sale, the purest lead, not mixed with silver, is selected for cupellation. The refining process is conducted as already described, but the oxide of lead at the commencement and termination of the cupellation is rejected.

The litharge, as it flows from the test, is received in large pots fitted on wheels, in which it is allowed slowly to cool. In some cases, the pots are heated so that the cooling may be more gradual, as the proportion of the flake litharge depends upon this condition. When the pots are emptied, the mass of litharge falls, and the whole is passed through a circular temse, working in a close wooden erection to protect the men from the dust. The fine flake litharge is collected and packed in casks.

Levigated Litharge.—The portion of litharge which does not fall, but remains in hard fused pieces, is employed for the manufacture of levigated litharge.

The process consists in simply grinding this fused litharge between horizontal stones with a supply of water. The mill employed for the purpose is seen in *figs. 621, 622.*

Fig. 621.

Fig. 622.

Motion is communicated to the driving wheel, *a*, on the upright shaft, *b*, which works into the wheels, *c c c*, on the spindle *d d d*, turning the upper stones of the three pairs *e e e*. The litharge, along with a small stream of water, is fed into the lower pairs, as it is seldom necessary to pass it through two sets of stones. The ground mass then falls into the dolly-tubs, *f f*, which are agitated by means of the shafts, *g g* driven by the belts, *h h*, working round a sheave, *i*, on the upright shaft. The levigated

the water runs away with the water along the spouts, *k k k*, and deposits in the large tanks, *l l*, which are kept full of water. The overflow escapes at *m*, into the shaft, *n*, in which there are three pumps, *o o* and *p*, all worked by gearing, *r*, *s*, in connection with the main shaft. The water from the pumps, *o o*, supplies the dolly-tube, for washing the litharge and promoting the separation of that portion which is coarse, which separation is completed in the broad spouts, *k k k*. The pump, *p*, supplies water for mixing with the litharge as it enters the eye of the stones, through the pipe, *t*, and for washing the outside cases and rims of the stones, through the pipe, *u*.

When the tanks are filled with litharge, they are allowed to stand for some time. The litharge subsides and the water is run off by plugs or siphons. The litharge is then removed and dried at a very low heat in a reverberatory furnace. It is afterwards packed in casks lined with paper.

3. REDUCTION OF THE POT-DROSS AND LITHARGE.

In the previous operations, more or less of the lead is converted into an oxide, in the form of dross in the desilverising pans, and as litharge in the cupellation.

The furnace in which these substances are reduced resembles the smelting furnace, and is of the ordinary reverberatory character. The sole slopes from the fire-bridge to a point near the flue, where an iron gutter is inserted in the brickwork, which is never closed, and through which the lead runs into an iron pot on the outside, whence it is ladled into pig moulds.

This furnace is shown in section and plan in *figs. 623, 624*, where *A* represents the

Fig. 623.

Fig. 624.

place; *B*, ash-pit; *C*, fire-bridge; *D*, hearth; *E*, working door; *F*, the iron spout; the pot outside heated by a small fire below.

The sole is covered with a small quantity of coal, on which a mixture of the oxides

and coal is thrown near to the fire-bridge. The ignition of the fuel and the reducing gases in the furnace soon causes a reduction of the metallic oxides, and the liquid metal trickling down through the porous mass, finds its way to the point, F, whence it flows into the metal pot, G. The charge is frequently turned over by an iron rake to present fresh surface to the reducing action of the fuel, and to facilitate the escape of the lead. Fresh charges are introduced during the shift, and at the close of the day, the residual matters, termed *cinders*, are raked out.

In smelting works, there ought to be at least three of these reducing furnaces, in which the oxidised products of the different operations can be reduced, viz., one for pot-drosses, another for litharges, and a third for calciner's dross, to be described in the next section. This necessity arises from the difference in the quality of the lead produced, and which, by being mixed, would afterwards entail an unnecessary expense.

The dross is reduced in precisely the same way as the litharge, but when it is very impure, the addition of a little soda-ash facilitates the operation and increases the produce of metal. The dross from the poor pans must also be kept distinct from that of the rich pans, as the difference in the contents of silver saves some expense in the subsequent desilverisation of the two leads.

The same remark applies to the litharge, especially that which flows off towards the conclusion of the cupellation.

The cost of reducing litharge and pot-dross is nearly the same, and the following details may be taken as an average:

	s.	d.
Labour . . .	2	8 7
Coals, 4·1 cwt. . .	0	8 2
Repairs . . .	0	1 0
	3 5·9 per ton.	

III. Softening of hard Lead.

All the lead produced at the blast-furnaces, and some leads obtained from poor ores in the reverberatory furnaces, are so hard from the presence of impurities or other causes, as to render them unfit for treatment in the desilverising process. The lead obtained from the English slag-hearth (p. 520) is also of the same character, and, until within about the last twenty years, was sold for running lead-joints, &c., irrespective of its contents in silver. The composition of some of these hard leads is given in the following table:

The writer having carefully examined the WB slag-lead, found that its hardness was mainly due to the presence of antimony. He then suggested the erection of furnaces in which this lead, in a melted state, could be exposed to a current of hot air. The result was the production of a good soft lead, at so reasonable a cost as to render the process available as a regular operation in smelt mills.

Soon afterwards, the first cargoes of the now well-known Spanish hard lead arrived at Liverpool; but the smelters there would not purchase them, and one cargo was transhipped to Newcastle-on-Tyne. This lead could not be softened in the brick furnaces, being so fluid when melted, as to find its way out of the furnace in all directions. The late Mr. G. Burnett, who consulted the writer on the subject, and witnessed the treatment of the slag-lead at Mr. Beaumont's works at Blaydon, then proposed the simple but admirable plan of lining the furnace with a metal pan. Thus was laid the foundation of a trade with Spain, which has gone on increasing, until, it is said, upwards of 20,000 tons of this description of lead are annually produced in that country.

Calcination of the Lead.

The furnace generally employed in this operation, termed *calcining* or *improving* by the workpeople, is represented in the *figs.* 625, 626 in elevation and vertical section. A is the fireplace; B, ash-pit; C, fire-bridge; D, cast-iron pan; E, flue; F F F.

channels for the escape of moisture; G, a working door; and H, the spout for running off the soft lead.

The lead is either thrown into the pan in pigs, or previously melted and ladled into

Fig. 625.

Fig. 626.

a spout, which carries it to the pan. The charge varies from 6 to 10 tons, and the time required for calcination depends upon the quality of the lead. With English slag lead, a few hours are sufficient, and the writer has witnessed a charge of hard lead, obtained from reducing the dross of previous operations, require 30 days for softening.

As soon as the furnace is at a working heat, the surface of the lead becomes coated with the impure dross, which is removed by skimming, and withdrawn through the working door. If the lead is very impure, this dross floats in a semi-fluid state on

Fig. 627.

Fig. 628.

the surface of the lead, and must be dried up with a little lime to bring it into a condition capable of being removed. The workman dips a ladle into the lead when he thinks the calcination is about complete, and pours it into a mould. The sample is

examined when cold, and if it is soft to the scratch, with a flaky, crystalline appearance on the surface, the contents of the pan are ready to be run off through the iron spout, into a pot on wheels, whence it is ladled into pig moulds.

An improvement has been made on the above simple form of furnace, which is shown in *figs. 627, 628*, representing a front view and a longitudinal section. The hard lead is melted in the pot, *a*, which is heated by the fire, *b*. The calcining pan, *c*, is supplied with melted lead from the pot by raising the plug, *d*. The soft lead is run into the pot, *e*, and then cast into pigs. This form of furnace possesses great advantages when softening extra-hard lead, as the calcining pan can easily be kept always full, with very little labour.

The produce of soft lead from the hard leads, of course, varies greatly, as will be seen from the following table, which contains the results of the treatment of many hundreds of tons of most of the descriptions named :

Good Spanish hard lead	93.2 per cent. soft lead.
Hard lead from crystallising dross	90.3 " "
Hard lead from economic furnaces	84.3 " "
English slag lead	87.1 " "
Slag lead from Spanish dross	66.9 " "
Slag lead from refuse products	67.3 " "
Tea lead	76.4 " "

We have mentioned tea lead as among the hard leads which can be treated by this process, and we have found that tin is as easily separated thereby as antimony.

The following hard leads were mixed and submitted to calcination :

	tons.	cwt.
Ordinary Spanish hard lead	1436	9
Ore slag lead	100	18
Dross "	69	12
Spanish "	60	9
Mill "	128	16
English "	76	15
Tea hard lead	9	15
Fume "	3	19
	tons 1885	13

At a cost, per ton, for :

	s.	d.
Labour	2	5.3
Coals, cwt. 6	0	10.0
Repairs	0	1.6
	3	4.9

Pontifer and Glasford's Process.—These gentlemen employ the ordinary calcining pan-furnace, and when the charge has been in operation for a few hours, the dross being removed as usual, a few pounds of the following mixture is spread evenly over the surface of the bright lead. The doors are closed, and in about 10 to 20 minutes, a brown or yellowish-brown cake collects on the surface. Fresh fuel is then thrown on the fire, and in a few minutes, when the smoke has cleared away, the doors are opened, and the cake is removed. This is repeated until the cake formed possesses a bright or brown colour. When the alkaline mixture is used, with a charge of 9 or 10 tons of lead, about 55 lbs. are required during the 24 hours' operation. When the other mixture is employed under the same circumstances, the quantity required varies between 40 and 60 lbs.

The mixtures recommended are as follows :

1. For lead containing from 3 to 15 per cent. of antimony, the mixture consists of:

3 parts of nitrate of soda.
4 " soda-ash.
4 " burnt lime.

2. For lead containing 2 to 3 per cent. of antimony, and from $\frac{1}{2}$ to $1\frac{1}{2}$ per cent. of silica, the mixture consists of equal parts of soda-ash and caustic lime.

We understand that this process has been discontinued, and if it be true that the antimony exists in the hard lead in the form of an alloy of antimony and lead, which when the whole is melted, rises to the surface in consequence of its lower specific gravity, we cannot see how the time of softening should be shortened with advantage, at the extra cost of so expensive an oxidising agent as nitrate of soda. In the old mode of working,

when the surface of the lead is kept constantly clear of dross by the calciner, the alloy, as it rises, is immediately oxidised by the current of hot air, whereas in this process, a considerable time is lost in allowing the mixture to act, and before the crusts are removed.

Mr. Barker of Sheffield has, however, succeeded in using the nitrate of soda and bisulphate of soda to advantage in this process, possibly from the fact that the impurities in his lead are so much smaller than in those of Spain, and by performing the operation, it is said, in crucibles.

Reduction of the Dross.

This process is performed in an ordinary reducing furnace, of smaller dimensions than usual, as the charges are smaller and require more attention to prevent the loss of antimony by volatilisation. The writer also introduced the use of a little soda-ash with the coal, when mixed with the dross, which was found to render the slag which is formed, more fusible, and enabled the workman to work at a lower heat. The following analyses of the hard lead obtained from this dross, with and without the addition of this flux, prove the advantage of its employment:

	Without the soda-ash.	With $2\frac{1}{2}$ per cent. of soda-ash.
Lead	82.88	58.70
Antimony	16.09	40.66
Copper	0.68	0.32
Iron	0.35	0.32
	<hr/> 100.00	<hr/> 100.00

With the use of this flux, and continuing the calcining operation on the produce of the reducing furnace, the metals obtained were found to possess the following composition, according to the analyses of the writer:

English Hard Lead.

	Original lead.	1st calcination.	2nd calcination.
Lead	99.27	86.63	62.84
Antimony	0.57	11.29	47.16
Copper	0.12	traces	traces
Iron	0.04	0.34	traces
	<hr/> 100.00	<hr/> 98.16	<hr/> 100.00

Spanish Hard Lead.

	Original lead.	1st calcination.	2nd calcination.
Lead	96.81	64.98	56.60
Antimony	3.66	29.84	43.40
Copper	0.32	6.90	traces
Iron	0.21	0.20	traces
	<hr/> 100.00	<hr/> 100.92	<hr/> 100.00

It was found impossible to separate any soft lead from the product of the second calcination, all the metal becoming oxidised. This alloy is found of great use in casting type furniture, and in making some of the coarser kinds of type.

The cost of reducing the dross, per ton of lead produced, is as follows:

	s.	d.
Labour	5	2.1
Coals, 7.6 cwt.	1	3.2
Soda-ash, 34 lbs.	2	1.6
Repairs	—	—
	<hr/> 8	<hr/> 6.8

Separation of the Antimony.

Instead of reducing the dross which yields the lead of the second calcination, the writer proposed to grind it to powder, and treat it with acetic acid, by which all the lead is dissolved, and yields sugar of lead by evaporation and crystallisation. The insoluble residuum, when reduced in the usual method employed for antimony ore, furnishes this metal very readily, and of fair quality.

The same process is applicable to the separation of the oxide of tin when the dross has been formed by treating tea lead.

LEAD: SMELTING OF SLAGS, &c.

Cost of treating Spanish Hard Lead.

The Spanish hard-lead trade has assumed such an important development, that in concluding this account of the treatment of hard lead, it may not be without some interest to give the cost of extracting its silver, and preparing the soft lead for market.

The cost of each item of expense is calculated on 20 cwt. of the original hard lead: thus the second item is on 5 per cent less; the third, on 9 per cent; the fourth, on 36½ per cent; the fifth, on 7 per cent. of the original lead; the seventh, eighth, and ninth items are an average on the whole work of the establishment. A similar statement has been published elsewhere, but in the absence of the above information, it must have been unintelligible to most readers.

Cost of Softening and Refining Spanish Lead.

	£	s.	d.
1. Calcining	0	3	4·9
2. Crystallising	0	10	4·4
3. Refining	0	0	11·1

6. Smelting refuse products	0	0	4·2
7. Grinding materials	0	0	5·8
8. General labour	0	2	4·1
9. General charges	0	3	8·2
	£1	3	4·7

IV. Smelting of the Slags and other Products.

All the waste products resulting from all the previous operations—viz. ore or grey slags from the reverberatory furnace and ore-hearths, test-bottoms, litharge and dross cinders from the reducing furnaces, &c., are finally submitted to a process of reduction, in this country in a furnace known as the slag hearth, but abroad they are generally mixed with poor lead-ores, and smelted in a blast furnace. We will describe the method adopted in this country, and then select one of the continental plans as an illustration of the other method.

1. The English Slag Hearth

is known among the Germans as the *Krummofen*, or crooked furnace, and among the French as the *fournai-à-manche*, or elbow-furnace. The general form and construction of this furnace are shown in *figs. 629, 630, &c.* It somewhat resembles the ore-hearth.

Fig. 629.

Fig. 630.

Hearth.—The sole-plate, *a*, is made of cast iron, and slopes slightly down to the fore-hearth, *b*. There are strong cast-iron pieces, or *bearers*, *c, c*, on each of the long sides of the sole-plate, which support the side walls as well as the cast-iron plate, or *forestone*, *d*, which forms the front of the shaft. The back is made of cast iron up to the horizontal tuyere in the middle, above which it is built of sandstone. A cistern, *e*, stands in front of the fore-hearth, and a stream of water constantly flows through to granulate the slag, and facilitate the subsequent separation of any pieces of lead disseminated through it by washing. The lead flows over the fore-hearth into an iron pot, *f*, heated from below by a fire.

The bottom of the furnace is filled with small cinders, beaten down, and reaching to within 4 or 5 inches of the tuyere. The pot is also filled with similar cinders, which filter the lead from the fusible slags which sometimes accompany the metal. Peat is then piled up above the bed of cinders, ignited, and the blast turned on.

When the peat is ignited, some coke is thrown in, and a layer of grey slag or other refuse lead product is added. This is continued at intervals as the operation proceeds, alternate layers of slag and fuel being added, metallic lead being produced, and a fusible slag, free or nearly free from lead. The smelter occasionally forces a bent iron bar through the layer of cinder, to liberate the slag, which flows off into the water cistern.

The lead obtained is always very hard and impure, and is afterwards sent to the calcining process for softening.

When cold air is employed in smelting, it is often difficult to prevent the nose of slag at the tuyere from growing too long. The use of hot air prevents this inconvenience, and also economises the expense of this operation, as the following comparative statements will prove:

a. 28 tons of slag smelted with cold air consumed 392 cubic feet of air per minute, and cost:

	£	s.	d.
Labour.		3	7 8
Coke 7 tons at 24s. 6d.		8	11 6
	11	19	2

b. 35 tons of similar slag with hot air, consumed 300 cubic feet of air per minute, and cost:

	£	s.	d.
Labour		3	7 8
Coke, 5 tons. 17 cwt. at 24s. 6d.		7	3 4
Turf for heating air, 11 loads at 1s. 8d.	0	18	4
	11	0	4

The saving is therefore very considerable when hot air at 500° to 600° F. is employed.

2. The Clausthal Blast Furnace.

This furnace varies in height from 20 to 25 feet, with a diameter of 3 feet in the widest part. The crucible at the bottom of the hearth projects beyond the blast of the furnace into a small elevated platform in front. The lining of the hearth is made of fire-stone, and the bottom is slightly hollowed. This part is covered to some depth with a mixture of fire-clay and charcoal, with a gentle slope from the back to beyond the front wall of the furnace. A tap-hole enters at the lowest part of this basin, through which the contents are drawn off.

The receiving basin, *a*, is placed on a level with the floor, and at some distance from the breast of the furnace, which is supplied with air forced through the tuyeres at *b*.

Fig. 631.

The charge of mineral is thrown towards the side of the tuyere, and the fuel towards the breast. The cold air from the tuyeres cools the slags, and forms channels round their nozzles, six or seven inches long, which are called the "nose of the tuyere." The

success of the operation greatly depends upon the proper management of this point, as these channels prevent the oxidation of the lead, which would give rise to the formation of fusible silicates of lead.

Under all circumstances, a large quantity of lead is volatilised, and the whole of the vapours escaping from the tunnel-hole, T, pass through a series of chambers, C C, before entering the chimney, D. The fume which condenses is occasionally removed through the doors, d, and is again thrown into the furnace along with other products.

The scoria flow continuously into the fore-hearth, where they solidify and are drawn down the inclined plane, p, by the workman, to the floor of the mill. When the basin, b, becomes filled with metal, it is tapped into the reservoir, a.

The products which are collected in the outer basin consist of lead, upon which a matt floats. This matt solidifies first, and is removed for further treatment, when the lead is passed through a metal sieve, and cast into pigs.

The matt contains sulphides of lead and other metals, and when they accumulate, they are roasted in heaps to expel the sulphur; but so imperfect is the operation, that some portions must undergo as many as four roastings.

When the roasting is finished, the residue is smelted in the German slag-hearth, along with test-bottoms and other waste products. The *lit de fusion* is composed of:

32	parts of roasted matt.
80	" rich grey slags.
4.5	" test-bottoms.
2	" abstrichs.
2	" litharge-cinders.
1	" granulated cast iron.

The furnace used in the smelting of these products is shown in *figs. 632—634*. It is

Fig. 632.

Fig. 633.

Fig. 634.

about $4\frac{1}{2}$ feet high, and increases in size in the upper portion, C. *Fig. 633*, represents a horizontal section at the level of the tuyere, and *Fig. 634*, a vertical section in the line XY. It is blown with one tuyere, T. From the bottom of the furnace, which is *brasqué*, the contents are drawn off by a tapping hole into the pot, F.

The fuel employed is coke, and during the smelting, part of the iron of the matt combines with the silica of the slags and cinders, forming a new, very fusible slag. Another portion of the iron reduces the sulphide of lead, producing metallic lead and a second matt.

The following table contains the analyses of some slags made in smelting cupel bottoms, &c.:

Analyses of Lead-slugs from Blast Furnace.

Authority .	Brüel.	Berthier.		Kars-ten.	Berthier.

Protosulphide of iron		2.20	9.00					
Sulphide of zinc . . .						10.20		
Baryta						17.60		

This matt is treated in the same manner as before, but in the fourth matt the copper has accumulated to such extent, that it is called the *copper matt*, and is treated for that metal.

This accumulation of copper is always observed, however small the percentage of copper in the original ore. The copper, having a stronger affinity for sulphur than lead, goes on accumulating in these matts, and generally pays for its extraction.

The mixture smelted in these Clausthal furnaces, consists of:

- 34 parts of ore containing 24 of galena.
- 4 to 5 " cupel bottoms.
- 1 " the abstrichs from the refinery.
- 39 " ore slags.
- 4½ " granulated cast iron.

which mixture is stated, by Regnault, to produce 19 pts. of metal, and 7 or 8 pts. of the first matt, containing 2½ pts. of metal.

V. Condensation of the Lead Fume.

Since attention has been drawn to the great loss of lead in smelting its ores, numerous plans have been proposed to recover a portion of the metal in the form of fume, no fewer than sixteen patents having been enrolled for this object.

Where sufficient space exists, the plan most generally adopted is that of long flues and chambers. In some cases these flues extend for 5 miles. In Mr. Beaumont's extensive works, his able engineer, Mr. Sopwith, added nearly 5 miles of flue to one mill, the flue being 8 ft. high by 6 ft. wide. The saving in lead in these flues of Mr. Beaumont, is said to exceed £10,000 per annum.

Of the many plans which have been suggested, we will select two which are in successful operation.

1. Stokoe's Condenser.

This apparatus is represented in *fig. 635*, and has been found to answer remarkably well at Langley mill, as the details of an experiment, given on p. 525 amply prove.

A is the top of the fume-flue; B is a wheel fixed in a metal case, set in motion by steam or water power, with a speed of 10,400 revolutions per minute, by which the fume is withdrawn from the flue and forced through the condenser. This condenser is rectangular, divided longitudinally by wooden rails, A, A, laid horizontally, on which a layer of pebble-stones, or other filtering material, is placed. The condenser is further separated into compartments, D, D, by the vertical divisions, C, C, which alternately reach the top, and dip below the surface of the water. The water flows from an open trough, M, divided crossways, immediately above D D, into the compartments, E, E, each of which is again subdivided by four or five low parallel partitions. The bottom

of these cisterns, E E, is perforated. The water is supplied by a pipe, D G, and the bottom of the condenser is kept filled with water to the level shown at F F.

The fume is withdrawn from the flue, and forced up and down through the filtering beds, in the direction of the arrows, until the residual gases escape at H, into the chimney, L. These fumes, in their passage through the condenser, come in contact with the water from E E, which is constantly falling in fine showers over the filtering

Fig. 635.

beds. The water carries down all the fume into the reservoir, F F, whence it is occasionally drawn off at K.

The following table (p. 525) gives the results of an experiment, on the large scale, with one of these condensers.

Stagg's Condenser.

This apparatus is represented in fig. 636, in which *a* is the fume flue, *b b b b*, a cistern constructed of wood or any other material, with partitions, dividing it alternately

Fig. 636.

at top and bottom; *c*, one or more air-pumps, or exhausting machines; and *d*, the exit-flue for the uncondensed gases. The air-pumps being set in motion, the fume is drawn through the water in the cistern, in which the metallic vapours are condensed, so perfectly, that the writer has walked along the exit-flue without being soiled with a single particle of fume. The passage of the vapours under the water creates a great agitation and spraying of the water, which materially assists in the condensation. When the water becomes charged with fume, it is drawn off by cocks, and run into tanks to allow the fume to subside.

Mr. Stagg has drawn up the following table from his experiments, to show the annual saving of lead which may be effected by his condenser, and the volume of gases for which the exhausting apparatus must be constructed :

Nature of furnace.	Quantity of lead operated upon or produced per annum.	Volume of smoke emitted from such furnace per minute.	Annual saving effected on each operation in lead.
	tons.	cubic feet.	tons.

LEAD, ALLOYS OF. Lead forms alloys with several metals by simple fusion, and many of these alloys are definite chemical compounds, which produce mechanical mixtures when fused with either of the constituents in excess. This latter fact has given rise to the metallurgical operation of eliquation.

1. With Antimony.—Lead alloys itself with this metal in several proportions, and the alloys are harder, more tender, and oxidise more easily than lead; they are also more fusible, as well as harder than either metal.

An alloy of equal parts of the two metals is porous and brittle; 2 pts. of antimony with 1 pt. of lead produce a very hard alloy, capable of receiving a fine polish, and used to make the keys of wind instruments; 3 pts., and even 4 pts. of antimony to 1 pt. of lead produce a hard but malleable alloy. An alloy of lead and antimony is used in making *type-metal*, a little zinc being sometimes added. Some type-founders add $\frac{1}{2}$ pt. of tin, but this addition is only suitable for stereotype plates. The plate on which music is printed is composed of 12 pts. tin, 7 lead, and 1 antimony. The ordinary composition of type-metal is 83 pts. lead and 17 antimony.

Emery wheels and grinding tools for the lapidary are formed of an alloy of antimony and lead.

Mr. Jas. Nasmyth has suggested the use of lead as a substitute for all works of art hitherto executed in bronze or marble. He states that the addition of 5 per cent. of antimony gives it not only hardness, but greater capability to run into the most delicate parts of the work. An alloy of this description, analysed by Karsten, and corresponding with the formula Pb^2Sb , was found on the hearth of a smelting furnace at the Mulder Works: it contained 90.10 p.c. Pb, 6.48 Sb, 1.42 Zn, 1.50 Cd, 0.24 Ag, and traces of Ni, As, and S.

2. With Arsenic.—The presence of this substance renders lead brittle, greyish white, and very fusible. The application of heat expels a portion of the arsenic, but the remainder resists the highest temperature.

This alloy constitutes the metal of which shot are cast, 40 lbs. of metallic arsenic being mixed with 20 cwt. of lead. It also exists native at Clausthal in the Hartz, and is composed of 67.63 p.c. Pb, 24.19 As, 4.41 mispickel $FeAsS$, 2.26 Fe, 0.54 S, and 0.7 Co.

3. With Bismuth.—This metal unites with lead in all proportions, with condensation. Some of the alloys are more malleable than lead, but the malleability diminishes as soon as the quantity of bismuth equals that of the lead.

When 3 at. lead are united to 2 at. bismuth, the mixture has only one solidifying point, viz. $129^{\circ}C$, but in $PbBi$, this point is 146° ; in $PbBi^2$ it is 143° , and with Pb^2Bi the temperature is between 163° and 171° .

These alloys have no special application in the arts, but they are used to adulterate mercury. An alloy of 1 pt. lead, 1 pt. bismuth, and 3 pts. mercury, is really an amalgam, which is sufficiently fluid to pass through chamois leather.

An amalgam of 2 pts. bismuth, 4 pts. lead, and 1 pt. mercury, is solid in the cold, but when pieces of it are rubbed together, they immediately melt.

Lead and bismuth occur associated in nature, in the mineral *Kobellite*, already described (p. 448).

4. With Bismuth and Antimony.—When antimony is added to the previous alloy in quantity equal to the bismuth, a metal is obtained which expands on cooling. Advantage is taken of this in casting stereotype plates. This alloy, according to Mackenzie, contains 70 p.c. lead, 15 antimony, and 15 bismuth.

5. With Chromium.—The alloy which contains 0.25 of chromium is fusible at $150^{\circ}C$, ashy-grey, but whiter than lead. It can be hammered into thin sheets, which are very brittle. Nitric acid dissolves the lead without attacking the chromium.

6. With Copper.—The alloys of lead and copper are difficult to prepare and to preserve at a high temperature. The copper must be introduced into a bath of lead heated above redness, and the alloy rapidly cooled; even then some portions are reddish-coloured, indicating the commencement of a disunion of the elements. If the alloy is heated to the melting point of lead, the latter abandons the copper, which is left in the form of a porous mass.

The process of eliquation is founded upon this fact, and as the silver present in the copper has a great affinity for the lead, the latter carries off the silver, which is separated in the manner already described (ii. 32).

In smelting sulphide of copper containing sulphide of lead, the latter metal passes off in great measure in the scoriae in the first operations, but is found in the copper of the subsequent treatment.

There would appear to be two alloys of these metals, one containing more copper, and melting at a higher point than the other, which contains more lead.

Small quantities of lead diminish the ductility of copper at ordinary temperatures, and at a red heat. Copper containing even 0.1 per cent. of lead, may still be used for ordinary purposes, but it cannot be formed into thin sheets or wire.

The alloy of 4 pts. of lead to 1 pt. of copper is employed for casting large movable types.

7. With Manganese.—When a mixture of 892 pts. of protoxide of manganese and 2789 pts. of litharge are heated with a little charcoal in a charcoal-lined crucible, a homogeneous, compact, and ductile alloy is obtained, which can be rolled into thin sheets of great lustre.

8. With Mercury.—This metal is easily alloyed with lead, either by introducing the former into the latter in a melted state, or by triturating lead filings with the mercury.

The amalgam possesses a brilliant white colour, and still remains liquid even with as much as 33 per cent. of lead, but it soils the fingers. The amalgam of equal parts can be crystallised, and a piece of lead plunged into this amalgam is found covered with crystals when it is withdrawn.

The amalgam has a higher specific gravity than either of the metals, owing to the contraction which they undergo in combining.

The presence of 0.0002 to 0.00025 of lead improves the mercury for use in barometers and thermometers, as the latter metal has then not so great a tendency to form globules on the convex surface of the glass.

9. With Mercury and Antimony.—Wetterstedt has found that the addition of a small quantity of mercury to the alloy of antimony and lead removes the tendency of this metal to oxidation. He has proposed to use the triple alloy as a sheathing for ships. It is composed of 94.4 per cent. lead, 4.3 antimony, and 1.3 mercury, and is said not to be so rapidly encrusted with barnacles, &c. as copper sheathing.

10. With Potassium and Sodium.—The alloys of lead with these metals are formed when a reducing alkaline flux is fused with oxide of lead, as first noticed by Vanquelin; and Serullas has described the properties of one of these alloys, obtained when 100 pts. of litharge are strongly heated with 60 pts. of cream of tartar. The alloys can also be prepared directly; that containing 25 per cent. of its volume of potassium is brittle, with a coarse-grained fracture. A similar alloy with sodium is bluish and malleable, but that with one-third of sodium is brittle. These alloys, distilled with the iodides of ethyl, methyl, &c., yield the lead-compounds of the alcohol-radicles. (See LEAD-RADICLES, ORGANIC, p. 560.)

11. With Tin.—Lead may be fused with this metal in all proportions, but the density of the resulting mixtures does not correspond with the specific gravities of the two metals. The following table contains the results of Kupffer's experiments:—

Composition of the Alloys.	Specific Gravity.		Difference.	Melting Point.
	Found.	Calculated.		
Lead, pure . . .	11.3803	336°
Tin, pure . . .	7.2911	230
SnPb* . . .	9.4263	9.4366	0.0103	241
SnPb ² . . .	10.0782	10.0938	0.0156	
SnPb ³ . . .	10.3868	10.4122	0.0254	239
SnPb ⁴ . . .	10.6551	10.6002	0.0431	
PbSn ² . . .	8.7454	8.7518	0.0064	196
PbSn ³ . . .	8.2914	8.3983	0.0069	186
PbSn ⁴ . . .	8.1730	8.1516	0.0096	189
PbSn ⁵ . . .	8.0279	8.0372	0.0093	194
PbSn ⁶ . . .	7.9210	7.9526	0.0116	

The lead, so soft in itself, has the singular property of increasing the hardness of the tin: it slightly darkens the colour, gives a grained fracture, and causes the peculiar creaking sound, produced on bending tin, to disappear.

The alloys of lead and tin are distinguished by the facility with which they ignite and burn. The alloy of 4 or 5 pts. of lead and 1 pt. tin burns like charcoal at a red heat, the combustion continuing like that of an inferior peat, with the formation of

* Sn = 118 : Pb = 207.

cauliflower excrescences. This action appears to be due to the affinity which exists between the two oxides. The oxides so formed, when fused either alone or with silica and an alkali, produce a white opaque enamel used for dial-plates, &c., and also in earthenware.

The solders used by plumbers vary much in composition, but there are three commonly known as *fine solder*, composed of 2 pts. of tin and 1 pt. of lead; *common solder*, containing equal pts. of each metal; and *coarse solder*, composed of 2 pts. of lead to 1 pt. of tin. Tomlinson gives the following table of the composition of these alloys and their melting points:—

	Tin.	Lead.	Melting Point.		Tin.	Lead.	Melting Point.
No. 1.	1	25	558°	No. 7.	1½	1	334°
" 2.	1	10	541	" 8.	2	1	340
" 3.	1	5	511	" 9.	3	1	366
" 4.	1	3	482	" 10.	4	1	365
" 5.	1	2	441	" 11.	5	1	378
" 6.	1	1	370	" 12.	6	1	381

No. 5 is also called plumber's *scaled solder*, which is assayed in the same way as pewter, and then stamped by the officer of the Plumbers' Company. No. 8 is used for soldering cast iron and steel, sal-ammoniac or common resin being used as flux. This alloy is also used for tinned iron, with chloride of zinc or resin as the flux. Gold and silver are also soldered with No. 8, and Venice turpentine for a flux. The same alloy is used with copper, brass, gilding metal, gun metal, &c., and sal-ammoniac, chloride of zinc, or resin as the flux; with zinc, and chloride of zinc as flux; with lead and tin pipes, with a mixture of sweet oil and resin as flux; with Britannia metal, and chloride of zinc or resin as flux. The alloys 4 to 8 are used for ordinary plumber's work, with tallow as flux.

Pewter is another alloy of these metals, and the trade in this article is so important in this country, that the pewterers have formed an incorporated company ever since 1474.

Common pewter is composed of 80 pts. of lead and 20 pts. of tin, but other metals are sometimes added, such as copper, antimony, and zinc. The manufacturers of pewter state that a better pewter is obtained by working up old pewter with fresh ingredients.

Holtzapfel gives the following account of these alloys:—"Some pewters are now made as nearly as common as that of equal parts of the metals: when cast they are black, shining, and soft; when turned, dark and bluish. Other pewters only contain $\frac{1}{2}$ or $\frac{1}{4}$ of lead; these, when cast, are white, without gloss, and hard; such are pronounced very good metal, and are but little darker than tin. The French legislature sanctions the employment of 18 per cent. of lead with 82 per cent. of tin, as quite harmless in vessels for wine and vinegar. The finest pewter, frequently called *tin and temper*, consists mostly of tin, with a very little copper, which makes it hard and somewhat sonorous, but the pewter becomes brown-coloured when the copper is in excess. The copper is melted, and twice its weight of tin is added to it, and from about $\frac{1}{2}$ to 7lbs. of this alloy, or the *temper*, are added to every block of tin weighing from 360 to 390lbs. Antimony is said to harden tin, and to preserve a more silvery colour, but is little used in pewter. Zinc is employed to cleanse the metal, rather than as an ingredient. Some stir the fluid pewter with a thin strip, half zinc and half tin; others allow a small lump of zinc to float on the surface of the fluid metal, while they are casting, to lessen the oxidation."

Plate pewter is the hardest, and is used for making plates and dishes. The pewter called *trifle* is used for beer-pots, and *ley* for the larger wine measures.

Pewter wares are formed either by hammering or by casting, plates and dishes being hammered, while measures and spoons are cast. Pewter is also made in the form of sheets for engraving cheap music, the softness of the metal allowing the notes to be formed by means of punches, instead of engraving with a burin.

Lapidaries, jewellers, and watchmakers use laps and polishers of pewter.

Although lead is so poisonous a metal, it can be employed in domestic utensils, when alloyed with tin, which would appear to neutralise this action of the lead. In an alloy of 3 pts. of lead and 1 pt. of tin, Proust and other chemists have found that vinegar dissolves out nothing but the tin; but for domestic utensils, Vauquelin has shown that the lead ought not to exceed 17 or 18 per cent. An alloy of 3 pts. of lead and 6 pts. of tin is used for tinning certain articles of copper.

The *brilliant* of *Fahlun* are made with an alloy of 19 pts. of lead and 29 pts. of tin, which are fused together and allowed to cool for a short time. At this point the alloy adheres to a glass tube cut into facets, on which it is allowed to solidify, and

from which it can afterwards be easily removed. A lens plunged into this alloy forms a brilliant mirror.

These alloys form superior baths in which to temper various articles of steel; the following table contains all the information on the subject:—

Alloy.		Temperature.		Objects to be tempered.
Lead.	Tin.	C.	F.	
14	8	213·4°	415·4°	Lancets.
15	8	221	429·8	Other surgical instruments.
16	8	225	437	Razors.
17	8	240	464	Penknives, scalpels, cold-chisels.
28	8	257	494·6	Shears, gardeners' tools.
38	8	262	503·6	Hatchets, axes, planes, dressmakers' scissors.
60	8	275	527	Table-knives, large scissors.
98	8	284	543·2	Swords, watch-springs, &c.
100	8	289	552·2	Strong springs, poniards, augers, small saws, &c.

For higher temperatures recourse must be had to other baths.

Alloys of lead and tin are also employed in making anatomical injections.

12. With Tin and Bismuth.—These ternary compounds are well known under the name of *fusible alloys*. They melt at low temperatures, some even below the heat of boiling water. This is one cause why they are so rarely obtained in a perfectly homogeneous condition.

There are several of these alloys known by the name of the first observer; thus, the following all melt below the boiling point of water:

Observer.	Lead.	Bismuth.	Tin.	Melting point.
Homborg.	1	1	1	122·00 C.
Rose	1	2	1	93·75
Newton	5	8	3	94·44
Lichtenberg	2	5	3	
Krafft	2	5	1	104·00

In whatever proportions the three metals are mixed, they exhibit one fixed solidifying point, at 98° C., and two higher points which are variable.

When 120 lbs. of an alloy, consisting of 3 pts. tin, 2 lead, and 5 bismuth, are melted, they yield, on cooling, tolerably definite crystals, which melt below 100° C., and contain nearly equal numbers of atoms of the three metals, or 15·76 per cent. tin, 26·56 lead, and 57·68 bismuth.

The melting point of fusible metal is raised by the addition of potassium.

This alloy presents many anomalies in its dilatation and contraction; thus, at a temperature from zero up to 35° C., the volume increases in the proportion of 100 : 100·83, and it diminishes up to 56° C. in the ratio of 100·83 : 99·13, which is its point of greatest density; it then begins to expand. It is remarkable that its maximum volume, reached at 35° C. is the same as that which it possesses at 95° C., which is the melting point of Rose's alloy.

It is impossible to determine the melting point of these alloys except by experiment; thus, in Newton's fusible metal, which melts between 198° and 200° F., the theoretical point ought to be 520°, as shown by the calculation,

$$\frac{8\text{Bi} \times 500^\circ + 5\text{Pb} \times 600 + 3\text{Sn} \times 442}{16} = 520^\circ \text{F.}$$

The following table contains the melting points of various alloys of these three metals:

Bismuth.	Lead.	Tin.	Melting point.	Bismuth.	Lead.	Tin.	Melting point.
8	12	8	130·90° C.	8	8	8	122·10° C.
8	5	3	94·44	8	10	8	127·60
8	6	3	97·78	8	16	8	147·40
8	8	3	109·64	8	16	10	149·60
8	8	4	112·20	8	16	12	141·90
8	8	6	116·05	8	16	14	139·70

Bismuth.	Lead.	Tin.	Melting Point.	Bismuth.	Lead.	Tin.	Melting Point.
8	16	16	140·80° C.	8	28	24	163·00° C.
8	16	18	144·10	8	30	24	170·50
8	16	20	147·40	8	32	24	176·00
8	16	22	152·80	8	32	28	165·00
8	18	24	154·00	8	32	30	163·90
8	18	24	152·90	8	32	32	158·40
8	20	24	151·90	8	32	34	157·30
8	22	24	151·80	8	32	36	158·40
8	24	24	152·90	8	32	38	159·50
8	26	24	158·40	8	32	40	160·60

It is remarkable that the tin, which melts below the fusing points of both lead and bismuth, should raise the melting point of these alloys.

These alloys are of great value in regulating the tempering of delicate articles of cutlery. They are also used for taking impressions of medals, bas-reliefs, and on the Continent for producing casts of metals by the *cliché* process. They can also be employed to take casts from the surface of wood and embossed paper. Beautiful casts of the internal ear, showing the complexities of its bony cavities, have been made with them; also cake-moulds for the manufacture of toilet soaps.

Two of these alloys are well known in this country under the names of *Britannia metal* and *Queen's metal*. The former is composed of equal parts of brass, tin, antimony and bismuth; the latter of 1 part each of antimony, lead and bismuth, with 9 parts of tin. Both are used for making teapots, spoons, &c.

A safer and better alloy is said to be made by adding to 100 pts. of French pewter, 5 pts. antimony and 5 pts. brass, to harden it.

In Birmingham, teapots, milk-jugs, &c. are made into form by a process called *spinning*, which consists in bringing the sheet of pewter against a rapidly revolving tool, by which, with a little dexterity on the part of the workman, it is gradually fashioned.

13. With Tin, Mercury, and Bismuth.—The addition of mercury to the three metals forming the previous alloys renders them much more fusible, and communicates some new properties.

D'Arcet's alloy, similar to Newton's, when amalgamated with mercury, melts at 45° C. This alloy or amalgam is specially valuable in making anatomical preparations. It is introduced into the parts of the body in the liquid state, and allowed to solidify. The flesh and other animal matters are afterwards dissolved and removed by a strong solution of potash.

The interior of glass tubes, globes, &c. are tinned by means of this amalgam, which is poured into the vessel by means of a funnel, in the liquid state, and gently agitated. The surplus is then poured off, and the operation is complete. Glass of different colours is employed, and objects of great beauty are thus easily prepared.

The best compound is composed of 1 pt. lead, 1 tin, 2 bismuth, and 10 mercury. The first three are fused together, and then the mercury is added.

14. With Tin and Copper.—An alloy of these metals was used by the Romans for casting statues, &c. It was formed of 67·12 per cent. natural bronze, 22·37 old bronze, 5·25 tin, and 5·26 lead.

Bronze is made of copper and tin, to which some manufacturers add a little lead, and in the analyses of several ancient coins by Phillips, lead appears to have been an important constituent. (See Table, vol. ii. p. 45.)

When lead is mixed with copper in the proportion to 6 to 1, ordinary pot-metal is formed, called *dry pot-metal*, a quality which is characteristic of these alloys.

British bell-metal consists of 5·6 per cent. zinc, 10·1 tin, 4·3 lead, and 80·0 copper.

Biddery ware is made in India by combining 2 pts. of tin, 4 pts. lead, and 16 pts. copper, and is afterwards melted in the proportion of 3 pts. to 16 pts. of zinc.

The other alloys of copper to which small quantities of lead are added are described in another part of this dictionary.

15. With Zinc.—This metal communicates hardness to lead, and the property of receiving a fine polish, without diminishing the malleability. The two metals may be fused in any proportion, but the alloys are all decomposed at a white heat, the zinc being volatilised, and carrying off with it large quantities of the lead.

The presence of lead in zinc, however, is said to be injurious to the latter metal when rolled into sheets, diminishing its elasticity and probably its tenacity.

When equal quantities of lead, zinc, and bismuth are fused, an alloy is obtained which melts in boiling water.

The alloy of *lead, tin, and zinc*, $\text{ZnSn}^*\text{Pb}^2 = \text{ZnSn}^*.2\text{PbSn}^*$, has but one solidifying point, viz. at 168°C ., but all other alloys have also two higher points, *b* and *c*.

T. R.

LEAD, ANTIMONIDE OF. (See p. 532.)

LEAD, ARSENIIDE OF. (See p. 532.)

LEAD, BROMIDE OF. PbBr^2 , is obtained by the same processes as the chloride, which it resembles in crystalline form. It is somewhat less soluble in water, and melts out of contact with air, at about the same temperature as the chloride, to a white horny mass. By fusion, in contact with the air, it is converted into a basic bromide or oxybromide. It unites with the bromides of potassium and sodium, forming crystalline double salts, which, however, are decomposed by water.

Acetobromide of lead, $\text{Pb}^*\text{Br}^2.\text{Pb}^*(\text{C}^2\text{H}^3\text{O}^2)^2$, or *Plumbobromacetin*, $\text{C}^2\text{H}^3\text{O}^2 \text{O}$
 $\text{Pb}^* \left\{ \text{Br}^* \right.$
 is obtained like the corresponding chlorine-compound (p. 539), which it resembles in its properties and reactions. (Carius.)

LEAD, BROMOCARBONATE OF. An insoluble compound, produced by boiling together equivalent quantities of bromide and carbonate of lead. It fuses readily, and when further heated gives off carbonic anhydride, and leaves an oxybromide of lead.

A bromophosphate and bromophosphite of lead may be formed in like manner.

LEAD, CHLORIDE OF. PbCl^2 , *Magisterium plumbi*, sometimes called *Horn-lead*.—Lead unites but slowly with chlorine, the combination not being attended with visible combustion; it is also but slowly attacked by hydrochloric acid, and only when in contact with the air; on the application of heat, it dissolves slowly, with evolution of hydrogen. The chloride is prepared by boiling the protoxide, or carbonate, or sulphide of lead, with water, into which hydrochloric acid is dropped as long as the resulting chloride of lead continues to dissolve, or by adding hydrochloric acid or chloride of sodium to a concentrated solution of a lead-salt. Chloride of lead has also been found, as a natural product, called *cotunnite*, in the crater of Vesuvius, after the eruption of 1822, mixed with chloride of sodium, and chloride and sulphate of copper. This native chloride occurs in trimetric crystals, in which $\infty P : \infty P = 99^\circ 46'$; $\infty P : P\infty = 149^\circ 14'$; and the ratio of the principal axis, brachydiagonal and macrodiagonal, is as 0.5953 : 1 : 1.1868. The observed planes are ∞P , $\infty P\infty$, $\infty P\infty$, $2P\infty$, $P\infty$. Also acicular crystals. It is soft enough to be scratched by the nail, and has a specific gravity of 5.238. Lustre adamantine, inclining to silky or pearly. Colour white. Streak white. (Dana, ii. 97.)

Chloride of lead dissolves in 135 pts. of cold water, in less than 30 pts. of boiling water, and separates from the solution in long, flat, needle-shaped crystals. It dissolves in pure water, and in strong *hydrochloric acid* more easily than in the dilute acid, and therefore separates from the acid solution on moderate dilution with water, and from the saturated aqueous solution, on addition of hydrochloric acid. It is also somewhat soluble in weak alcohol, very sparingly in alcohol of 76 per cent., and insoluble in alcohol of 94 per cent. Its solubility in water is greatly diminished by the presence of chloride of calcium. In solutions of alkaline hyposulphites, or of acetate of sodium, on the contrary, it is much more soluble than in water, so that, on mixing a solution of 190 pts. acetate of lead with 58.5 pts. chloride of sodium, only 43 to 48 pts. of lead-chloride are precipitated, whereas 139 pts. are formed. A solution of the chloride in strong hydrochloric acid is not precipitated by *sulphydric acid*, but on addition of water, precipitation immediately takes place. A solution of lead-chloride mixed with aqueous *sulphydric acid* containing hydrochloric acid, forms a yellow or reddish-brown precipitate of sulphochloride of lead (p. 559). An aqueous solution of the chloride mixed with *sal ammoniac* is not precipitated by sulphuric acid.

Chloride of lead melts when heated out of contact with air, and may be sublimed, though with difficulty; the fused mass solidifies on cooling, to a white translucent

* Atomic weight of zinc = 65; of tin = 118; of lead = 207.

assured mass of specific gravity 5.8, formerly called horn-lead. When heated in contact with the air, it fumes strongly before the heat rises to redness, then turns yellow, and is converted into an oxychloride (p. 555). When it is heated in a stream of carbonic oxide, chloride of carbonyl (phosgene) COCl_2 is formed, and metallic lead is separated (Göbel). It quickly absorbs ammonia-gas. When it is moderately heated in phosphoretted hydrogen gas, hydrochloric acid is given off, phosphorus distils over, and metallic lead remains. A solution of hypochlorous acid converts it into peroxide of lead.

Acetochloride of lead, $\text{Pb}''\text{Cl}^2.\text{Pb}''(\text{C}^2\text{H}^3\text{O}^2)^2$, or *Plumbochloracetin*, $\text{C}^2\text{H}^3\text{O}^2\left\{\begin{smallmatrix} \text{O} \\ \text{Pb}'' \end{smallmatrix}\right\}\text{Cl}^2$ is obtained in monoclinic crystals, by mixing recently precipitated chloride of lead with acetate of lead, and a sufficient quantity of glacial acetic acid to form a viscous mass, which solidifies in a short time, and either freeing this mass from excess of acetic acid by pressure, or heating it in a sealed tube to 130° or 140° ;—or together with acetate of ethyl, by the action of acetate of lead on chloride of ethyl. It dissolves, though with difficulty, in acetic acid without decomposition, but is decomposed by water, with separation of a small quantity of lead-chloride, and formation of the compound $\text{Pb}''\text{Cl}^2.3\text{Pb}''(\text{C}^2\text{H}^3\text{O}^2)^2$ or $\text{Pb}''\left\{\begin{smallmatrix} (\text{C}^2\text{H}^3\text{O}^2)^2 \\ \text{O} \end{smallmatrix}\right\}\text{Cl}^2$ which dissolves in the water, and may be recrystallised without decomposition. It is decomposed, however, by glacial acetic acid, which leaves the original compound. The compound, $\text{C}^2\text{H}^3\text{O}^2\left\{\begin{smallmatrix} \text{O} \\ \text{Pb}'' \end{smallmatrix}\right\}\text{Cl}^2$ is analogous to glycolic chloracetin, $\text{C}^2\text{H}^3\text{O}^2\left\{\begin{smallmatrix} \text{O} \\ (\text{C}^2\text{H}^3)'' \end{smallmatrix}\right\}\text{Cl}^2$ (ii. 568), and may therefore be called plumbochloracetin. (Carius, Ann. Ch. Pharm. cxxvii. 87.)

LEAD, CHLOROCARBONATE OF. 2PbCl.PbCO_3 , or $\text{Pb}\left\{\begin{smallmatrix} (\text{CO})'' \\ \text{O} \end{smallmatrix}\right\}\text{Cl}^2$.—This compound is produced as a white insoluble powder, by boiling 1 at. carbonate of lead with 2 at. (or more) of the chloride, and water. It also occurs native, though rarely, as corneous lead or kersan, in acute quadrate pyramids in which P : P in the lateral edges = $113^\circ 48'$, and in the terminal edges = $107^\circ 22'$. Observed faces $\infty\text{P}\infty$, P, ∞P , P and others. Cleavage distinct parallel to ∞P . The mineral likewise occurs in botryoidal and stalactitic forms. Hardness = 2.5 to 3.0. Specific gravity = 6.0 to 6.1. Colour white, grey, and yellow. Streak white. Transparent to translucent. Fracture conchoidal. Rather sectile. It occurs at Crawford, near Matlock in Derbyshire, in minute crystals at a lead mine near Elgin in Scotland, and at Tarnowitz, in Upper Silesia, where also large pseudomorphs of lead-carbonate (cerusite) in the form of this mineral are found.

Both the natural and the artificial compound fuse readily, and are converted at a higher temperature, with loss of 7.5 per cent. CO_2 , into the oxychloride, $\text{PbCl}^2.\text{PbO}$.

LEAD, CHLORIODIDE OF. Obtained in pale yellow four-sided needles, from a solution of the iodide in boiling hydrochloric acid; it is gradually decomposed by water, which extracts the chloride of lead. (Labouré, J. Pharm. [3] iv. 328.)

LEAD, CHLOROFLUORIDE OF. PbClF .—Formed by precipitating aqueous fluoride of sodium with a boiling solution of chloride of lead, or with a mixture of acetate of lead and chloride of sodium. It is a white powder, which melts when heated, without giving off water or acid. Dissolves in water without decomposition, and easily in nitric acid. (Berzelius.)

LEAD, CHLOROPHOSPHATE OF. When a boiling solution of chloride of lead is poured into a boiling solution of phosphate of sodium, the latter being in excess, a precipitate containing $\text{PbCl}^2.\text{Pb}^2(\text{PO}_4)^2.\text{H}_2\text{O}$ is formed, insoluble in water, but soluble in nitric acid, which converts it into a nitrophosphate (Heintz, Pogg. Ann. lxxiii. 122). When, on the contrary, a boiling solution of phosphate of sodium is poured into an excess of chloride of lead, a precipitate is formed which, according to Heintz, is composed of $\text{PbCl}^2.2\text{Pb}^2(\text{PO}_4)^2$, but according to Gerhardt (Ann. Ch. Phys. [3] xxii. 505), of $\text{PbCl}^2.\text{Pb}^2\text{H}^2(\text{PO}_4)^2$. The same compound is formed when a soluble phosphate is precipitated by a lead-solution in presence of a soluble chloride.

The compound $\text{PbCl}^2.3\text{Pb}^2(\text{PO}_4)^2$ occurs native as pyromorphite, sometimes pure, sometimes having part of the phosphorus replaced by arsenic, sometimes associated with fluoride and phosphate of calcium. (See PYROMORPHITE.)

LEAD, CHLOROPHOSPHITE OF. Lead-salts added to a solution of alkaline phosphite, obtained by dissolving trichloride of phosphorus in water, and neutralising with an alkali, throw down a precipitate containing a compound of chloride and phosphite of lead, from which boiling water extracts the former.

LEAD, DETECTION AND ESTIMATION OF. I. Reactions in the dry way.—Lead-salts heated on charcoal with carbonate of sodium or cyanide of potassium, give, in the inner blowpipe flame, bluish-white, malleable beads of metallic lead, surrounded by an incrustation of oxide, brownish-yellow while hot, but light lemon-yellow on cooling. Added, in rather large quantity, to a bead of microcosmic salt, they give on cooling, a bead having an enamel-white colour, or yellow if quite saturated.

II. Reactions in Solutions.

Soluble lead-salts are colourless; the metal is precipitated from their solutions by zinc or iron.

Sulphydric acid and alkaline sulphides throw down sulphide of lead as a black or brownish-black precipitate, insoluble in cold and dilute solutions of acids, alkalis, and alkaline sulphides. In extremely dilute solutions, only a brown colouring is produced. If the solution of the lead-salt contains free hydrochloric acid, the precipitate is red or yellow, and a large excess of hydrochloric acid prevents it altogether.

Hydrochloric acid, added to solutions not too dilute, throws down chloride of lead, as a white precipitate, slightly soluble in cold water, but more so in boiling water, deposited in needles on cooling; less soluble in dilute hydrochloric acid than in water, but pretty freely in the strong acid; apparently unaffected by ammonia, but rendered insoluble in water, from conversion into oxychloride.

Sulphuric acid and soluble sulphates throw down sulphate of lead as a white precipitate, scarcely soluble in cold water, ($\frac{1}{22,300}$ Fresenius), and in dilute sulphuric acid ($\frac{1}{35,500}$ Fresenius), almost absolutely insoluble in alcohol; soluble in strong hydrochloric acid on heating; in nitric acid more readily when strong and hot; in concentrated sulphuric acid, slightly; in ammoniacal salts, more especially the acetate.

Caustic potash or soda throws down the hydrate of lead as a white precipitate, soluble in acids, or in excess of the reagent.

Ammonia throws down a white precipitate of basic lead-salt, insoluble in excess.

Chromate of potassium throws down chromate of lead as a yellow precipitate, insoluble in water (slightly soluble in excess, according to Conybeare), soluble in potash, insoluble in dilute nitric acid, converted by ammonia into a red basic chromate.

Iodide of potassium produces a bright yellow precipitate of iodide of lead, which dissolves in boiling water, and separates on cooling in crystalline spangles, exhibiting a beautiful play of colours.

LIMITS OF REACTIONS OF TESTS FOR LEAD.

One part of	In water,	Reagent.	Authority.
Lead	100,000 or more.	Sulphydric acid.	A. S. Taylor.
Lead, as nitrate	200,000	"	Lassaigne.
Oxide of lead, as do.	350,000	"	Harting.
Nitrate of lead	100,000	"	Pfaff.
Oxide, as nitrate	20,000	Sulphuric acid in exc.	Pfaff and Harting.
Lead, "	25,000	{ Sulphate of sodium }	Lassaigne.
Oxide, "	70,000	{ (in 15 minutes). }	Harting.
		Chromate of potassium.	

The reactions with sulphydric, sulphuric and hydrochloric acids, taken together, serve to distinguish lead from all other metals. The reactions with iodide and chromate of potassium are also very characteristic.

III. Quantitative Estimation.

1. *Gravimetric methods.*—Lead is generally most conveniently estimated as sulphate. The concentrated solution is mixed with a slight excess of dilute sulphuric acid and about twice its volume of alcohol, filtered after a few hours, the precipitate then washed with alcohol, and dried, and the filter burnt off. Or, a considerable amount of sulphuric acid may be substituted for the alcohol, in which case the wash-waters must be also acidulated with sulphuric acid, and the last washings displaced by alcohol. In burning off, as much of the precipitate as possible is to be detached from the filter, which should be burnt separately, to guard against reduction of lead. In all cases it is safest to employ a porcelain crucible.

2. Lead may also be weighed as oxide, into which it may be converted directly by ignition, or after previous precipitation as oxalate or carbonate (results low), or as chromate on a tared filter.

Volumetric methods.—Many methods have been proposed for the volumetric estimation of lead, but the greater number give only approximate results. 1. Flores Domonte adds to the lead-solution a quantity of caustic potash or soda sufficient to redissolve the lead-oxide at first precipitated, and then adds to the boiling liquid from a burette, a graduated solution of *sulphide of sodium* as long as a precipitate is thereby produced. The greater part of the sulphide of lead cakes together, but the liquid remains brownish, so that it is difficult to see when the precipitation is complete. The method is, however, useful for technical purposes. The strength of the solution of sulphide of sodium must be determined every two days.

2. Margueritte adds to an alkaline lead-solution, a graduated solution of *permanganate of potassium*, which throws down the peroxides of lead and manganese, continuing the addition till the liquid exhibits a permanent green colour. The solution bumps very strongly when boiled, and the ready alterability of the solution of the permanganate necessitates frequent titration.

3. Pappenheim, according to Mohr, adds to the lead-solution a graduated solution of *sulphate of potassium*, till the liquid no longer produces a yellow spot of iodide of lead on paper prepared with solution of iodide of potassium. This method yields nearly exact results.

4. Streng (Ann. Ch. Pharm. xcii, 413) supersaturates a solution of a lead-salt, or sulphate of lead suspended in water, with potash; adds an excess of solution of *chloride of lime*, and boils for a while, whereby the lead is entirely converted into peroxide. The precipitate is collected on a filter and washed with hot water; a hole is then made in the bottom of the filter, and the precipitate washed through into the vessel in which it was formed; solution of *stannous chloride* is passed through the filter from a burette till all the peroxide of lead is washed off; the filter is again washed with hot water; and an excess of the tin-solution is added, whereby the peroxide of lead is converted into chloride, which is then dissolved by heating it with water and hydrochloric acid. If the excess of *stannous chloride* in the liquid be then determined by means of a standard solution of chromate of potassium, the whole of the data for calculating the amount of lead present in the liquid under examination will be obtained. This method is exact and often convenient.

5. The following process, given by Hempel (Jahresber. 1853, p. 627), is, however, simpler, and has the advantage of admitting of a double verification. The lead is precipitated with a measured quantity of a graduated solution of *oxalic acid* added in excess; the liquid is neutralised with ammonia, and the precipitate collected on a filter; the amount of oxalic acid in the filtrate is then determined by means of a standard solution of *permanganate of potassium*, and by deducting this amount from the total quantity of oxalic acid used, the quantity of oxalic acid combined with the lead is found, and thence the amount of the lead may be calculated.

The result may be checked, either by digesting the precipitate in dilute sulphuric acid, which sets the oxalic acid free, and estimating the amount of oxalic acid in the filtrate with a solution of permanganate—or by igniting and weighing the precipitate.

Mohr completes the determination without filtration. He adds to the solution, in a flask holding 300 cubic centimetres, a drop of tincture of litmus; then adds, from a burette, a standard solution of oxalic acid as long as a white precipitate is formed; saturates with ammonia till the liquid turns blue; fills the flask with water; leaves the liquid to stand for about half an hour till it is sufficiently clarified to allow of 100 cubic centimetres being removed clear with the pipette; and determines the free oxalic acid therein by means of a solution of permanganate, the quantity of which, multiplied by 3, gives the data required for determining the quantity of oxalic acid added in excess. It appears, however, that a small quantity of nitrate of lead is always precipitated together with the oxalate, so that the quantity of oxalic acid used always appears too small. Mohr estimates the errors thence arising at 2 per cent. (Handw. d. Chem. 2^{te} Aufl. ii. [2] 33). On the whole, the volumetric methods of estimating lead do not appear to be so advantageous as the gravimetric methods.

IV. Separation of Lead from other Metals.

From all metals, not precipitable as sulphides in acid-solution, lead may be separated, by passing *sulphydric acid gas* to saturation through the solution, previously made moderately acid with hydrochloric or nitric acid. The solution should also be moderately dilute. If no other metal, precipitable by the gas, be present, the precipitate will be sulphide of lead with an uncertain quantity of sulphur. If this is deflagrated with nitre, and the sulphur estimated as sulphate of barium, the difference between its weight and that of the precipitate, thoroughly dried at 100°, will give the lead. Or, by oxidising the precipitate in a porcelain vessel with fuming nitric acid, after detaching

it as much as possible from the filter, burning the filter, and adding the ash, we obtain a mixture of sulphate of lead with a little nitrate. This may be converted into sulphate by a slight excess of pure concentrated sulphuric acid; the precipitate is then ignited and weighed, and the lead calculated therefrom.

Of the metals precipitable by sulphydric acid, gold, platinum, arsenic, tin, and antimony may be further separated by digestion of the mixed sulphides in sulphide of ammonium containing an excess of sulphur. If, after this treatment, any silver, mercury, bismuth, cadmium, or copper be left with the lead-sulphide, they may be separated by one of the two following methods:—

If no bismuth is present, the solution containing the mixed oxides, is treated with carbonate of sodium, and then digested with cyanide of potassium, when, on filtering, carbonate of lead will remain alone on the filter.

From bismuth, the lead may be separated by the following method, applicable also to its isolation from mercury, copper, and cadmium, but not from silver, if present in any quantity:—Evaporate with excess of sulphuric acid until fumes of acid appear, cool, and dilute with water; filter at once from the sulphate of lead; wash with acidulated water and alcohol; then dry and weigh.

The method of precipitation by sulphuric acid, or a soluble sulphate, serves, indeed, to separate lead in solution without any preliminary treatment, from all metals, excepting barium, strontium, and calcium (and perhaps silver, *vid. sup.*), and from these earth-metals it is easily separated by sulphydric acid.

In alloys, lead may be very conveniently separated from bismuth, tin, and antimony, and with rather more difficulty from arsenic, by converting all the metals into sulphides, and heating the sulphides in a stream of dry chlorine gas; all the other metals will then be volatilised, the lead alone remaining.

V. Valuation of Lead Ores.

a. *By the wet way.*—A very convenient process for determining lead in ores, especially in galena, consists in oxidising them with fuming nitric acid, adding sulphuric acid in considerable excess to the slightly diluted solution, filtering and washing the residue, as before directed, and after weighing, boiling it repeatedly with a strong solution of acetate of ammonium, which dissolves the lead-sulphate. The insoluble residue deducted from the first weight gives the amount of lead-sulphate, from which the lead may be calculated.

b. *By the dry way.*—For the purposes of assaying, lead ores may be divided into two principal classes:—

A. Ores &c. which contain no sulphur, arsenic, or phosphorus.

B. Ores containing one or more of the above elements.

A. *First class.*—In the assay of these ores, two points require attention; heating with a reducing agent for the separation of the lead, and with an alkaline flux to facilitate the formation of a clean button. Charcoal and argol are among the best reducing agents; carbonate of sodium, borax, deprived of its water by previous fusion, and salt, are useful as fluxes. Black flux, or a mixture of carbon in a fine state of division with carbonate of potassium, may also be employed. The following mixtures will give some idea of the proportions in which these reagents should be employed, but they must, of course, vary somewhat for different ores:

	Sample.	Argol.	Charcoal.	Carbonate of sodium.	Borax glass.	Salt.
No. 1.	200 gr.	100	.	300	.	200–250 grs.
2.	400 "	200	.	400	200	"
3.	400 "	200	.	400	200	"
4.	400 "	.	50–60	600	.	"
5.	400 "	200	.	400	.	"
6.	400 "	600	black flux, and a cover of borax	.	.	"

1. Recommended by Mitchell for oxides, carbonates, cupel-products, &c.

2. " " cupel-bottoms and other refractory products.

3. " " fumes, siliceous slags, &c.

4, 5, 6. Phillips:—The salt is not mixed with the other reagents, but employed to cover the whole mixture.

Ores of this class may also be assayed by the following process, proposed by the writer:—Weigh out 50 grs. of ore on a counterpoise. Fuse, at a red heat, about an ounce of crude cyanide of potassium in a crucible capable of holding at least double the quantity; when fused remove it from the furnace, and add the ore in small portions

with a spatula; rinse the last traces off with a little more cyanide, and replace it for a minute or two in the fire, then take out the crucible, and tap to collect the lead into a button.

B. *Second class*.—Galena, pure, and mixed with gangue, is included in this class, for the assay of which several methods, more or less accurate, are employed, as—

1. *Roasting the galena*, by which it is converted into oxide, and treating the product as an ore of the first class. This process, besides being exceedingly troublesome, gives little more than three-fourths of the lead actually present.

2. *Fusion with 3–4 parts of alkaline carbonate*; the mixture to be heated slowly till fused, which gives about 90 per cent. of the lead present.

3. *Fusion with carbonate of sodium and nitre*, by which the sulphur of the ore is removed as sulphate of potassium; if an excess of the nitrate is employed, a portion of the lead is oxidised and lost. Several assays must therefore be made to discover the best proportions. This process answers very well for obtaining a button to be afterwards assayed for silver, in which case a slight excess of nitre must be used to ensure complete oxidation of the sulphur, without which some silver is liable to be retained as sulphide in the slag.

4. *Fusion with metallic iron*, which has been variously modified as to details. The oldest plan is that given by Berthier, in which the galena is simply mixed with about 30 per cent. of finely divided iron, covered with a layer of some flux and heated; it gives an amount of metal 7–10 per cent. below that actually present. Small iron nails are also recommended by Berthier, which is not a satisfactory process, as the nails become fixed in the button. Mitchell suggests the use of tenpenny nails; Phillips, of iron crucibles, and lastly, a mixture of iron-oxide with a reducing flux. Of these different modifications, the process of Mitchell is especially useful on account of its simplicity and accuracy. We extract Mr. Mitchell's own description in full:

"To 200 grains of finely pulverised galena add 50 of argol, and 200 carbonate of soda; place the mixture in a crucible, the inside of which has been smeared with black-lead; introduce three tenpenny nails head downwards; tap the crucible on the mixing bench, so that the contents may occupy as little space as may be; cover with about 200 grains of salt, over that 200 grains of borax. Prepare two crucibles thus, place them in the furnace, and raise the heat rapidly to nearly a bright red; uncover the furnace, and allow the crucibles to remain for 8–10 minutes; again cover the furnace and raise to a bright red: the crucibles will then be ready for removal. Besides the time occupied, the termination of the assay may be judged by the flux flowing smoothly. When this occurs, seize hold of the crucible with the large tongs, and with a smaller pair take hold of one of the nails; rinse it well in the flux to remove any small globules of lead; and then reject it. The two other nails are to be treated in the same way, the crucible removed, tapped on the furnace top to collect all globules, and set aside to cool. So also with the second crucible. When cold they are broken, &c., as usual; the assays should correspond within one-eighth of a grain."

The following is an account of the process employed in the lead-works of North and South Wales, as an example of the rougher methods often adopted in smelting works with good practical results.

In the Welsh lead-works, the assays are generally made on 10 ounces of the ore as received, wet or dry. This is melted in a stout iron dish (fig. 637) with a cover, in a smithy fire; when melted, the slag is skimmed back and the produce weighed, each ounce representing 10 per cent., and each dwt. $\frac{1}{2}$ per cent. In the assay of galenas, some modification may be required; according to Mitchell, by fusing antimonial galenas with carbonate of sodium, pure lead is obtained, but with black flux, the lead contains much antimony; and if iron, either alone or mixed with black flux, be employed, all the antimony is obtained with the lead; but repeated tentative assays must be made to obtain the best possible result. When a lead ore contains oxidised compounds of sulphur and arsenic, reducers alone will not answer; but if they are mixed with an alkaline carbonate and metallic iron, good results are obtained. The assay may be conducted as in Mitchell's process for galenas.

A notable loss of lead is sustained in all the above processes, arising chiefly from the volatility of this metal and its oxide: hence the necessity of making all lead-assays at the lowest temperature compatible with perfect fusion, and of not keeping the assay in the furnace longer than is actually necessary. An error in the opposite direction may arise from the presence of foreign metals in the ore, which are more or less completely reduced, and alloyed with the lead, increasing its weight; such, for example, as silver, copper, tin, or antimony. Zinc is completely removed if the heat

Fig. 637.

LEAD: ESTIMATION.

be sufficient, but it entails a loss of lead. Iron does not go down with the lead, unless the assay be much overheated. The separation of most of these metals from lead, by the dry way, is impracticable, with the exception of silver in argentiferous lead, which will be described under *Cupellation* (see below).

Whatever process is employed to determine the lead, some standard is adopted by the manufacturer, to which to refer in calculating the value of the ores. For example, in Wales the "standard" is 77 per cent. or 7 oz. 14 dwts. on the assay. The value of this standard fluctuates with the market price of lead, and for every variation of a dwt. or half a per cent. an established addition or deduction is made in the price. Any silver present is calculated in ounces on the ton, and paid for per ounce.

The following tables have been constructed to save trouble in calculating the results of assays:—

Produce of Lead per ton of Ore, calculated from Assay.

Estimation of the Silver.—The separation of lead and silver in the dry way, by the process known as cupellation, depends on the fact, that while lead, when exposed to the air at temperatures above its melting point, is rapidly oxidised, silver remains unaltered. If, therefore, an argentiferous lead is heated in a current of air, on a support of such a texture that the litharge formed from the lead shall be absorbed as fast as produced, the silver will be finally left in the form of a button. This support is called the "cupel," a flat, slightly hollowed-out dish of pounded bone-ash, compressed by a mould into the proper form. The process is conducted in a furnace, such as is shown in *figs.* 638, 639, where *a* is the ash-pit door; *d'* and *f*, doors for supply of fuel; *d'*, the opening by which access is obtained and the supply of air regulated to the muffle *m*. This muffle is a small fire-clay oven, situated in the centre of the fire, and pierced by slits at the sides and inner end, which, when the door is opened, establish a current of air through the apparatus, while it is maintained at any desired temperature by means of a damper. In using the apparatus, the muffle is first raised to a red heat; 4 to 8, or more, well-dried cupels are then introduced, and the door closed. When they have attained a clear red heat, the door is opened, a button of lead is placed in each cupel by tongs, and the door again closed. On opening it partially, the buttons are seen "uncovered," or presenting a bright metallic surface, and a dark ring instantly begins to form round the circumference of the lead, as the litharge formed by its oxidation is absorbed by the cupel, the rings gradually extending as the buttons diminish. The moment when the oxidation is completed and pure silver left, is recognised by a peculiar phenomenon known as the "brightening" of the silver button, which appears, for an instant, to revolve rapidly on its axis, while covered with a play of prismatic colours. The play of colours disappears, and the button becomes still and lustrous. It is then withdrawn from the furnace, detached from the cupel, cleaned, and weighed in a balance turning with .001 gr. Simple as the process appears, some practice is required, and many points demand attention, before uniform results can be obtained.

The temperature should be the lowest at which the assay will proceed steadily, as a sensible amount of silver is volatilised with the vapour of lead. The temperature, on the other hand, must not be reduced *too* low, as the absorption of the litharge by the cupel is then impeded. Again, the draught, if too rapid, cools the cupel unduly, and if too slow, does not effect the oxidation with sufficient rapidity, thereby increasing the loss by volatilisation. Further, the absolute quantity of silver remaining the same, if the quantity of lead be much increased, the loss in silver will be greater. But, if the silver-lead be very rich, a loss will arise from the absorption of the alloy into the pores of the cupel. When the heat is too great, the cupels are whitish and the metallic matter they contain can scarcely be seen; the fume is scarcely visible, and rises rapidly

Fig. 638.

Fig. 639.

to the arch of the muffle. When the heat is not strong enough, the smoke is thick and heavy, falling in the muffle, and the litharge can be seen forming lumps and scales about the assay. When the heat is properly managed, the cupel is red, and the fused metal luminous and clear.

Lastly, a source of loss arises from what is termed "vegetation" of the button, which is due to the absorption of oxygen by the molten metal. When the metal is cooling, in a button of any size, the surface cools and solidifies before the centre has abandoned its mechanically dissolved gas, which, when it is liberated, forces its way through the external crust, raising it into fantastic arborescent forms, which, once seen, sufficiently explain the term. But as portions are frequently projected outwards by the sudden action, it is necessary to cover the cupel, while still hot, with a previously heated old cupel to secure its very gradual cooling. It is only, however, in the case of buttons much larger than a pin's head that this precaution is essential. The weight of the cupel ought to be about one-third greater than that of the lead to be cupelled; a good cupel will absorb its own weight of litharge under ordinary circumstances.

Lead is not the only metal which may be separated from silver by this process. Bismuth may be perfectly "cupelled," and copper, antimony, iron, tin, &c., may be "passed" by the addition of sufficient lead to carry their oxides into the cupel.

The following tables are useful in an assay office, where numerous assays are made from time to time, and they are constructed for different weights of lead cupelled, as well as the produce per 20 cwt. or ton and per 21 cwt. or fobler of lead:—

Yield of Silver per ton, calculated from Assay of 400 grs.

VI. Atomic Weight of Lead.

The atomic weight of this metal has been determined chiefly by the experiments of Berzelius, made in 1830 and 1845 (Pogg. Ann. xix. 300; *Lehrbuch*, 5^{te} Aufl. iii. 1187). By reducing pure protoxide of lead with hydrogen gas, he found that 100 pts. of the protoxide contain 7·1724 pts. oxygen, whence, regarding the protoxide as Pb^oO , and putting oxygen = 16, the atomic weight of lead is 103·54; if, however, a certain number of the determinations, which do not agree very well with the rest, be left out of account, the atomic weight is found to be 103·57. The extreme limits of the determinations in question were 103·36 and 103·65. Within the same limits also are comprised the older determinations of Berzelius (1818), which gave 103·56; also those of Turner in 1835 (Ann. Ch. Pharm. xiii. 14), which gave 103·61, and nearly also those of Longchamp in 1827 (Ann. Ch. Phys. [2] xxxiv. 105), which gave numbers ranging from 103·64 to 103·74. The mean of all the best determinations is 103·56; or if lead

be regarded as diatomic, and the protoxide be represented by the formula Pb^oO , then the atomic weight is 207.12.

T. R.

LEAD, FLUORIDE OF, PbF^2 , is obtained by precipitating acetate of lead with hydrofluoric acid, or by decomposing carbonate of lead with the same acid, as a white powder, sparingly soluble in water, easily fusible, soluble in hydrochloric and in nitric acid, by which it is decomposed on evaporation. When treated with aqueous ammonia or fused with oxide of lead, it is converted into a more soluble oxyfluoride, the solution of which has an astringent taste, and on standing in the air, deposits carbonate of lead, mixed or combined with fluoride of lead.

A chlorofluoride of lead has been already described (p. 539).

LEAD, HYDROALUMINOUS. See PLUMBORESINITE.

LEAD, IODIDE OF, PbI^2 , is obtained by precipitating nitrate of lead with iodide of potassium, avoiding an excess of either salt. It is a precipitate of a fine light yellow colour; soluble in 1,235 pts. of cold water (Denort), and in 194 pts. of boiling water, forming a colourless solution, whence it crystallises on cooling in flexible, six-sided, laminar crystals. It is obtained in the same form by mixing the solutions of iodide of lead and iodide of potassium at the boiling heat. It is not more soluble in water containing acetic acid than in pure water. According to Henry, it is not quite insoluble in alcohol. Ether, according to A. Vogel, extracts iodine from it, leaving oxyiodide of lead. It dissolves in cold, and still more in warm aqueous sal-ammoniac, and crystallises therefrom on cooling in yellowish white needles (Boullay). In caustic ammonia, nitrate, succinate, carbonate, and sulphate of ammonium, it turns white (Wittstein). When boiled with the carbonates of the alkalis or alkaline earths, it yields carbonate of lead and a soluble iodide.

Iodide of lead, when heated, turns reddish-yellow and brick-red, then red-brown, and melts to a liquid of the same colour, which solidifies to a yellow mass. When fused in contact with the air, it gives off a part of its iodine, and leaves an oxyiodide of lead. It is easily decomposed by chlorine. Zinc or iron boiled with it under water takes up the iodine and precipitates metallic lead.

Iodide of Lead and Hydrogen, $PbI^2.2HI$, crystallises from a solution of iodide of lead in warm aqueous hydriodic acid, in concentrically grouped, silky needles, which give off the whole of the hydriodic acid when heated, and part of it even when exposed to the air at ordinary temperatures. The acid may also be extracted by water.

Ammonio-iodide of lead, or *iodide of plumbammonium*, $N^3H^4PbI^2$, is obtained as a white powder by passing ammonia-gas for a long time over finely-pulverised iodide of lead, or by digesting it at ordinary temperatures with sal-ammoniac. It gives off its ammonia spontaneously on exposure to the air, and even in an atmosphere of ammonia when heated.

Aceto-iodide of lead, $PbI.C^2H^3PbO^2$, or $\frac{C^2H^3O\}O}{Pb^2\}I$, analogous to glycolic iodacetin (ii. 568), is obtained in a similar manner to the corresponding chlorine-compound (p. 539), with which it is isomorphous. (Carius, Ann. Ch. Pharm. cxxv. 87.)

An *iodochloride of lead*, $Pb^2Cl^2I^2$, has been already described (p. 539).

An *iodide of lead and ammonium* is formed, as a white precipitate, on adding iodide of ammonia in excess to nitrate of lead.

A compound of *iodide of lead with chloride of ammonium*, $3NH^4Cl.PbI^2$, is obtained by dropping a solution of neutral acetate of lead into a boiling mixed solution of iodide of potassium and sal-ammoniac, as long as no permanent precipitate is formed. On cooling, the double salt crystallises in slender yellow, shining needles, which, however, are decomposed by water, the sal-ammoniac dissolving out first.

Another compound, $2NH^4Cl.PbI^2.2H^2O$, crystallises in white silky needles.

Iodides of lead and potassium.—When 1 at. iodide of lead (PbI^2) and 1 at. iodide of potassium are dissolved in the smallest possible quantity of boiling water, the solution yields on cooling, large yellow, shining, six-sided laminae, having the composition $KI.PbI^2$, and on dissolving these crystals in a hot solution of iodide of potassium, white silky needles, consisting of $4KI.PbI^2$, are deposited as the liquid cools. Both salts are decomposed by water and by alcohol.

LEAD ORES. The following is a list of minerals containing lead as an essential constituent, and available, when they occur in sufficient quantity, for the extraction of the metal:

Aciculite.	Aikinite.	Belonite.	Needle-ore.	Aluminate of lead (hydrated).	Plumbo-
Patrinite.	$\left. \begin{matrix} Pb^2 \\ (Cu^2)^n \end{matrix} \right\} S^2.Bi^2S^2.$			resinite.	$\left. \begin{matrix} Pb \\ Al^3 \end{matrix} \right\} O^2.6H^2O.$
Altaite.	Telluride of lead.	$PbTe.$			

- Anglesite. Sulphate of lead. Lead-vitriol. $PbSO_4$.
- Antimonial sulphides of lead: see Boulangerite, Bournonite, Brogniardite, Freislebenite, Geocronite, Heteromorphite, Jamesonite, Kobellite, Plagionite, Zinkenite.
- Antimonate of lead. Bleinierite. $Pb^2Sb^2O^4 \cdot 4H^2O$.
- Aræoxene. Zinkiferous vanadate of lead.
- Arsenate of lead: see Mimetite.
- Arsenomelane. $2PbS \cdot As^2S^3$.
- Binnite. A mixture of Arsenomelane and Scleroclase.
- Bleinierite. Antimonate of lead.
- Boulangerite. $3PbS \cdot Sb^2S^3$.
- Bournonite (to which is related Wölchite).
- $$(2PbS \cdot Cu^2S) \cdot Sb^2S^3 = \left. \begin{matrix} Pb^2 \\ (Cu^2) \end{matrix} \right\} S^4.$$
- Brogniardite. $PbAg^2S^3 \cdot Sb^2S^3$.
- Caledonite. $(Pb;Cu)CO^2 \cdot PbSO^4$.
- Carbonate of lead. Cerusite. White lead ore. $PbCO^2$.
- Cerasin. Corneous lead. Horn-lead. Chlorocarbonate of lead. Phosgenite. $PbCl^2 \cdot PbCO^2$.
- Cerusite: see Carbonate of lead.
- Chileite. Vanadate of lead and copper. $(Pb;Cu)(VO)^2 \cdot 3(Pb;Cu)O$.
- Chiviatite. $2PbS \cdot 3Bi^2S^3$.
- Chloride of lead. Cotunnite. $PbCl^2$.
- Chlorarsenate of lead: see Mimetite.
- Chlorocarbonate of lead: see Cerasin.
- Chlorophosphate of lead: see Pyromorphite.
- Chromate of lead: see Crocoisite, Melano-chroïte, Red lead ore, Vauquelinite.
- Clausthalite. Selenide of lead. $PbSe$.
- Corneous lead. Syn. with Cerasin.
- Cotunnite: see Chloride of lead.
- Crocoisite. Chromate of lead. PbO .
- $$CrO^2 = \left. \begin{matrix} Pb^2 \\ Cr^2 \end{matrix} \right\} O^4.$$
- Cupreous sulphate of lead: see Linarite.
- Cupreous sulphatocarbonate of lead: see Caledonite.
- Cuproplumbite. $2PbS \cdot CuS$.
- Dechlorite. Vanadate of lead. PbV^2O^4 .
- Descliozite. $Pb^2V^2O^7$ or $2PbO \cdot V^2O^5$.
- Embrothite: see Boulangerite.

The ores which are actually worked for lead have been already described (pp. 480, 481): for the rest, see the several articles.—Respecting the working of lead ores, see pp. 481—531; methods of assaying them, p. 543.

LEAD, OXIDES OF. Lead forms five oxides, viz.:

• The Suboxide	Pb^2O .
The Protoxide	PbO .
The Red oxide	Pb^2O^4 .
The Sesquioxide	Pb^2O^3 .
The Dioxide or Peroxide	PbO^2 .

The protoxide is a strong base; the sesquioxide and peroxide also unite with acids. The red oxide is decomposed by most acids. All the oxides of lead are easily reduced to the metallic state by charcoal at a red heat.

Suboxide. Pb^2O .—This oxide, which was discovered by *Dulong*, remains when oxalate of lead is cautiously heated in a retort from which the air is excluded. According to *Pelouze* (*Ann. Ch. Pharm.* xlii. 209), the retort should be heated in an oil-bath to a temperature not exceeding 300° , the heat being continued as long as any gas is given off: the gas thus evolved is a mixture of 1 vol. carbonic oxide and 3 vol. carbonic anhydride:

The whole is suffered to cool before the suboxide is removed. It forms a black powder, sometimes dull, sometimes having a velvety lustre. It contains no metallic lead, for mercury extracts nothing from it, either dry or under water; neither does it contain any protoxide, for the aqueous solution of acetate of lead does not extract any protoxide from it on boiling. But when heated to dull redness, out of contact of air, it is resolved into a greenish-yellow mixture of lead and protoxide (*Boussingault*, *Pelouze*). After this treatment, mercury extracts lead from the substance, and a boiling solution of acetate of lead or acetic acid leaves the lead in the form of a network, which, when pressed together between the fingers, forms a dense mass having the metallic lustre. The suboxide heated in the air takes fire, burns with a glimmering light, and is converted into protoxide. Dilute *sulphuric*, *nitric*, *hydrochloric*, or *acetic acid* resolves it into protoxide, which combines with the acid, and very finely-divided metallic lead. The same effect is produced by a strong solution of *normal nitrate of lead*; a dilute solution, on the contrary, takes up the whole of the suboxide and forms basic nitrate of lead. The suboxide, when moistened with *water*, rapidly absorbs oxygen from the air, and is converted into the white hydrated protoxide, the action being attended with rise of temperature. A mixture of finely-divided lead and litharge does not yield the same result.

The grey pellicle which forms upon lead exposed to the air, has also, according to *Berzelius*, the composition Pb^2O .

Protoxide. *Lead-oxide*. PbO .—This oxide occurs native as lead-ochre, a massive mineral, sometimes with scaly crystalline structure. Specific gravity 8.0. Lustre dull. Opaque. Colour between sulphur- and orpiment-yellow. Streak lighter than the colour. It does not soil. It is said to occur at *Badenweiler*, in *Baden*, and, according to *Gerolt*, has been ejected from the volcanoes *Popocatepetl* and *Iztaccitull*, in *Mexico*. It is found also at other localities in *Mexico*, and at *Austin's mines*, *Wythe county*, *Virginia*. (*Dana*, ii. 109.)

Protoxide of lead is obtained pure by igniting the basic nitrate, or the carbonate or oxalate of lead, in a platinum crucible, in contact with the air, taking care that the oxide does not fuse, otherwise it will take up metal from the crucible, and if heated in a porcelain crucible, would take up silica. The pure oxide thus obtained has a lemon-yellow colour, and a specific gravity of 9.4214.

On the large scale, protoxide of lead is obtained in the forms of *massicot* and *litharge*.—1. *Massicot* is prepared by heating lead to low redness on a flat hearth, and continually removing the film of oxide as it forms, till the lead-ash at first obtained is, for the most part, converted into the yellow oxide; the latter is then freed from the still remaining metallic portions by grinding and levigation.—2. *Litharge* is obtained in the oxidation of *pig-lead* containing gold and silver—the resulting lead-oxide, which is

generally contaminated with silica, ferric oxide, cupric and cuprous oxide, antimonious oxide, and other oxides, is fused by the high temperature, and solidifies in a scaly, shining mass, sometimes of a yellowish tint (*Argyritis*, *Silber-glätte*), sometimes rather inclining to red (*Chrystitis*, *Goldglätte*). The oxide of copper may be completely removed by digesting the levigated litharge with aqueous solution of carbonate of ammonia (Bischof, Schw. J. 64, 65).—The antimonious oxide is left behind on dissolving the litharge in boiling nitric acid, and may then be dissolved in hydrochloric acid (Anthon, Repert. 58, 387).—The difference between red and yellow litharge is attributed by Leblanc (J. Pharm. [3], Sept. 8, 1845) to a mere diversity of physical structure, not of chemical composition; for either modification may be obtained at pleasure by properly regulating the temperature and the rate of cooling; the red variety, which is specifically lighter than the yellow and more crystalline substance, is formed most abundantly when the cooling is slow. (See also p. 514.)

Properties.—Protoxide of lead appears to be both dimorphous and amorphous, occurring in pale-yellow rhombic octahedrons and cubes, and regular dodecahedrons, and as a red amorphous powder. By the following processes it may be obtained in the crystalline state:—1. *By slow cooling after fusion.* Litharge, when quickly cooled, solidifies in a mass of crystalline scales; but the portion which remains on the muffle sometimes crystallises in yellow, translucent, six-sided tables (Marx); in trimetric octahedrons with a distinct plane of cleavage (Mitscherlich); in regular dodecahedrons, the angles of which are indefinite, in consequence of the curvature of the faces (Gaultier de Claubry and Beudant). White lead fused by the blowpipe-flame on a copper plate or other non-reducing support, crystallises in scales on cooling; but from the middle of it there generally shoots out a mass, half a line long, sometimes in the form of a triangular pyramid, sometimes in that of a nearly perfect rhombic dodecahedron, of a hyacinth-red tint while hot, becoming sulphur-yellow and translucent as it cools, and opaque and dull when perfectly cold. This alternate fusion and crystallisation may be repeated several times.—2. *By fusion with hydrate of potassium.* If 1 part of lead-oxide and from 4 to 6 of hydrate of potassium be fused for a short time in a silver crucible at an incipient red heat, and the mass after cooling exhausted with water, the lead-oxide remains in the form of cubes and square tables (Beccuere), Ann. Ch. Phys. [2], li. 105).—3. *By treating lead-oxide with potash or soda-ley.* From a solution of lead-oxide in soda-ley, saturated while hot, placed in a stoppered bottle, and then left to itself all through the winter, the lead-oxide crystallises in small, white, translucent rhombic dodecahedrons (Houton-Labillardière, J. Pharm. iii. 335). The crystals are trimetric octahedrons, having the same angles as those obtained by fusion (Mitscherlich). Strong boiling potash-ley saturated with lead-oxide yields, on cooling, yellow scales similar to those of litharge; if the potash-solution is less fully saturated with lead-oxide, or if it has deposited the excess of that oxide in scales, no further deposition takes place till after perfect cooling, whereupon red scales are thrown down, perfectly soluble in acetic acid, and therefore free from minium; if these scales are heated, they turn yellow on cooling. Hence it appears that litharge may have a red colour without containing minium or red oxide of copper (Mitscherlich, J. pr. Chem. xix. 451).—Boiling soda-ley of 40° – 41° B., saturated with hydrate of lead, yields rose-red crystals of the protoxide on cooling. These crystals yield an orange-yellow powder, similar to that of litharge. At about 400° they turn black, increase in bulk, decrepitate with loss of 0.1 per cent. of water—and when heated to low redness, assume a sulphur-yellow colour without changing their form. While still in the red state, they dissolve, though very sparingly, in nitric acid, either concentrated or dilute (Calvert, Compt. rend. xvi. 136). If hydrated lead-oxide be boiled with a quantity of aqueous alkali not sufficient to dissolve it, the undissolved portion becomes converted into crystalline anhydrous oxide; the resulting solution, when evaporated, yields more crystals of the anhydrous oxide, distinguished from the former portion by their easy solubility in alkalis, even when dilute (Frémy, J. Pharm. [3], iii. 30).—4. *By precipitating a lead-salt with excess of alkali.* Solution of neutral acetate of lead mixed with excess of ammonia and exposed to the sun for a few days, yields olive-green, very hard crystals of anhydrous oxide (Tünnermann, Kastn. Arch. xix. 339). Behrens (J. Pharm. [3], iv. 4, 18) supersaturates the sugar-of-lead solution with a quantity of ammonia sufficient to re-dissolve the precipitate; filters to separate any carbonate of lead that may have been formed; puts the filtrate into a stoppered bottle; and exposes it to the rays of the sun. After a few hours, transparent crystals make their appearance, colourless at first, but afterwards becoming yellowish, and finally yellowish-grey. Their powder is white, but assumes a dark brown-red colour after long trituration.—4 measures of solution of lead-acetate, saturated at 30° , mixed with 100 measures of boiling water, and then with 45 measures of aqueous ammonia, deposit, in the course of half a minute, a large number of very delicate, yellowish-white rhomboidal laminae, having a silvery lustre and united in tufts; these laminae must be

separated by levigation from the crystalline granules of hydrated oxide, which fall down at the same time, then washed with boiling water, and dried in vacuo. When ignited, they do not give off any water—or only a trace of it, with decrepitation—neither do they lose their transparency. They may be obtained without admixture of hydrate, by boiling 100 measures of a saturated solution of triplumbic acetate with 50 measures of water, adding thereto a mixture of 50 measures of water at 80°, and 8 measures of aqueous ammonia, and heating the mixture in the water-bath. In the course of a minute, crystals of the oxide separate, free from hydrate, the formation of the latter being prevented by the high temperature (Payen, Ann. Ch. Phys. [2], lvi. 64).—6. *By placing lead in contact with air and water.* On the bottom of a leaden vessel filled with water, there are first formed a number of white flakes of hydrated basic carbonate of lead, then shining grey crystals of anhydrous oxide, partly in scales like mica, partly in rhombic dodecahedrons with cube-faces. When heated, they become opaque and orange-coloured, but without losing weight or lustre. (Yorke, Phil. Mag. [3] v. 82.)

The specific gravity of protoxide of lead is 9.20092 (Karsten), 9.277 (Herapath), 9.363 (Playfair and Joule); after fusion 9.50 (Boullay). According to Leblanc (Ann. Ch. Pharm. lvi. 235), the specific gravity of litharge is greater after slow than after quick solidification. The cubical expansion between 0° and 100° is 0.00795. At a red heat it melts to a clear dark red liquid, which solidifies to a reddish-yellow crystalline mass.

Protoxide of lead unites readily with *acids*, forming neutral and very soluble salts, and likewise exhibits a decided chlorous or negative reaction towards strong *bases*. It dissolves readily in caustic *potash* and *soda*. *Baryta*-water and *lime*-water also dissolve it, and the lime-compound is said to crystallise in sparingly soluble needles. By boiling the protoxide with milk of lime, a liquid is obtained which may be used for producing a black dye on hair, nails, horn, and wood.

An *oxide of lead and silver*, $\text{Ag}_2\text{O} \cdot 2\text{PbO}$ or $\text{Ag}_2\text{Pb}_2\text{O}_3$, is obtained by adding caustic potash to a solution of a lead-salt mixed with a silver-salt, as a yellow precipitate insoluble in excess of the alkali, and thereby easily separated from admixed lead-oxide. It is easily soluble in nitric acid; blackens on exposure to light; leaves, when ignited, a mixture of lead-oxide and metallic silver; and when quietly heated in hydrogen gas is reduced to an easily fusible alloy of the two metals. (Wöhler, Pogg. Ann. xli. 311.)

Protoxide of lead dissolves, according to Binou, in 7,000 pts. of pure water, forming a solution which decomposes most salts of the alkali-metals. The solubility is greatly diminished by the presence of certain salts, *e.g.* sulphates, phosphates and carbonates, and increased by that of ammonia and its salts (p. 47).

Hydrate, or Hydrated Oxide of Lead, is obtained on adding a solution of neutral acetate of lead to excess of ammonia, as a white amorphous precipitate containing $3\text{PbO} \cdot 2\text{H}_2\text{O}$ (Payen), or $2\text{PbO} \cdot \text{H}_2\text{O}$ (Schaffner), or, according to older statements, $\text{PbO} \cdot \text{H}_2\text{O}$ or PbH_2O_2 . If the solution be heated, the anhydrous protoxide is formed at the same time. When lead is immersed in pure water, hydrate of lead is formed, and partly dissolves (v. Bonsdorff). The hydrate precipitated on treating nitrate or acetate of lead with caustic potash is always mixed, according to Winkelblech, with a certain quantity of basic salt. According to other statements, however, the acid which it contains may be completely removed by digestion with a slight excess of alkali.

The hydrate prepared by precipitation with ammonia, as above, appears under the microscope to be composed of prismatic crystals. It must be protected from the air during washing, otherwise it will absorb carbonic acid. It retains its water at 100°, but gives it up at a somewhat higher temperature, and is converted into the anhydrous protoxide, which is red while hot, yellow after cooling.

Hydrate of lead takes up ammonia, forming the two compounds $2\text{NH}_3 \cdot \text{PbO} \cdot \text{H}_2\text{O}$ and $2(\text{NH}_3 \cdot 4\text{PbO}) \cdot \text{H}_2\text{O}$. (Calvert, Compt. rend. xxii. 480.)

Red Oxide of Lead. *Red Lead. Minium.* $\text{Pb}_3\text{O}_4 = 2\text{PbO} \cdot \text{PbO}_2$ or $\text{PbO} \cdot \text{Pb}_2\text{O}_3$.—This oxide is formed when the protoxide is kept at a low red heat for a considerable time in contact with the air; also, after previous formation of hydrated protoxide and basic carbonate of lead, when lead-shavings are strewn upon water, the vessel being loosely covered, and then set aside for some months, the formation of red lead taking place chiefly on those surfaces of the metal which are exposed to the air. In like manner, drawings made with lead turn red in the course of years. (v. Bonsdorff.)

The red oxide also occurs native in certain localities, mixed with other ores of lead, and probably resulting from their oxidation, viz. at Bleialf and Kall in the Eifel, at Badenweiler in Baden; at Brillon in Westphalia; on Grassington Moor, and in Weir-dale, Yorkshire; in the Isle of Anglesey, and at Austin's Mine, Wythe County, Virginia, where it accompanies cerussite.

Red lead is extensively used as a pigment, and in the manufacture of flint-glass. It is prepared on the large scale in this country, chiefly in Derbyshire, by oxidising lead in a reverberatory furnace having two fire-hearths, covered by an elliptically arched roof; they are situated at the extreme end of the furnace, and are separated from the middle hearth, or lead-hearth, by low walls or fire-bridges. The fuel used is coke. About 1,500lbs. of lead (one-tenth consisting of hard lead) are placed upon the lead-hearth, and worked about, as soon as it is melted, with an iron crutch, the oxide (massicot) as it forms being pushed to the side of the hearth. The temperature must not be raised above low redness, so that the oxide may not melt. After 24 hours, the massicot is taken out, reduced, to very fine powder by grinding and levigation, again placed upon the lead-hearth, and exposed to the same temperature as before for 48 hours, or till a sample taken out appears dark red when hot, and bright red on cooling. The furnace must then be closed, and left to cool slowly, a condition mainly essential to the success of the operation. In Germany the conversion of the massicot into red lead is effected in a peculiar furnace, in which the massicot is placed, not on a hearth, but in barrel-shaped vessels open at both ends. Sometimes the operation is repeated in order to improve the colour. Carbonate of lead may also be used, instead of massicot, for conversion into red lead, but when the temperature is properly regulated, another pigment is obtained, called *Orange Lead*. Red lead thus prepared, which, however, retains a little carbonic acid, is known as a pigment by the name of Paris red.

To free commercial red lead from the yellow oxide mixed with it, Dumas digests it repeatedly with solution of lead-acetate; Berzelius and Dalton recommend treatment with cold, very dilute acetic acid; Phillips recommends 144 pts. at most, of strong acetic acid diluted with a large quantity of water to 100 of minium, inasmuch as if more acid be used, the brown peroxide is likewise formed. According to Dumas, however, peroxide of lead is always formed in the purification of minium, before the whole of the free protoxide is extracted, even when the dilutest acetic acid is employed.

Commercial red lead likewise contains all the foreign metallic oxides—such as the oxides of copper, iron, and silver—with which the massicot or litharge used in preparing it is contaminated. Red lead is likewise often adulterated with oxide of iron, red bole or brick-dust; these substances remain undissolved when the red lead is digested in warm dilute nitric acid; boiling hydrochloric acid extracts sesquioxide of iron from the residue. When red lead thus adulterated is ignited, there remains a mixture of yellow lead-oxide and the red substances that have been added to it.

On the small scale, red lead may be obtained of very fine colour by the following processes:—1. When 4 pts. of lead-oxide, prepared by igniting white lead, are heated in a silver or platinum crucible with 1 pt. of chlorate of potassium and 8 pts. of nitre (the latter acting as a flux and thereby saving the chlorate), brown peroxide of lead is first obtained; but this, when further heated to dull redness, is converted, with intumescence and thickening of the mass, into red lead. As soon as the red lead begins to decompose at the edge of the crucible, the mass is suffered to cool, and the red lead well boiled with water containing potash.—2. By boiling peroxide of lead with aqueous plumbate of potassium, or 1 pt. of the peroxide with 5 pts. of lead-nitrate and a quantity of aqueous potash or soda sufficient to redissolve the hydrate of lead first precipitated, till a brown-red mixture of minium with a small quantity of the peroxide is produced, and digesting this mixture, after washing, with oxalic acid, which decomposes the peroxide without acting on the minium. The minium obtained by this process is rather dark-coloured, but becomes brighter when rubbed up with water; it has the same composition as that which is obtained by the ordinary method. (Levol, Ann. Ch. Phys. [3] lxxv. 108.)

Properties.—Red oxide of lead is a scarlet, crystalline-granular powder; when heated, it first assumes a finer red colour, and then turns violet. Specific gravity 8.62 (Karsten), 8.94 (Muschenbroek), 9.082 (Herapath); of native minium 4.6 [?], 8.6. (Dana, ii. 126.)

Red lead was formerly supposed, according to analyses by Richter, Wiegleb. Thomson, and Berzelius, to be a sesquioxide, Pb^2O^3 ; but it is probable that the products examined by these chemists contained protoxide or carbonate of lead; for Dumas has shown that the perfectly pure red oxide specially prepared for analysis, or the commercial product freed from protoxide by digestion with solution of acetate of lead, contains 90.63 per cent. lead and 9.37 oxygen, numbers agreeing exactly with the formula Pb^2O^4 . It may be regarded either as a compound of the protoxide and peroxide of lead, $2PbO.PbO^2$, or perhaps of the protoxide and sesquioxide, $PbO.Pb^2O^3$, analogous to magnetic oxide of iron. Jacquelin (J. pr. Chem. liii. 151) found that a mixture of 1 at. PbO and 1 at. PbO^2 , heated to 450° , assumed a fine red colour, gave off no oxygen, and was afterwards perfectly soluble in potash-ley and glacial acetic acid. It is possible, however, that there may be more than one red oxide of

lead intermediate in composition between the proto- and peroxides; for a crystallised red lead from a minium furnace, analysed by Houton-Labillardière, exhibited the composition $3\text{PbO} \cdot \text{PbO}_2$.

Decompositions.—1. By rather strong ignition, red lead is resolved into the protoxide and 2·4 per cent. of oxygen gas (Dumas).—2. By many oxidable bodies, at various temperatures, it is reduced to the protoxide. Aqueous *sulphurous* and *nitrous* acids, at ordinary temperatures, convert it respectively into sulphate and nitrate of lead; *sulphurous acid* acts very slowly in the cold, but rapidly on the application of heat. *Dichloride of tin* converts it, with a rise of temperature of 13° , into chloride of lead and stannic oxide (A. Vogel, Kastn. Arch. xxiii. 84). It is likewise reduced by boiling with a solution of *sugar*, and oxidises many organic acids. When 2 pts. of red lead and 1 pt. crystallised tartaric acid are rubbed up to a thin paste with a small quantity of water, the mixture becomes hot and whitish, and the odour of formic acid is given off (Böttger).—3. By a small quantity of *hydrochloric acid*, red lead is converted into chloride of lead, peroxide of lead, and water:

By a larger quantity of hydrochloric acid, into chloride of lead, chlorine gas, and water:

4. By *chlorine-water*, into chlorine and peroxide of lead:

Similarly with *bromine-water* (Löwig). Minium is not decomposed by mercurous nitrate or oxalic acid. (Levol.)

Heated with *strong sulphuric acid*, it yields sulphate of lead and free oxygen. By *nitric acid*, *dilute sulphuric acid*, and likewise by weaker acids, such as ordinary *acetic acid*, it is resolved into protoxide and peroxide, the former dissolving in the form of an ordinary lead-salt, while the latter remains undissolved. In *glacial acetic acid*, however, it dissolves completely; and when considerable quantities of it, but not quite sufficient for saturation, are dissolved in that acid at 40° , the liquid on cooling deposits prismatic crystals of acetate of peroxide of lead, while an acetate of the sesquioxide remains in solution (Jacquelin, J. pr. Chem. liii. 151). According to Schönbein (*ibid.* lxxxiv. 315), concentrated acetic acid shaken up for about 15 minutes with levigated minium, takes up about 9 per cent. of it, forming a solution which is quickly decomposed by heat or by dilution, but appears to be stable at -18° . Sulphuric acid added to this solution throws down all the protoxide of lead contained in it, leaving a pure solution of acetate of peroxide, which deposits the peroxide slowly at ordinary temperatures, quickly when warmed. Potash added to the solution of minium in acetic acid, throws down, not minium, but a mixture of the proto- and peroxides, which blues tincture of guaiacum and iodised starch-paste, reactions not produced by pure minium. The solution of minium, and that of the pure peroxide in acetic acid, immediately decolorise solution of indigo; when shaken up with finely divided zinc, iron, lead, copper, or even silver, they form acetates of these metals and lose their oxidising properties. The same solutions convert iodine into iodic acid, sulphurous acid into sulphuric acid, sulphide of lead into sulphate, and act strongly at common temperatures on oil of turpentine. (Schönbein.)

Minium likewise dissolves in cold concentrated aqueous *phosphoric* and *arsenic acids*, forming salts of the peroxide. (Jacquelin, see p. 555.)

Sesquioxide of Lead. Pb_2O^3 .—Hypochlorite of sodium throws down from lead-salts, a reddish-yellow mixture of sesquioxide and chloride of lead, which, if warmed or left to stand for some time, turns brown from formation of peroxide. To obtain the sesquioxide free from chloride, nitrate of lead is supersaturated with potash in sufficient quantity to redissolve the precipitate, and then treated with hypochlorite of sodium. The yellow precipitate, when washed and dried, yields a soft, non-crystalline, reddish-yellow powder, which may be dried over oil of vitriol. At a red heat, the sesquioxide is resolved into 6·17 per cent. of oxygen gas, and 96·53 per cent. of protoxide. By oxalic acid and by formic acid it is reduced to protoxide, with evolution of heat. With nitric, sulphuric, hydrofluosilicic and acetic acids, generally without the application of heat, it is converted into peroxide and a salt of the protoxide. It dissolves in cold hydrochloric acid, forming a yellow liquid from which it is again precipitated by alkalis: the liquid, however, resolves itself in a few minutes into chloride of lead and free chlorine. (Winkelblech, Ann. Ch. Pharm. li. 175.)

The sesquioxide may also be obtained by precipitating a solution of the red oxide in acetic acid (*vid. sup.*) with caustic alkalis or alkaline carbonates. If the fixed alkalis are used, the sesquioxide always retains a portion of the precipitant, which cannot be removed by washing; but by pouring the acetic solution into very dilute ammoniacal

separating the precipitate quickly from the liquid, washing it with hot water containing a very small quantity of acetic acid, and drying at 100° , the sesquioxide is obtained pure, having the colour of ferric oxide, and differing in external appearance from that obtained by Winkolblech, but agreeing with it in composition and reactions. When heated to 150° , it becomes darker, like ignited ferric oxide, but does not decompose.

The acetic solution of the sesquioxide may be mixed, without decomposition, with from 4 to 6 times its volume of alcohol of 96° Tr. (Jacquelain, *loc. cit.*)

Dioxide or Peroxide of Lead. *Brown or puce Lead.* PbO_2 .—This oxide is obtained: 1. By exposing the protoxide suspended in water to a stream of chlorine gas. Wöhler precipitates a solution of 4 pts. of acetate of lead with a solution of 3 pts. or rather more of crystallised carbonate of sodium, and passes chlorine gas through the resulting thin pulpy mass, till the whole of the carbonate of lead is converted into brown peroxide, amounting to $2\frac{1}{2}$ pts., which may then be washed. No chloride of lead is formed in this reaction, the whole of the chlorine combining with the sodium, while acetic and carbonic acid are set free.—2. By fusing protoxide of lead with chlorate of potassium at a temperature short of redness.—3. By digesting the red oxide in dilute nitric acid, which dissolves the protoxide, decanting off the nitrate of lead, and washing the remaining powder with boiling water.—4. By fusing the protoxide for a considerable time with hydrate of potassium, it then crystallises in black six-sided tables (Becquerel).—5. According to Schönbein (*J. pr. Chem.* lxxv. 88), it is obtained, but always mixed with protoxide, when basic acetate of lead is shaken up with aqueous peroxide of hydrogen or ozonised oil of turpentine; if, however, the oil of turpentine is in excess, the peroxide is reduced to protoxide with separation of oxygen.—6. When a solution of a lead-salt (nitrate or acetate) is electrolysed, metallic lead is deposited on the negative, and peroxide of lead on the positive electrode.

According to Becquerel (*Ann. Ch. Phys.* [3] viii. 405), a hydrated peroxide of lead may be obtained electrolytically.

The peroxide is also said to occur native, as plattnerite, at Leadhills in Scotland, in hexagonal prisms with replaced basic edges, pseudomorphous after pyromorphite. Cleavage indistinct. Lustre metallic adamantine. Colour iron-black. Streak brown. Opaque.

The artificially prepared peroxide is a brown powder, which when heated gives off oxygen, and is converted into red lead or the protoxide. According to Suckow, it is also reduced to the red oxide by exposure to bright sunshine. When touched with the moist hands, it gives off an odour of chlorine or peroxide of hydrogen. With *hydrochloric acid*, it yields chloride of lead and free chlorine; *nitrous acid* converts it into nitrate of lead. In an atmosphere of pure *sulphurous anhydride* it becomes red-hot, and is converted into sulphate of lead, and therefore serves to separate sulphurous anhydride from other gases. With *ammonia* it forms water and nitrate of lead; and when triturated with one-sixth of its weight of *sulphur*, it takes fire, and burns with a bright flame, forming sulphide of lead (Vauquelin); the addition of phosphorus or of strong sulphuric acid causes a strong detonation (Grindel). *Organic substances* are rapidly oxidised by it; when triturated with crystallised *tartaric acid*, it becomes red-hot, and eliminates carbonic anhydride and formic acid (Walker). With $\frac{1}{4}$ th *grape sugar*, vivid ignition likewise takes place; also with *mannite*, or with $\frac{1}{4}$ th of *cane sugar*. *Racemic acid*, and especially *gallic acid*, also take fire in contact with it; a less violent action takes place with *muic* and *oxalic acids*, carbonic anhydride being formed in the latter case (Böttger). The peroxide likewise oxidises organic compounds in presence of water; thus it converts *uric acid* into allantoin and urea, forming at the same time oxalate of lead and carbonic anhydride (Liebig and Wöhler). Boiled with *grape-sugar* and water, it oxidises the sugar, producing formic acid and carbonate of lead. (Stürenburg.)

According to Munk af Rosenschöld, it is the strongest of all negative electromotors (ii. 421).

Peroxide of lead does not unite readily with *acids*; compounds of this oxide with acetic, phosphoric, arsenic acid, &c., may however, be produced by treating red lead with the respective acids. (See p. 553.)

The prismatic crystals of acetate of peroxide of lead, or peroxyplumbic acetate, which separate from a solution of red lead in glacial acetic acid may be dried to a certain extent between bibulous paper, but if the paper be renewed to complete the drying, the crystals turn yellow, and are resolved into acetic acid and the brown peroxide; if still moist with acetic acid, they may be kept undecomposed in closed vessels. They melt at 160° , and at a somewhat higher temperature, decompose quickly and completely, leaving metallic lead, and emitting an odour of acetone and acetic acid. When moistened with water, they are resolved into acetic acid and peroxide of lead; the latter may be obtained pure by washing them with hot water. This reaction

affords an easy means of distinguishing between the solution of the crystals of peroxyplumbic acetate in acetic acid, and that of the sesquioxide in the same acid, as the latter yields, besides free peroxide and acetic acid, a certain quantity of neutral acetate of lead, which may be detected in the water. (Jacquelin, J. pr. Chem. liii. 151.)

A solution of peroxyplumbic phosphate is obtained by dissolving minium in moderately concentrated aqueous phosphoric acid, and precipitating the dissolved protoxide with dilute sulphuric acid. The solution may be facilitated by mixing the phosphoric acid with sulphuric, nitric, or acetic acid. Peroxyplumbic phosphate is more stable than the acetate, but on boiling the solution, oxygen is rapidly evolved, and protoxide of lead remains dissolved, without separation of peroxide. The same decomposition takes place slowly at common temperatures. Phosphoric acid added to a solution of peroxyplumbic acetate increases its stability, and prevents the separation of peroxide.—A corresponding arsenate may be obtained in like manner, but it is more prone to decomposition than the phosphate.—A concentrated solution of tartaric acid shaken up with minium takes up peroxide, and a clear solution may be decanted from the residue, but the dissolved peroxide is quickly decomposed, its oxygen oxidising a portion of the tartaric acid, and a precipitate of ordinary tartrate of lead being formed.

With bases, peroxide of lead unites more readily than with acids, behaving towards alkalis like a weak acid, and may therefore be called plumbic acid.

Plumbate of potassium, $K_2O \cdot PbO_2 \cdot 3H_2O$ or $K^2PbO_3 \cdot 3H_2O$, is obtained in small crystals by fusing the peroxide with excess of hydrate of potassium, and dissolving the product in a small quantity of water. The solution, evaporated in a vacuum, yields rhombohedral crystals (Frémy, J. Pharm. [3] iii. 32). It may also be prepared by boiling the peroxide in a silver dish with very strong potash-ley, till a sample dissolved in water yields a copious precipitate of the peroxide on addition of nitric acid. A little water is then poured upon the hot mass, and the resulting solution is decanted and left to cool; it then deposits plumbate of potassium in octahedrons (Regnault). The crystals are decomposed by a small quantity of water, yielding peroxide of lead, and a solution of that oxide in the excess of alkali, which, however, is decomposed by a larger quantity of water, the whole of the peroxide being precipitated as a brown powder.

The solution of plumbate of potassium forms with metallic salts precipitates of analogous composition.

Plumbate of calcium is obtained by digesting nitrate of lead at 57° for five hours, with excess of lime and chloride of lime. A colourless insoluble compound is then formed, from which acids withdraw the lime, leaving pure peroxide of lead. (Crum, Ann. Ch. Pharm. lv. 218.)

LEAD, OXYBROMIDE OF. $Pb^2Br^2O = PbBr_2 \cdot PbO$.—This compound is formed by igniting bromide of lead in contact with the air till it ceases to emit white fumes (Balard); by heating bromocarbonate of lead (p. 540), till all the carbonic anhydride is expelled (Löwig); or by immersing bromide of lead for some days in a solution of the acetate, and agitating from time to time. It is a yellow powder, which when heated to fusion, gives off dense white fumes, and solidifies on cooling to a yellowish-white, translucent, pearly mass. When decomposed at a high temperature by chlorine, it yields 94.9 per cent. chloride of lead.

LEAD, OXYCHLORIDES OF. Chloride of lead unites in five different proportions with the protoxide, forming the following compounds:

a. $Pb^2Cl^2O = 3PbCl^2 \cdot PbO$.—Four parts of chloride of lead ignited with one part of litharge yield a fused laminar pearl-grey mixture, which when triturated with water swells up to a bulky mass, having the above composition. (Vauquelin.)

b. $Pb^2Cl^2O = PbCl^2 \cdot PbO$.—This compound occurs native as matlockite, in the old mine of Cromford, near Matlock in Derbyshire. It forms dimetric tabular crystals exhibiting the combination, $oP \cdot \infty P \cdot P \cdot 2P \cdot P$. Angle $P : P$ in the terminal edges = $104^\circ 6'$; in the basal edges = $120^\circ 52'$. Cleavage basal, not perfect. Hardness = 2.5 to 3. Specific gravity = 7.21—5.3917. Lustre adamantine, occasionally pearly. Colour clear yellowish, sometimes a little greenish. Transparent to translucent. (Greg, Phil. Mag. [4] ii. 120; Rammelsberg, Pogg. Ann. lxxv. 141.)

The same compound is formed by igniting chloride of lead in contact with the air, till it no longer fumes, or by fusing chloride and carbonate of lead together. Carbonic anhydride is then set free, and a compound is formed which is deep yellow while fused, but on cooling assumes a lemon-yellow colour, and becomes mucous and crystalline (Döbereiner). It is also obtained as a hydrate, $2Pb^2Cl^2O \cdot H_2O$, when recently precipitated chloride of lead is digested in a cold solution of neutral acetate of lead; also when a solution of common salt is dropped into the neutral acetate. The

precipitate when heated gives off its water and melts to a deep yellow mass, becoming nearly white on cooling.

Pattinson prepares this oxychloride on the large scale, for use as a pigment, by the following process:—Finely pulverised galena is heated with strong hydrochloric acid, whereby chloride of lead is formed, and sulphydric acid evolved; this gas is collected in large gasometers, and used for the preparation of sulphuric acid by combustion in the ordinary lead-chambers. The liquid is allowed to cool completely in contact with the undissolved residue; this residue, which consists chiefly of chloride of lead, is washed with cold water to remove the easily soluble chlorides of copper and iron, and then gradually introduced into a vessel containing boiling water, which dissolves the chloride of lead, leaving a smaller residue consisting of gangue, chloride of silver, and undecomposed galena. By melting this last residue with lime, a quantity of silver containing a little lead is obtained, even from ores in which the proportion of silver is too small for profitable extraction, either by the ordinary process of calcination, or by Pattinson's condensation process. The hot clear solution of chloride of lead obtained as above is mixed with very thin milk of lime, sufficient to neutralise only half the hydrochloric acid present. A precipitate of oxychloride, $\text{Pb}^2\text{Cl}^2\text{O}$, is then formed, which may be used advantageously as a pigment in place of white lead, as it covers well when mixed with oil, and does not turn yellow in the dark, or blacken from exposure to air containing sulphuretted hydrogen, more quickly than white lead.

c. $\text{Pb}^4\text{Cl}^2\text{O}^2 = \text{PbCl}^2.2\text{PbO}$.—This compound forms the rare mineral mendipite (also called *berzite* and *cerasite*) found on the Mendip Hills in Somersetshire, where it occurs in yellowish-white, trimetric prisms exhibiting the faces, αP , ∞P , $\infty\bar{\text{P}}\infty$, and having the angle $\infty\text{P} : \infty\bar{\text{P}} = 102^\circ 36'$. Cleavage very distinct, parallel to ∞P ; less distinct diagonally. Hardness = 2.5–3. Specific gravity = 7 to 7.1. The crystals are translucent, and have an adamantine lustre on the cleavage-faces. It occurs in a state of greater purity at Brilon, near Stadtbergen in Westphalia; the crystals there found are white, translucent, and have a mother-of-pearl lustre on the cleavage-faces. It is also found in opaque prismatic crystals at Tarnowitz in Silesia.

d. $\text{Pb}^4\text{Cl}^2\text{O}^2 = \text{PbCl}^2.3\text{PbO}$.—This compound is obtained in the anhydrous state by fusing 1 at. chloride of lead with 3 at. of the protoxide; also as a hydrate, $\text{Pb}^4\text{Cl}^2\text{O}^2.11\text{H}_2\text{O}$, by decomposing chloride of lead with ammonia; by precipitating basic acetate of lead with common salt; and by decomposing a solution of common salt with protoxide of lead. The hydrate is a white flocculent mass, and when ignited leaves the anhydrous compound, which is a greenish-yellow laminated mass, yielding a yellow powder, known as *Turner's yellow*. It is prepared as a pigment, by mixing litharge with $\frac{1}{4}$ to $\frac{1}{2}$ of its weight of common salt, and pouring water on the mixture; it then becomes hot, swells up, yields a solution of caustic soda containing a very small quantity of lead, and a residue of basic chloride, which is washed and ignited at a moderate heat. The hydrated compound was formerly used as a white pigment in place of white lead, being known as *Pattinson's monobasic chloride*; but it has not so much body as white lead.

e. $\text{Pb}^4\text{Cl}^2\text{O}^2 = \text{PbCl}^2.5\text{PbO}$.—Obtained by fusing chloride of lead with 5 at. of the protoxide. Orange-yellow substance, yielding a deep yellow powder.

f. $\text{Pb}^4\text{Cl}^2\text{O}^2 = \text{PbCl}^2.7\text{PbO}$.—Produced by fusing a mixture of 10 pts. of pure oxide of lead and 1 pt. of pure sal-ammoniac, a portion of the lead being at the same time reduced. The fused product affords cubic crystals on cooling slowly. It forms in that state a beautiful yellow pigment, known as *Cassel yellow*.

LEAD, OXYCYANIDE OF. See ii. 253.

LEAD, OXYFLUORIDE OF. See p. 547.

LEAD, OXYGEN-SALTS OF. Protoxide of lead is a strong base, uniting readily with acids, and forming salts, the general characters of which have been already described (p. 540). Those which are soluble have a sweetish taste and are poisonous. They resemble the salts of barium and strontium in being readily precipitated by sulphuric acid, and many of them are isomorphous with the corresponding salts of those metals. Lead has a very great tendency to form basic salts, which may be regarded either as compounds of the normal salts with oxide or hydrate of lead, or as salts derived from two or more molecules of water, in which less than half the hydrogen is replaced by an acid radicle: thus, there is a basic nitrate of lead containing

$\text{Pb}(\text{NO}^3)^2.\text{PbH}^2\text{O}^2$ or $\left. \begin{matrix} \text{NO}^3 \\ \text{Pb} \end{matrix} \right\} \text{O}^2$, and a tribasic acetate containing $\text{Pb}(\text{C}^2\text{H}^3\text{O}^2)^3.\text{PbO}$ or $\left. \begin{matrix} (\text{C}^2\text{H}^3\text{O}^2)^3 \\ \text{Pb}^3 \end{matrix} \right\} \text{O}^4$. These basic oxygen-salts are analogous to the oxychlorides, oxyiodides, &c. (For descriptions of the individual salts, see the several Acids.)

The sesquioxide and peroxide of lead also unite with acids, but the salts thence resulting are not very stable. They are produced by the action of certain acids on the red oxide of lead (p. 553).

LEAD, OXYIODIDES OF. Five of these compounds have been described:

a. $\text{Pb}^{\text{I}}\text{I}^{\text{O}} = \text{PbI}^{\text{I}}\text{PbO}$, is obtained, according to Brandes and Kühne (Pharm. Centralbl. 1847, p. 593), by precipitating acetate of lead with iodide of potassium. Denot (J. Pharm. xx. 1) uses a solution of the neutral acetate mixed with a small quantity of basic acetate, and dissolves out the iodide of lead contained in the precipitate with water. The same compound is said to be formed when iodide of lead is digested for some time in a solution of the neutral acetate. Acetic acid is said to dissolve out the oxide of lead from this compound, leaving the iodide. By immersion in solution of iodide of potassium it is converted into iodide of lead. It contains 1 at. water, which is given off at 100° (Kühne), at 200° (Denot). It melts with partial decomposition at 300° , and solidifies to a clear yellow glass on cooling.

b. $\text{Pb}^{\text{I}}\text{I}^{\text{O}}\cdot\text{H}^{\text{O}} = \text{PbI}^{\text{I}}\cdot 2\text{PbO}\cdot\text{H}^{\text{O}}$, is obtained, according to Kühne, by digesting levigated oxide of lead with a boiling solution of iodide of potassium as long as it continues to increase in weight. By precipitating basic acetate of lead with iodide of potassium, Kühne obtained nothing but the compound a, whereas Denot states that compounds containing 2 at. and 5 at. oxide of lead to 1 at. iodide are obtained by precipitating iodide of potassium with dibasic or pentabasic acetate of lead.

c. $\text{PbI}^{\text{I}}\cdot 3\text{PbO}\cdot 2\text{H}^{\text{O}}$.—Obtained by treating a boiling solution of iodide of lead with caustic ammonia. (Kühne.)

d. $\text{PbI}^{\text{I}}\cdot 2\text{PbO}\cdot\text{Pb}^{\text{I}}\text{O}^{\text{I}} (?)$.—This is a wine-red compound, obtained by triturating recently precipitated hydrate of lead with a fourth of its weight of iodine, and boiling with water as long as fumes of iodine are given off. (Jammes.)

e. $\text{PbI}^{\text{I}}\cdot 5\text{PbO}$.—Remains in the form of a yellow powder when the compound d is dried and heated. (Handw. d. Chem. 2^e Aufl. ii. [2], 60.)

LEAD, PHOSPHIDE OF. a. When phosphorus is thrown upon melted lead, or when lead-filings are ignited with an equal weight of glacial phosphoric acid, or chloride of lead with phosphorus, a compound is formed containing not more than 15 per cent. of phosphorus: it has the colour of lead; may be cut with a knife, but splits into laminae when hammered; tarnishes quickly when exposed to the air; and, when heated before the blowpipe, yields a phosphorus-flame and a globule of lead (Pelletier, Ann. Ch. Phys. [2], xiii. 111).—b. Phosphoretted hydrogen gas passed for two hours through a solution of neutral acetate of lead, yields a brown precipitate, which burns before the blowpipe with a small phosphorus-flame, forming beautifully crystallised lead-phosphate. (H. Rose, Pogg. Ann. xxiv. 326.)

LEAD, SELENIDE OF. Very small quantities of selenium combined with lead render it harder and less fusible.

The *protoselenide*, PbSe , is formed when lead and selenium are heated together, combination then taking place attended with incandescence, and a grey porous mass being formed, which becomes silver-white by polishing. When ignited in an open vessel, it first gives off selenium, then a small quantity of selenide of lead in white fumes, leaving a residue of basic selenite of lead. Cold nitric acid dissolves the lead, leaving red selenium, which, on heating the liquid, dissolves in the form of selenious acid. (Berzelius.)

Selenide of lead also occurs native, as clausenthalite, sometimes pure, sometimes having part of the lead replaced by other metals, as cobalt, copper, mercury, and silver. It is found in fine-grained masses, sometimes foliated, with cubic cleavage. Hardness = 2.5 to 3. Specific gravity = 7 to 8.8. Lustre metallic. Colour lead-grey, sometimes bluish; cupreous varieties yellowish. Streak darker. Opaque. Fracture granular and shining. Rather sectile. Before the blowpipe it emits the odour of horse-radish and exhibits various other reactions characteristic of selenium (g. v.). Heated in a tube it yields a sublimate of selenium.

The following are analyses of clausenthalite and its varieties:—a, H. Rose (Pogg. Ann. ii. 416; iii. 281); b, Stromeyer (*ibid.* ii. 403); c, Selenide of lead and silver (Rammelsberg, *Mineralchemie*, p. 34); d, Selenide of lead and cobalt; e, f, Selenides of lead and copper (H. Rose, Pogg. Ann. iii. 288); g, h, The same (Korsten, *ibid.* xlv. 265):

	Tillkerode.		Clausthal.		Tillkerode.		Clausthal.		Tillkerode.		Glashach.	
	a.	b.	c.	d.	e.	f.	g.	h.	i.	j.	k.	l.
Selenium . . .	27.59	28.11	26.52	31.42	34.98	30.26	32.09	29.97				
Lead . . .	71.81	70.98	60.15	63.92	48.43	60.28	57.48	65.16				
Silver . . .			11.67			1.32						
Cobalt . . .		0.83		3.14			0.05	0.68				
Copper . . .					15.77	7.94	8.58	4.09				
Iron . . .				0.45		0.78						
	99.40	99.92	98.34	98.93	100.50	99.26	98.20	99.30				

The varieties *e, f, g, h*, which contain copper, are by some mineralogists regarded as distinct species; but it is perhaps better to regard them as varieties of clausthalite, in which a part of the lead is replaced by copper; *e* and *f* are called *raphanosome* by Kobell; *d* is called *Tilkerodite* by Haidinger; *d, e*, and *f* are called *Zorgite* by Brooke and Miller; *e* and *h* agree nearly with the formula $\frac{1}{2}\text{Pb} \left\{ \begin{smallmatrix} \frac{2}{3}\text{Pb} \\ \frac{1}{3}\text{Cu} \end{smallmatrix} \right\} \text{Se}$; *f* and *g* with $\frac{2}{3}\text{Pb} \left\{ \begin{smallmatrix} \frac{2}{3}\text{Pb} \\ \frac{1}{3}\text{Cu} \end{smallmatrix} \right\} \text{Se}$.

Clausthalite and its varieties occur at Harzgerode, in the Harz, and at Clausthal, Tilkerode, Zorge, Glashach, near Hildburghausen, and Lehrbach; also at Ramsberg and Freiberg in Saxony.

Lehrbachite, which is a selenide of lead and mercury, and is described as having the structure and colour of clausthalite, is, perhaps, a mechanical mixture of that mineral with selenide of mercury. It emits the odour of selenium before the blowpipe, and gives mercury with soda. H. Rose found in one specimen 24·97 per cent. selenium, 55·84 lead, and 16·94 mercury (= 97·75); in another, 27·98 selenium, 27·33 lead, and 44·69 mercury (= 100).

LEAD, SULPHIDES OF. There are four compounds of lead and sulphur, namely, the protosulphide, two subsulphides, and a persulphide; but the protosulphide is the only one whose constitution is accurately known.

Tetartosulphide. Pb_4S .—A finely divided mixture of 100 pts. of galena and 84 of lead heated for a quarter of an hour in a well-closed charcoal-lined crucible, placed in a wind-furnace with a strong draught, yields 144 pts. of a dull, lead-coloured, fine-grained, semi-malleable, soft mixture, exhibiting a dark-grey colour on the cut surface. When oxidised by nitric acid, it yields 36 per cent. of lead-sulphate, and must therefore contain 3·96 per cent. of sulphur. (Bredberg, Pogg. Ann. xvii. 274.)

Hemisulphide. Pb_2S .—1. By the same process as for the preceding compound—excepting that the mixture is fused in an earthen instead of a charcoal-lined crucible, and covered with borax—150 pts. of a more brittle mixture are obtained, having a dark leaden-grey colour, a finely laminar fracture, and containing 7·207 per cent. of sulphur (Bredberg).—2. Sulphate of lead ignited in a charcoal-lined crucible gives off sulphurous anhydride and leaves hemisulphide of lead, which at a higher temperature, partly volatilises and is partly decomposed, leaving a residue of metallic lead. (Berthier, Ann. Ch. Phys. [2] xxii. 240.)

Protosulphide. PbS .—This compound is found native as galena (*blue lead*, *galène*, *Blieglunz*), the most abundant and important ore of lead. It occurs frequently in very fine crystals belonging to the monometric system, with cubic cleavage, perfect and easily obtained. The ordinary forms are the octahedron, cube, and rhombic dodecahedron, occurring alone or in combination with other forms, 20 for example, subordinate; twins like *fig.* 320 (ii. 160), and others in which the intersecting cubes are of different sizes, or in which the diagonals do not exactly coincide; also pseudomorphs after pyromorphite. The crystals are frequently imbedded, or united in granular aggregations. The mineral likewise occurs in tabular, reniform or botryoidal masses, coarse or fine granular, sometimes impalpable, occasionally fibrous. Hardness = 2·5. Specific gravity = 7·25 to 7·7. Lustre metallic. Colour and streak pure lead-grey; surface of crystals occasionally tarnished. Fracture scarcely perceptible in the crystals, on account of the perfect cleavage; in the massive varieties, flat sub-conchoidal, or uneven. Before the blowpipe, it decrepitates strongly, melts and yields a globule of lead as soon as the sulphur is volatilised.

For analyses of galena, see p. 480.

Galena is found abundantly in England and in many parts of Europe; in the Daouria Mountains, Siberia; in Algeria; near the Cape of Good Hope; in Australia; and in many parts of North America. It occurs in beds and veins, both in crystalline and uncrystalline rocks, often associated with blende, iron and copper pyrites, carbonate of lead and other lead ores, and in a gangue of heavy spar, calcspar or quartz. It often suffers decomposition, and gives rise to the formation of other plumbiferous minerals.

Breithaupt's antimonial galena from Freiberg in the Breisgrau, with specific gravity = 6·9 to 7·0, is perhaps the same as steinmannite from Příbram in Bohemia. Whether the tetragonal galena of the same mineralogist, also containing antimony, is a dimetric variety of galena, is not exactly known.

Protosulphide of lead is produced artificially:—1. When sulphur is mixed with melted lead, the whole becoming red-hot. Strips of lead even of moderate thickness, take fire in sulphur-vapour, and burn with vivid glow, depositing half-fused globules of the protosulphide.—2. By heating the protoxide with excess of sulphur.—3. By the action of sulphydric acid or an alkaline sulphide on the oxide or salts of lead.—4. Becquerel, by immersing cinnabar in a solution of chloride of magnesium contained in a glass tube, dipping a lead plate to the bottom, and leaving the tube well closed for six

weeks, obtained grey, metallic-shining, regular tetrahedrons of the protosulphide, which formed on the sides of the tube.

Sulphide of lead obtained by fusing its elements together is of a lead-grey colour, with granular fracture; that which is precipitated by sulphydric acid is a brown-black powder, and, according to Karsten, has a density of 7.5052 after fusion. Sulphide of lead melts at a strong red heat, volatilises at a stronger heat, and sublimes undecomposed if kept from contact with the air.

Decomposition.—1. Sulphide of lead, when gently ignited in the air, gives off the greater part of its sulphur in the form of sulphurous anhydride, while metallic lead (amounting to about half the total quantity) and sulphate of lead remain behind (Descotils, Ann. Ch. Phys. [2] lv. 441).—2. The protosulphide and protoxide of lead decompose one another when heated together, evolving sulphurous anhydride and leaving metallic lead:

—3. The protosulphide heated in vapour of water gives off sulphydric acid and yields metallic lead. The first products formed are sulphydric acid and the protoxide, which then reacts on the remaining sulphide in the manner just described. —4. When sulphide of lead is fused with alkaline carbonates, half the lead is separated in the metallic state, and on addition of metallic iron, the whole.

Protosulphide of lead is insoluble in *dilute acids*, in caustic *alkalis*, and *alkaline sulphides*. When boiled with *dilute nitric acid* it gradually dissolves as nitrate, with evolution of nitric oxide, and separation of sulphur. The finely divided sulphide treated with *fuming nitric acid* is completely converted into sulphate of lead; but if any portion of the sulphur remains unoxidised, a corresponding quantity of the lead is converted into nitrate. By strong *hydrochloric acid* it is converted into chloride of lead with evolution of sulphydric acid. *Nitro-hydrochloric acid* converts it into chloride and sulphate of lead. *Chlorine* decomposes it slowly, forming chloride of lead and chloride of sulphur.

Persulphide. A solution of a lead-salt mixed with pentasulphide of potassium yields a precipitate, which has at first a fine blood-red colour, but quickly loses this colour, even while immersed in the liquid, and is resolved into the protosulphide and free sulphur. Higher sulphides of lead are also said to be formed by the action of sulphydric acid on the sesquioxide and peroxide of lead; but their composition has not been made out.

LEAD, SULPHOCARBONATE OF. See SULPHOCARBONATES.

LEAD, SULPHOCHLORIDE OF. If a lead-salt, *e.g.* aqueous chloride of lead, be precipitated by a mixture of aqueous sulphydric and hydrochloric acids, there is produced, first a yellowish-red, and then a red precipitate containing about 56 per cent. (3 at.) of lead-sulphide, and agreeing very nearly with the formula, $\text{PbCl}_2 \cdot 3\text{PbS}$. An excess of sulphydric acid turns it black and converts it into pure sulphide of lead; the same change is produced by boiling with water, which extracts the chloride; the compound is also blackened by potash, which extracts the chlorine (Hünefeld, J. pr. Chem. vii. 27).—When sulphydric acid gas is passed through a solution of $\frac{1}{2}$ pt. lead-acetate in 100 pts. of water mixed with 10 pts. of hydrochloric acid of specific gravity 1.168, a beautiful carmine-coloured precipitate of sulphochloride of lead is produced. If the solution contains 1 pt. of lead-acetate, 112 pts. of water, and 14 of strong hydrochloric acid, sulphydric acid produces a yellow precipitate, which gives up chloride of lead to boiling water, while black protosulphide of lead remains behind. If, instead of 14 pts. of strong hydrochloric acid, we use 14 pts. of a mixture of 2 pts. of strong hydrochloric and 1 pt. nitric acid, prepared two days before and containing pernitric oxide, the sulphydric acid produces, after a while, first a yellowish-red and then a cinnamon-red, granular precipitate. If the stream of sulphydric acid gas were continued for a longer time, the precipitate would become first carmine-coloured, then brown, and lastly black. The red granular precipitate, when boiled with water, gives up a considerable quantity of chloride of lead, and is converted into a brown-red, flocculent powder, which then undergoes no further change, but when heated alone in a glass tube, gives off sulphur and sulphydric acid, and fuses to a brown mass. According to this reaction, the pernitric oxide must have precipitated sulphur from the sulphydric acid, and the red precipitate is a compound of the chloride with a polysulphide of lead. (Reinsch, J. pr. Chem. xiii. 130.)

LEAD, SULPHOCYANATE OF. See SULPHOCYANATES.

LEAD, WHITE. Hydrated carbonate of lead used as a pigment (ii. 786). The native anhydrous carbonate is also called white lead ore.

LEAD-GLANCE. Syn. with galena (see p. 558).

LEAD-GLASS. *Vitrum plumbi.*—A term formerly applied to perfectly fused oxide of lead. Oxide of lead is used as an ingredient in various kinds of glass, as in flint-glass, crystal-glass, strass, &c. (ii. 841).

LEAD-GLAZE. *The glaze of the more common kinds of earthenware consists of an easily fusible silicate of lead, prepared from a mixture of finely ground red lead, litharge, white lead, or galena, with clay or sand. It melts more easily in proportion as it is richer in lead, but when the proportion of lead is very large, the glaze is decomposed by dilute acids, which dissolve part of the oxide of lead.*

LEADHILLITE. *Sulphato-tricarbonate of lead, $\text{PbSO}_4 \cdot 3\text{PbCO}_3 = (\text{CO}_3)^3 \text{Pb}_4 \text{SO}_4$.*

—A crystallised mineral occurring, together with other ores of lead, at Leadhills in Scotland; said also to be found in Grenada, in the island of Serpho, Grecian Archipelago, and in the Newberg district, South Carolina. The crystals are trimetric, exhibiting the planes ∞P_∞ (greatly predominant), ∞P_∞ , ∞P , $\frac{1}{2} P_\infty$, $\frac{1}{2} P$; $\frac{1}{2} P_\infty$; $\frac{1}{2} P$ and others. Angle ∞P : $\infty P = 103^\circ 16'$. Ratio of principal axis, brachy-diagonal and macrodiagonal = 1.7205 : 1 : 1.2632. The crystals are hemihedral in ∞P and some other planes; hence they are monoclinic in aspect, or rhombohedral when in compound crystals. Cleavage very perfect parallel, to ∞P_∞ ; in traces parallel to ∞P_∞ . Twins consisting of three crystals, with face of composition P_∞ ; also parallel to ∞P . Hardness = 2.5. Specific gravity = 6.2–6.5. Lustre of ∞P_∞ pearly, of the other faces resinous, somewhat adamantine. Colour white, passing into yellow, green, and grey. Streak uncoloured. Transparent to translucent. Conchoidal fracture scarcely observable. Rather sectile. Before the blowpipe, it intumesces at first, then turns yellow, but becomes white on cooling; easily reduced on charcoal. It effervesces briskly in nitric acid, and leaves a white residue of lead-sulphate.

Berzelius found in the mineral 28.7 per cent. sulphate, and 71.0 carbonate of lead (= 99.7); Stromeyer found 28.3 sulphate, and 72.7 carbonate (= 100); the formula requires 27.44 sulphate and 72.56 carbonate. (Dana, ii. 371.)

LEAD-MATT. *Matto de plombe. Blästein.*—This term is applied to the mixtures of sulphide of lead with other metallic sulphides, chiefly sulphide of iron, obtained in the metallurgic treatment of lead-ores (p. 492).

LEAD-OCBRE. Native protoxide of lead (p. 550).

LEAD-PLASTER. A mixture of the lead-soups of fatty acids, used in medicine as an external application. It is prepared by heating 9 pts. of olive-oil (sometimes also lard or rape-oil) nearly to its boiling-point, then adding by degrees 5 pts. of powdered litharge, incorporating thoroughly with a spatula, adding from time to time small portions of warm water, and continuing the heating and incorporation till a few drops of the mixture harden when thrown into water, and form a glutinous mass between the fingers. Sometimes a mixture of litharge and white lead is used instead of litharge alone.—Well-prepared lead-plaster forms a whitish-yellow homogeneous mass, somewhat flexible and tenacious in summer, brittle in winter. When gently heated, it melts to a thick liquid, which, at higher temperatures, turns brown, and finally black, giving off irritating vapours.

LEAD-RADICLES, ORGANIC. These compounds, the series of which is at present far from complete, are obtained by the action of the iodides of the alcohol-radicles on lead or its alloys with potassium or sodium, or of zinc-ethyl on chloride of lead. The formation of ethyl-compounds by the first of these processes was first observed in 1853 by Löwig (J. pr. Chem. lx. 304; Ann. Ch. Pharm. lxxxviii. 318), soon afterwards by Cahours and Riche. (Compt. Rend. xxxvi. 1002.)

The iodide of the radicle $\text{Pb}^*(\text{C}^2\text{H}^*)^2$ was discovered by Löwig, who designated the radicle methplumbethyl, and studied several of its compounds, but did not obtain it in the free state. It has since been isolated (1860) by Klippel (J. pr. Chem. lxxxi. 287), who has likewise obtained the corresponding amyl-compound.—The compound $\text{Pb}^*(\text{C}^2\text{H}^*)^2$ was discovered in 1858 by Buckton (Phil. Mag. [4] xviii. 212, xvii. 282; Ann. Ch. Pharm. cix. 218, cxii. 220); and the corresponding methyl-compound by Cahours in 1861 (Ann. Ch. Phys. [3] lxii. 257; Ann. Ch. Pharm. cxvii. 48), who likewise obtained by its decomposition, the compound $\text{Pb}^*(\text{CH}^*)^2$.

Amyl-compounds.

Plumbotriamyl. *Methplumbamyl.* $\text{Pb}^*(\text{C}^5\text{H}^{11})^2 = \text{Pb}^*\text{Am}^2$.—Prepared (like the corresponding ethyl-compound) by distilling an alloy of lead and sodium with iodide of amyl, shaking up the distillate with ether, distilling off the ether after addition of

a little alcohol, and treating the residue with a large quantity of water. Plumbotriamyl then separates as a yellowish, oily, non-volatile liquid, inodorous in the cold, smelling like plumbotriethyl when warm: its vapour exerts an irritating action on the mucous membranes. When set on fire it burns, with separation of lead-oxide. With fuming nitric acid it detonates, with emission of light and heat.

The *chloride*, $\text{PbAm}^{\text{I}}\text{Cl}$, is obtained by treating the oxide (*infra*) with hydrochloric acid. It crystallises in white needles.

The *iodide*, $\text{PbAm}^{\text{I}}\text{I}$, is obtained in white needles by adding iodine to the ethereal solution of plumbotriamyl, till the colour becomes permanent, and evaporating the filtrate. It is more stable than the corresponding ethyl-compound, melting at 100° without decomposition, and solidifying in the crystalline form on cooling. It is insoluble in water. It unites with *mercuric iodide*, forming the double salt $\text{PbAm}^{\text{I}}\text{I}.\text{HgI}^{\text{I}}$, which crystallises in golden-yellow laminae, insoluble in water, sparingly soluble in alcohol and ether.

Oxide.—By agitating the alcoholic solution of the iodide with recently precipitated oxide of silver, evaporating the filtrate, and treating the residue with water, oxide of plumbotriamyl separates as a faintly yellow viscid mass, insoluble in water, soluble in alcohol and ether; the alcoholic solution has a faint alkaline reaction, and precipitates ferric salts, but not copper or silver salts.

The *sulphate*, obtained by heating the oxide with dilute sulphuric acid, is a viscid uncrystallisable mass. (Klippel.)

Ethyl-compounds.

Plumbotriethyl. $\text{Pb}^2(\text{C}_2\text{H}_5)^2 = \text{Pb}^2\text{E}^2$. Löwig's *Methylplumbethyl*.—Löwig, by acting on an alloy of 6 pts. lead and 1 pt. sodium with iodide of ethyl, obtained a mixture of several lead-compounds of ethyl, which he was not able to separate. The mixture was perfectly colourless, tolerably mobile, volatile, and had a powerful odour; did not fume in the air, but when set on fire burnt and gave off dense clouds of oxide of lead. It took fire when strong nitric acid was poured upon it, and exploded with great violence in contact with iodine or bromine. It was insoluble in water, but dissolved readily in alcohol or ether; and the solutions, when exposed to the air, deposited an amorphous powder, insoluble in water, alcohol and ether, but capable of forming crystallisable salts with acids, while in solution there remained a strongly alkaline base, the oxide of plumbotriethyl, the radicle of which appeared to constitute the greater part of the product. This radicle, however, Löwig did not succeed in isolating.

Klippel prepares an alloy of lead and sodium, having nearly the composition Pb^2Na^2 , by melting 3 pts. of lead in a hessian crucible, and after removing it from the fire, adding 1 pt. sodium in small pieces still moistened with rock-oil, and stirring with an iron rod. Combination then takes place, attended with evolution of heat and inflammation of the rock-oil (the gases evolved by which protect the alloy from oxidation). When the action is completed, the crucible is filled with warm sand and left to cool slowly; the crystalline alloy is pulverised in a warm mortar, with addition of a small quantity of dry sand, then introduced into a number of small flasks and drenched with iodide of ethyl, and the flasks are immediately connected with a condensing tube, to prevent loss of iodide of ethyl, which distils over in consequence of the heat evolved by the violent action which immediately takes place. The iodide of ethyl is allowed to flow back into the flasks as long as any action goes on, and when it is completed the excess of iodide of ethyl is distilled off over the water-bath; the remaining liquid is poured out of the flasks into a dry glass cylinder and shaken up with ether, which dissolves the plumbotriethyl; and the ether is distilled off after addition of a little water: the plumbotriethyl then separates as an oil at the bottom of the water.

Plumbotriethyl is a yellowish mobile oil, of specific gravity 1.471 at 0° , insoluble in water, easily soluble in alcohol and ether. It volatilises undecomposed in small quantity with ether-vapour, but cannot be distilled alone. By the action of light, or by prolonged boiling with water, it decomposes, with separation of metallic lead (Klippel). When exposed to the air in ethereal solution, it is converted into oxide (Löwig), carbonate (Klippel). *Chlorine-water* decomposes it, with separation of chloride of lead. (Klippel.)

Bromide of plumbotriethyl, PbE^2Br , is obtained by adding an alcoholic solution of bromine to a solution of the sulphate in alcohol containing sulphuric acid, agitating the whole with ether, then with water to separate the ethereal solution, and evaporating the ether; it then crystallises in long needles. (Löwig.)

The *chloride*, PbE^2Cl , is obtained by adding chloride of barium to a solution of the sulphate in alcohol containing hydrochloric acid, agitating with ether, separating the ethereal solution by water, and leaving it to evaporate (Löwig); by neutralising

the oxide or carbonate with hydrochloric acid (Klippel); or by the action of hydrochloric acid gas on plumbotriethyl (Buckton, p. 563). It crystallises in beautiful long needles, having a high lustre, and giving off a strong odour of oil of mustard when gently heated. When heated in a glass tube, they detonate slightly, even at a moderate heat, yielding chloride of lead and metallic lead. (Löwig.)

The *chloromercurate*, $\text{PbE}^2\text{Cl.HgCl}^2$, separates from a hot alcoholic solution of the component salts in white nacreous scales; the *chloroplatinate*, $2\text{PbE}^2\text{Cl.PtCl}^4$, in copper-red crystals, sparingly soluble in water, more easily in alcohol and ether. (Klippel.)

The *cyanide*, $\text{C}^{\text{III}}\text{N}^{\text{I}}\text{Pb} = \text{PbE}^2\text{Cy}$, is obtained by heating cyanide of potassium with an alcoholic solution of chloride of plumbotriethyl, for a considerable time, in a sealed tube placed in a water-bath, mixing the resulting blood-red liquid with water, and recrystallising the resulting white precipitate from ether. It then separates in prismatic crystals, which, when heated in a tube, melt and decompose, with deflagration, separation of metallic lead, and evolution of inflammable vapours. (Klippel.)

The *iodide*, PbE^2I , formed by the action of iodine on plumbotriethyl (Klippel), or by the reaction of iodide of potassium and sulphate of plumbotriethyl (Löwig), is soluble in ether and very unstable, the ethereal solution quickly yielding a deposit of iodide of lead.—If the compound, while yet undecomposed, be distilled with water, iodide of lead separates immediately, and the water which passes over is accompanied by a colourless, mobile, very pungent liquid, no longer prone to spontaneous decomposition, and having nearly the composition $(\text{PbE}^2)^4\text{I}^2$. (Löwig.)

Oxide of plumbotriethyl is obtained in the hydrated state by adding a solution of nitrate of silver mixed with alcohol to the alcoholic solution of the mixed radicles as long as metallic silver is precipitated; filtering from the silver; agitating the resulting solution of nitrate of plumbotriethyl with alcoholic potash and afterwards with ether; adding a sufficient quantity of water to separate the ethereal solution of the oxide; and evaporating the ether in a retort. Hydrated oxide of plumbotriethyl then remains in the form of a thick oily liquid, which solidifies after a while in a crystalline mass, slippery to the touch, like hydrate of potassium (Löwig). It may also be prepared by gradually adding iodine to the ethereal solution of plumbotriethyl till the colour no longer disappears, and immediately agitating the liquid with moist oxide of silver. An alkaline solution is thus obtained which, on addition of water and removal of the alcohol and ether by distillation, deposits hydrate of plumbotriethyl as a nearly colourless thickish oil (Klippel). It is volatile, and forms white fumes when a rod moistened with hydrochloric acid is held over it. When heated, it gives off white vapours, which excite powerful sneezing—a property which also belongs to the radicle itself and many of its compounds. The hydrate dissolves sparingly in water, readily in alcohol and in ether; has a strong alkaline reaction, and a sharp, disagreeable, caustic taste (Löwig, Klippel); saponifies fats; precipitates the oxides of iron, copper and silver from their salts; also alumina and oxide of zinc, both of which it redissolves when added in excess. (Klippel.)

Oxygen-salts. The oxide unites readily with acids, forming crystallisable salts.

The *acetate*, *benzoate*, and *butyrate* form needle-shaped crystals, soluble in water, alcohol, and ether.

Carbonate, PbE^2CO^2 .—The hydrated oxide rapidly absorbs carbonic acid from the air, and by leaving the alcoholic solution to evaporate in the air, the carbonate is obtained in small hard crystals (Löwig); or it may be prepared by passing carbonic anhydride into the solution, and separated by addition of carbonate of ammonia, care being taken however to avoid an excess of the latter, which would give rise to the formation of an easily soluble double salt. Carbonate of plumbotriethyl has a strong burning taste, is nearly insoluble in water, sparingly soluble in alcohol and ether. Alcohol containing hydrochloric acid dissolves it with effervescence. (Löwig.)

Formate of plumbotriethyl resembles the acetate.

The *nitrate*, PbE^2NO^2 , is obtained by decomposing the alcoholic solution of the mixed plumbethyls (Löwig, p. 561), or the ethereal solution of pure plumbotriethyl (Klippel) with nitrate of silver. It remains on evaporation as a colourless, viscid liquid, which smells like butter, has a burning taste, and solidifies after a while to a crystalline unctuous mass. It is decomposed by heat, with slight detonation. It dissolves readily in alcohol and ether; the alcoholic solution when evaporated, deposits a small quantity of nitrate of lead. (Löwig.)

The neutral *oxalate* forms scaly laminar crystals, which when dried over oil of vitriol, contain $\text{C}^4(\text{PbE}^2)^2\text{O}^4.\text{H}^2\text{O}$. (Klippel.)

A *phosphate* $(\text{PbE}^2)^2\text{H}^2\text{PO}^4$, is obtained, by saturating the oxide or carbonate with phosphoric acid, in stellate groups of crystals which dissolve readily in water, alcohol, and ether, and are oxidised with vivid deflagration, when treated in the dry state with fuming nitric acid. (Klippel.)

Sulphate. $(\text{PbE}^2)\text{SO}^4$.—When sulphuric acid is added by drops to an alcoholic solution of the oxide, leaving the base in excess, a dazzling white crystalline precipitate of the sulphate is obtained, which must be washed with alcohol and afterwards with ether. The salt is nearly insoluble in water, absolute alcohol, and ether, but dissolves readily in alcohol mixed with sulphuric or hydrochloric acid. From the acid solution it crystallises in tolerably large, hard, shining octahedral crystals (Löwig). Klippel, by dissolving the carbonate in alcoholic sulphuric acid, obtained the sulphate in crystals like those of quartz. Buckton, by decomposing the chloride with sulphuric acid or sulphate of silver, obtained it in asbestiform needles.

The acid tartrate, $\text{C}^4\text{H}^2(\text{PbE}^2)\text{O}^4$ (at 100°), forms scaly laminar crystals.

Sulphide of plumbotriethyl is obtained by treating a solution of the oxide or a salt of plumbotriethyl, with sulphydric acid or sulphide of ammonium, as a white precipitate, which is nearly insoluble in water, alcohol, and ether, and blackens quickly with separation of sulphide of lead. (Klippel.)

The **sulphocyanate** is formed by heating an alcoholic solution of the chloride with recently precipitated sulphocyanate of silver to 100° in a sealed tube. It dissolves in water, alcohol, and ether, and crystallises from the ethereal solution in the same form as sulphocyanate of potassium. (Klippel.)

Plumbotetirethyl. $\text{Pb}^2\text{C}^2\text{H}^{10} = \text{Pb}(\text{C}^2\text{H}^5)^4$ or PbE^4 . *Diethylide of lead. Plumbodiethylide* (Buckton).—Produced by the action of zinc-ethyl on chloride of lead:

When dry chloride of lead is added to zinc-ethyl, decomposition takes place immediately, attended with separation of metallic lead, and slight rise of temperature; and on adding an excess of the lead-chloride, and warming gently for a few minutes, a clear liquid may be decanted, apparently consisting of several lead-radicles combined with zinc-ethyl, which cannot be completely removed by digestion with excess of lead-chloride, but may be expelled for the most part by distillation. The liquid remaining in the retort at 140° – 150° yields, when treated with water and hydrochloric acid, heavy colourless drops of a liquid, the greater part of which, consisting of plumbotetirethyl, distils over between 198° and 202° ; but the compound is most easily obtained in the pure state by distillation in a rarefied atmosphere. (Buckton.)

Plumbotetirethyl is a transparent colourless liquid of specific gravity 1.62. Under the ordinary pressure it boils with partial decomposition, at a few degrees above 200° , but under a pressure of 7.5 inches of mercury it boils without decomposition at 152° . When set on fire, it burns with pale-green-bordered flame, emitting a fume of lead-oxide. In a stream of hydrochloric acid gas, it is converted into chloride of plumbotriethyl, with evolution of hydride of ethyl:

Methyl-compounds.

Plumbotrimethyl. $\text{PbC}^3\text{H}^9 = \text{Pb}(\text{CH}^3)^3 = \text{PbMe}^3$.—This radicle has not yet been obtained in the free state, but its salts are produced, with evolution of hydride of methyl, by treating plumbotetramethyl with acids: e.g. with hydrochloric acid, the reaction being precisely similar to that which takes place in the case of the corresponding ethyl compound, as represented by the equation just given.

Chloride of plumbotrimethyl, PbMe^3Cl , thus obtained, separates from the solution on cooling in long needles very much like chloride of lead. If the boiling of the plumbotetramethyl with hydrochloric acid be too long continued, chloride of lead is apt to be formed.

Bromide of Plumbotrimethyl is somewhat more soluble than the chloride.

The *iodide*, PbMe^3I , is obtained by adding iodine to plumbotetramethyl till the colour becomes permanent (iodide of methyl being probably formed at the same time:

The product is a white solid mass, mixed with yellow iodide of lead, sparingly soluble in water, easily in alcohol, and crystallising in long colourless needles, which may be sublimed. By distillation with caustic potash, it yields the hydrate of plumbotrimethyl, as a strong basic oil, smelling like oil of mustard, and solidifying in prismatic needles. (Cahours.)

Plumbotetramethyl. $\text{PbC}^4\text{H}^{12} = \text{Pb}(\text{CH}^3)^4 = \text{PbMe}^4$.—Produced by the action of iodide of methyl on an alloy of 5 pts. lead and 1 pt. sodium, or, better, by treating chloride of lead with zinc-methyl. It is a colourless, mobile liquid, having a camphor-like odour, insoluble in water, but soluble in alcohol and ether. It boils at 160° , decomposes at a few degrees above that temperature, but may be distilled with-

out alteration in a gas which does not act upon it (Cahours). According to Buttlorow, however, it smells like strawberries or mould, not at all like camphor, boils at 100° ,* and when free from zinc-methyl, may be distilled without decomposition in contact with air; in a sealed tube containing chlorocarbonate of ethyl, it may be heated to 200° without decomposition. Its vapour-density, determined by Gay Lussac's method, is 9.66 at 115° , and 9.52 at 130° ; calculation = 9.25. It appears then that the compound is converted into a perfect gas at a temperature very little above its boiling point. (Buttlorow.)

Plumbotetramethyl, like the corresponding ethyl-compound, does not unite directly with oxygen, chlorine, or iodine, but is decomposed thereby, yielding compounds in which part of the methyl is replaced by the acting elements, but belonging to the same type as plumbotetramethyl itself; e.g. iodide of plumbotriethyl, $\text{Pb}(\text{CH}_3)_3\text{I}$, by the action of iodine. Treated with acids, it yields hydride of methyl and a salt of plumbotriethyl. (Cahours.)

LEAD-SOAPS. Lead-salts of the fat-acids. Common lead-plaster (p. 560) is a preparation of this kind.—Palmer in 1845 patented the preparation of a lead-soap for greasing the axles of railway carriages, &c. It is prepared by heating the impure oleic acid obtained from the manufacture of stearin-candles, and stirring litharge into it as long as the litharge is dissolved. Before use it is mixed with a certain quantity of oil or tallow.—A compound of lead-oxide with the acids of linseed-oil, prepared by decomposing the potash-soap of linseed-oil with solution of acetate of lead, serves, when dissolved in oil of turpentine, for printing on wall-paper, previous to gilding it with gold-leaf or Dutch metal, or dusting it with wool-shearings for the production of flock-patterns.

LEAD-SPEISS. The metallurgical name of certain products obtained in the working of lead-ores containing arsenic or antimony. The following table exhibits the composition of two lead-speisses analysed by Bodemann: *a*, from Clausthal; *b*, from Andreasberg, and another; *c*, by Ahrend from the Lower Harz:

	Pb	As	Sb	Cu	Ag	Fe	S	Co and Ni.
<i>a</i> .	68.2	.	30.3	trace	.	trace	1.5	
<i>b</i> .	90.5	0.1	1.3	0.3	0.1	2.6	5.0	
<i>c</i> .	26.1	13.0	5.2	44.5	0.1	5.5	2.8	2.3

LEAD-VITRIOL. Sulphate of lead (see SULPHATES).

LEAF-GREEN. See CHLOROPHYLL (i. 922).

LEAF-RED. See ERYTHROPHYLL (ii. 506).

LEAF-YELLOW. See XANTHOPHYLL.

LEATHER consists of the skins of animals prepared by a process, or rather series of processes, called tanning, by which they are preserved from putrefying while moist, and rendered soft and pliable when dry. The skins are first freed from epidermis, fatty matter and hairs, by steeping them in milk of lime, or in an acerecent infusion of barley- or rye-meal, or spent tan, which sets up a slow fermentation; by either of these modes of treatment, the epidermis and the cellular tissue in which the hairs are rooted, are disintegrated, so that the hair and epidermis can then be easily removed by scraping. The skins thus prepared are then steeped in an infusion of some substance capable of uniting with the true skin and converting it into leather. The materials used for this purpose are:

1. *Tannin* or *tannic acid*, in the process of tanning properly so called, which is applied chiefly to the stouter kinds of leather, made from the hides of oxen and horses. The true skin of animals is a gelatinous tissue (ii. 326) and gelatin unites with tannic acid, forming a tough insoluble substance possessing the properties of leather (ii. 765). Several substances are used by the tanner as sources of tannic acid; but the most valuable and most extensively used of all is oak-bark. The following substances are also used, sometimes alone, but more generally as additions to the oak-bark:—Sumach, from the bark of *Rhus cotinus* or *Rhus coriaria*; catechu, or *Terra Japonica*, chiefly from various species of *Acacia* (i. 816); dividivi, the crushed pods of *Cassipouia coriaria*; mimosa, from the bark and pods of various kinds of *Prosopis*, a genus of leguminous plants; valonia, the acorn of the great prickly-cupped oak (*Quercus Egilops*); and nut-galls.

2. *Alum* and *common salt*, in the process called *tawing*, which is applied chiefly to the lighter kinds of skin, namely these of sheep, goats, and calves.

* This boiling point differs from that of plumbotetramethyl (about 260°) by 90° , or 22.5° for a difference of CH_2 in the formulae, whereas the boiling point of plumbotetramethyl found by Cahours, viz. 100° , differs from 260 by only 40° , or by 10° for each difference of CH_2 in the formulae. Now on comparing the differences of boiling points in the corresponding methyl- and ethyl-compounds of phosphorus, arsenic, antimony, and tin, it is found that the difference always amounts to 20° or upwards for each molecule of CH_2 added to the compound. The boiling point of plumbotetramethyl found by Buttlorow is therefore more in accordance with analogy than that determined by Cahours.

3. *Oil*, for the preparation of chamois, shamoy, or wash-leather, which is prepared from the skins of the goat, doe, or chamois, and is a soft, spongy leather, capable of washing.

4. *Lime*, for parchment, which is prepared from calf or sheep skins, and for the stronger kinds, from asses' or pig's skin.

For the details of all these processes we must refer to *Ure's Dictionary of Arts, &c.* (ii. 674—686), and the *Handwörterbuch der Chemie* (iv. 792—810).

LECANORIC ACID. $C^6H^{10}O^7$? *Lecanorin*. *a-Orsellic acid*. (Schunck, *Ann. Ch. Pharm.* xli. 167; liv. 261; lxi. 72.—Rochleder and Heldt, *ibid.* lxviii. 1.—Stenhouse, *ibid.* lxviii. 61; lxx. 218.—Strecker, *ibid.* lxviii. 13.—Laurent and Gerhardt, *Ann. Ch. Phys.* [3], xxiv. 316.—Robiquet, *Ann. Ch. Phys.* xlii. 236; Gm. xii. 377.)—This substance, which was discovered by Schunck in 1842, is extracted from several lichens belonging to the genera *Lecanora* and *Variolaria*. The lichens, in the state of fine powder, are exhausted with ether in a percolator, and, on evaporating the ether, a residue is obtained which is to be washed with ether on a large funnel till it is colourless, then exhausted with water, and crystallised from alcohol (Schunck). Rochleder and Heldt exhaust the lichen (*Evernia prunastri*) with a mixture of ammonia and alcohol, dilute the alcohol with a third of its volume of water, and saturate with acetic acid. Lecanoric acid then separates in grey flocks, which are washed, dried at 100° , dissolved in a small quantity of boiling absolute alcohol, and purified by recrystallisation.

Stenhouse macerates the lichen (*Rocella tinctoria*) with water mixed with slaked lime, precipitates the filtered liquid with hydrochloric acid; washes and dries the gelatinous precipitate, and digests it, when nearly dry, with absolute alcohol, taking care not to boil the liquid, which, on cooling, deposits the acid in crystals.

Lecanoric acid crystallises in colourless stellate needles, sparingly soluble in cold water and in cold alcohol; moderately soluble in boiling alcohol, soluble in ether and in acetic acid. According to Schunck, 1 pt. of lecanoric acid requires for solution 2,500 pts. of boiling water, 150 pts. of alcohol of 80 per cent. at 15° ; 5.15 pts. of boiling alcohol, and 80 pts. ether at 15.6° . The solution reddens litmus. The crystallised acid does not lose weight at 100° .

Lecanoric acid gives by analysis 59.45 to 60.59 carbon, and 4.40 to 5.00 hydrogen, whence Stenhouse deduced the formula $C^6H^{10}O^7$, which Gerhardt altered to $C^6H^{10}O^7$ (60.37 per cent. C, 4.40 H, and 35.23). This latter formula readily explains the conversion of lecanoric into orsellic acid (*infra*).

Lecanoric acid yields by dry distillation, a viscid oil, together with orcin. It dissolves readily at ordinary temperatures in lime-water or baryta-water, and is precipitated therefrom by acids in the form of a jelly, and without alteration; but if the saturated solution be boiled, the lecanorate of barium or calcium changes into the much more soluble orsellinate. If the ebullition be prolonged, carbonate of barium or calcium is precipitated, and orcin remains in solution:

A solution of lecanoric acid in aqueous ammonia acquires by exposure to the air a fine purple colour, due to the formation of orcein. In contact with hypochlorite of calcium, lecanoric acid immediately assumes a red tint, quickly changing to brown and yellow. The acid heated with sulphuric acid, is gradually converted into orcin. Boiling nitric acid converts it into oxalic acid. Boiling acetic acid dissolves it readily, and deposits it in small needles on cooling. By boiling with alcohol, it is converted into orsellate of ethyl. The same change is produced by passing hydrochloric acid gas into a solution of lecanoric acid in absolute alcohol, saturated at the boiling heat.

The ammoniacal solution of lecanoric acid forms white precipitates with basic acetate of lead and nitrate of silver; but the silver precipitate is quickly reduced. The alcoholic solution gradually produces, with an alcoholic solution of acetate of copper, a light apple-green precipitate. It does not precipitate the alcoholic solutions of neutral acetate of lead, mercuric chloride, chloride of gold or nitrate of silver. A few drops of ferric chloride impart to it a deep purple colour.

The lecanorates gradually decompose, especially when heated, yielding orsellinic acid, and ultimately orcin. The barium-salt, $C^6H^{12}BaO$, is obtained by dissolving the acid in cold baryta-water, passing carbonic acid into the liquid, and treating the precipitate with alcohol, which dissolves the lecanorate of barium, and deposits it in small stellate needles. According to Stenhouse's analysis, it contains 49.27 per cent. C, 3.81 H, and 19.49 baryta; the formula requires 49.87 C, 3.37 H, and 19.73 baryta. The calcium-salt is a gelatinous precipitate, slightly soluble in water and alcohol, obtained by mixing an ammoniacal solution of the acid with chloride of calcium. The

lead-salt is precipitated, according to Rochleder and Heldt, on mixing the boiling alcoholic solutions of *lecanoric acid* and acetate of lead; the precipitate thus obtained probably consists for the most part of *orsellinate*.

LECANORIN. Syn. with *LECANORIC ACID*.

LECITHIN. Goble's *Matière visqueuse*. (Gobley, J. Pharm. [3] ix. 1, 83, 161; xi. 409; xii. 5; xvii. 401; xviii. 107; xix. 406; xxi. 241; xxx. 241; xxxiii. 161.)—The eggs and milt or soft roe of the carp and herring, the yolk of poultry-eggs, the brain of the domestic fowl, of man and of the sheep, venous blood, ox-bile, and the fat of the garden-snail, contain, together with cholesterin, olein and margarin, a viscous substance which is decomposed by boiling with acidulated water, yielding *cerebrin*; *oleic acid*, *margaric acid* and *phosphoglyceric acid* (ii. 891). Of these products, Gobley regards the *cerebrin* as adventitious, the other three as resulting from the decomposition of a non-soluble substance, *lecithin*. The portion of pig's bile soluble in alcohol and not precipitable by ether contains, besides cholesterin and ordinary fats, a phosphoretted fat corresponding with Gobley's *lecithin*, and resolvable by boiling with baryta-water into *phosphoglycerate* of barium and insoluble barium-salts (Strocker, Ann. Ch. Pharm. cxxiii. 356). A constituent of yolk of egg, resembling ear-wax, described by Kodweiss (Ann. Pharm. lix. 261), agrees also in properties with the substance described by Gobley.

When carps' eggs are exhausted with ether or boiling alcohol, and the solution is evaporated, there remains a reddish-yellow soft mass, which when redissolved in boiling alcohol, leaves a small quantity of oil, and separates again as a viscous mass on cooling. It may also be obtained in the same manner, but less pure, from yolk of egg (ii. 364).—When the comminuted and partially dried milt of the carp is shaken up with ether, the ether takes up the greater part of the viscous matter, and the rest may be obtained by repeated boiling with alcohol. On evaporating the alcoholic solution, transferring the viscous matter contained in the residue to ether by agitation therewith, and evaporating the ether, the viscous matter is obtained free from the salts taken up by the alcohol, which remain in the lower watery layer of liquid.

The viscous matter is colourless, or has merely a faint yellow or orange tint; it is soft, neutral, and has for the most part the odour of the material from which it has been prepared. It is frequently contaminated with earthy phosphates and albumin. It swells up when heated, chars without melting, gives off ammoniacal vapours, and leaves an acid carbonaceous residue containing phosphoric acid. When exposed to the air, it does not turn acid, and afterwards yields the same decomposition-products as that which has been prepared without exposure to the air. When shaken up with water, it forms an emulsion which does not become sour or exhibit the presence of *phosphoglyceric acid*, even after 12 hours' boiling, but on boiling it with water containing *sulphuric* or *hydrochloric acid*, *oleic* and *margaric acids* are formed, which rise to the surface as an oil, and *phosphoglyceric acid*, which remains dissolved in the water. Addition of alcohol accelerates this decomposition, which, in viscous matter from yolk of egg, takes place at the mere heat of the water-bath, but in that derived from other sources, not till after half an hour's actual boiling. The oxygen of the air has no influence on the decomposition. Besides the products above mentioned, there are obtained *cerebrin*, and sometimes also *cholesterin*, *olein* and *margarin*, which however are regarded by Gobley as accidental admixtures.—Aqueous *alkalis* and *alkaline carbonates* at the boiling heat produce the same decomposition as the mineral acids. When the viscous matter of yolk of egg is shaken up with water containing potash and heated in the water-bath, acetic acid separates *oleic* and *margaric acids* from it; with the viscous matter of the brain or from any other source, boiling with alcoholic potash is necessary to effect the decomposition. Carbonate of potassium also does not decompose the viscous matter merely at the heat of the water-bath, but only on actual boiling.—Six hours' boiling with *acetic* (lactic or tartaric) acid does not produce any decomposition, 12 hours' boiling only an imperfect decomposition of the viscous matter; but by 24 hours' boiling, it is completely decomposed, with formation of phosphoric acid and glycerine. (Gobley.)

From the emulsion formed by water, which froths like soap (Gobley), it is precipitated by common salt. (Kodweiss.)

The viscous matter dissolves sparingly in cold, easily in boiling alcohol; it is also soluble in ether. (Gobley.)

LECONTITE. This name is given by W. H. Taylor (Sill. Am. J. [2]. xxvi. 273) to an alkaline sulphate, found by Le Conte in the cavern of Las Piedras, near Comayagua in Honduras, and probably formed from the excrements of bats, which frequent the cavern in large numbers. The mineral, when freed from adhering organic matter, is colourless, permanent in the air, and has a saline, bitter taste. It forms prismatic crystals, which, according to Dana, are trimetric combinations,

$\alpha P : \alpha P_2 : \frac{1}{2} P_{\infty} : \alpha P_{\infty}$. Angle $\alpha P : \alpha P = 103^{\circ} 12'$; $\alpha P_2 : \alpha P_2 = 116^{\circ}$; $\frac{1}{2} P_{\infty} : \frac{1}{2} P_{\infty}$ over the principal axis = $127^{\circ} 30'$ to 128° . Hardness = 2 to 2.5. According to Taylor's analysis, it contains 12.94 per cent. $(NH_4)_2O$, 2.67 K_2O , 17.56 Na_2O , 44.97 SO_3 , 19.45 water, 2.30 organic residue, and a trace of phosphoric acid, agreeing with the formula $M'SO_4 \cdot H_2O$.

The form of this substance agrees essentially with that assigned by Mitscherlich (Pogg. Ann. lviii. 469) to the salt $\frac{NH_4}{Na} SO_4 \cdot 2H_2O$. (Jahresber. 1858, p. 729.)

LEDERERITE. A mineral from Cape Blomidon, Nova Scotia, having the form of gmelinite (ii. 924) and the same formula, but with only one-third the amount of water. Specific gravity = 2.169. Analysis by Hayes (Sill. Am. J. [2], xxv. 78): 49.47 per cent. SiO_2 , 21.48 Al_2O_3 , 11.48 CaO , 3.94 Na_2O , 0.14 FeO , 3.48 P_2O_5 , and 8.58 water (= 98.57).

LEDERITE. Syn. with SPHERE.

LEDITANNIC ACID. $C^{20}H^{30}O^{15}$? (E. Willigk, Ann. Ch. Pharm. lxxiv. 363.—Reichleder and Schwartz, *ibid.* 366.)—A variety of tannic acid, obtained from the leaves of the marsh wild rosemary (*Ledum palustre*). It is prepared by precipitating the alcoholic decoction of the leaves with water, after distilling off the alcohol; precipitating the filtrate with neutral acetate of lead; dissolving the precipitate in dilute acetic acid; filtering again, precipitating the filtrate at the boiling heat with basic acetate of lead; decomposing the precipitate under water with sulphydric acid; and evaporating the filtrate in a stream of carbonic anhydride (Reichleder and Schwartz). Leditannic acid then remains as a reddish inodorous powder, easily soluble in water and in alcohol. The aqueous solution is coloured dark-green by ferric chloride, and forms yellow precipitates with acetate of lead and stannic chloride.

LEDIXANTHIN. A yellow or red pulverulent substance, produced by boiling aqueous leditannic acid with sulphuric or hydrochloric acid. According to Willigk, it contains $C^7H^8O^4$, and is therefore produced from leditannic acid by elimination of water: $C^{20}H^{30}O^{15} - 3H_2O = 4C^7H^8O^4$. It dissolves easily in alkalis, and when dissolved in alcohol, forms a red-brown precipitate with an alcoholic solution of neutral acetate of lead. By dry distillation, it yields an oil and crystals of pyrocatechin. (Willigk.)

LEDUM, OIL OF. The statements of different observers respecting this oil, which is obtained by distilling the leaves of *Ledum palustre*, or the entire plant at flowering time, with water, exhibit considerable diversities. According to Willigk (Wien. Akad. Ber. ix. 302), it consists for the most part of a hydrocarbon isomeric with oil of turpentine, and of an oxygenated oil, $C^{20}H^{28}O^2$. According to Grassmann (Report. Pharm. xxxviii. 53), it consists of 1 pt. volatile oil and 2 pts. camphor or steareptene, which may be separated by slow distillation, the volatile oil passing over first. The camphor forms colourless, slender, transparent prisms, which melt at a gentle heat, and sublime at a stronger heat, diffusing a pungent odour, which produces head-ache and giddiness. The camphor consists, according to Buchner (J. Pharm. [3] xxix. 318), of a hydrocarbon isomeric with oil of turpentine, and a hydrate of that hydrocarbon, $C^{20}H^{28}O^2 = 5C^{10}H^{14}.3H_2O$. It is nearly insoluble in water, dissolves easily in hydrochloric acid, less in acetic acid, and is quite insoluble in aqueous ammonia, but dissolves readily in alcohol and ether. (Buchner.)

According to A. Fröhde (J. pr. Chem. lxxxii. 181), the oil obtained from the plant by distillation is reddish-yellow, has an acid reaction, smells like the flowering plant, is slightly soluble in water, easily in alcohol and ether, and does not deposit any solid camphor, even when cooled to a very low temperature. When heated with strong potash-ley, it gives up to the alkali, besides small quantities of acetic, butyric, and valerician acids, an oily acid, having the penetrative odour of the plant, and consisting probably of $C^7H^8O^4$, a formula closely related to that of ericinone, $C^7H^8O^3$ (ii. 600), which substance likewise exists in the plant. The portion of the oil which does not unite with potash, yields, by rectification in a stream of hydrogen, a portion boiling at 160° , and isomeric with oil of turpentine, while between 240° and 242° an oxygenated oil passes over, having the composition of ericinol, $C^7H^{10}O$.

LEEDSITE. A mineral found near Leeds in Yorkshire, containing, according to Thomson's analysis, 71.9 per cent. sulphate of calcium and 28.1 sulphate of barium. It appears to be merely a mechanical mixture of the two. (Dana, ii. 607.)

LEEK. The bulbs of this plant yield 0.46, the stems 0.84 per cent. ash, containing, according to T. Richardson (Ann. Ch. Pharm. lxxvii, Appendix to Part 3):

Vol. III,

O O

	K ₂ O	Na ₂ O	CaO	MgO	SO ₃	SiO ₂	P ₂ O ₅	Ferric phosphate	NaCl	
Bulb .	32.35	8.04	12.66	2.70	8.34	3.04	15.09	13.29	4.49	= 100.00
Stem .	13.98	14.43	25.10	trace	16.50	19.77	..	10.06	trace	= 99.84

LEELITE. Syn. with **HELLEFLINTA** (p. 141).

LEGUMIN, or *Vegetable Casein*, was discovered by Einhof in 1806, and was called by him *végéto-animale* (N. allgem. J. d. Ch. v. A. Gehlen, vi. 126, 548). He found it in peas, beans, and lentils. A similar nitrogenised substance, extracted from sweet and bitter almonds and termed *amandin*, has been investigated by Proust, H. Vogel, Boullay, and others, who considered the substance in question to be identical with animal casein. Braconnot, and afterwards Liebig, have arrived at the same result; they find, indeed, that legumin and casein are perfectly identical in composition and properties. Dumas and Cahours on the other hand, always obtained a substance containing less carbon and more nitrogen than casein, and possessing somewhat different properties. Their analyses agree very closely with one another, but it is highly probable that the substance analysed contained some foreign body, perhaps arising from the partial decomposition of legumin. It is also not unlikely that legumin prepared by the ordinary methods is not a homogeneous substance.

Preparation.—Dumas and Cahours employ the following method for the preparation of legumin, the most advantageous source of which are peas or sweet almonds:—The bruised substance is digested for two or three hours with tepid water; the product is then crushed in a mortar so as to form a pulp; and to this is added about its own weight of cold water. After the whole has been macerated for an hour, it is thrown on a cloth and pressed, and the liquid portion on standing deposits a certain quantity of starch. The solution is now clarified by filtration, and acetic acid, diluted with 8 or 10 times its weight of water, is gradually added. Immediately on the addition of the acid, a perfectly white flocculent precipitate is formed, which may be easily collected on a filter and washed with water. Care must be taken to avoid an excess of acetic acid, in which legumin is readily soluble. The legumin is then washed with alcohol, dried, pulverised, and digested with ether, which removes all fatty matters. The product is again dried in vacuo at 140° (Gerhardt, *Traité*, iv. 491). Haricot-beans cannot well be substituted for the above substance, since they contain a gummy matter which renders the filtration and washing exceedingly tedious. According to Löwenberg, the product, obtained as above, is a mixture of legumin and albumin, and after it has been washed with boiling water, contains a decomposition-product of legumin, mixed with albumin. The separation of these two substances may be effected by dissolving the mixture in ammonia, evaporating off the excess of ammonia, adding chloride of sodium, boiling, filtering, and precipitating the filtrate with acetic acid. The precipitate is washed first with cold water, then with boiling alcohol and ether. The infusion of peas and almonds also contains a third body, which is precipitated by acetic acid; it is insoluble in excess of the acid, but soluble in pure water. The ammoniacal solution is partly precipitated by boiling with chloride of sodium after evaporating the excess of alkali.

Rochleder purifies legumin, prepared by the first method, by treating it with concentrated potash, which readily dissolves the legumin, and leaves a flocculent residue of another substance. The solution is allowed to stand, decanted, then filtered and precipitated by acetic acid. The well-washed precipitate is dissolved in ammonia, filtered again, and reprecipitated by acetic acid.

Properties.—The solution of legumin does not coagulate by ebullition; but when evaporated, becomes covered with a pellicle, like milk (Liebig). Purified legumin is insoluble in cold water; with boiling water it yields a product richer in carbon, soluble in water and insoluble in acetic acid, together with a less carbonised body, insoluble in water (Löwenberg). The body analysed by Dumas and Cahours had the following properties:—When precipitated from a concentrated solution by weak acetic acid, it always presented a nacreous and iridescent appearance; from a weak solution it is deposited in flakes. It is insoluble in cold alcohol and ether; also in boiling water and in weak boiling alcohol. It dissolves largely, however, in cold water, and when the liquid is heated almost to boiling, it coagulates, and gives a precipitate of cohering flakes very like coagulated albumin (Gerh. iv. 493). Gerhardt thinks that Liebig may have experimented with the aqueous extract of legumin obtained directly from peas, &c., which probably contains that substance in combination with alkali, forming an incoagulable solution like the alkaline albuminates. The fresh aqueous extract of the fruit of the leguminosæ is always neutral; the legumin precipitated therefrom by an acid always reddens litmus, even after prolonged washing. When this solution is left to itself, it coagulates in 24 hours, at a temperature of 15 or 20° C., yielding a gelatinous precipitate like the coagulum of milk. The mother-liquor is decidedly acid, and appears to contain lactic acid. (Liebig.)

In the following analyses the ash is deducted:—

	Dumas and Cahours.* <i>Lentils. Sweet almonds.</i>		Rochleder.† <i>Haricots.</i>			Killing.‡ <i>Peas.</i>	Löwenberg.‡ <i>Peas.</i>
Carbon	50.46	50.93	54.0	54.3	53.9	50.68	53.9
Hydrogen	6.65	6.70	7.5	7.4	7.3	6.74	7.2
Nitrogen	18.19	18.77	14.7	14.6	15.0	16.50	•
Sulphur						0.48	0.3
Oxygen							

Purified legumin sometimes contains as much as 7.1 per cent. ash (Rochleder). The ash is perfectly white, has an alkaline reaction, and contains a large quantity of potash, partly in combination with phosphoric acid. The insoluble portion of the ash is composed of phosphate of calcium and magnesium, as well as a little phosphate of iron. (Liebig.)

Völeker (Rep. Brit. Assoc. 1857, p. 60; J. p. Chem. lxxv. 320) found in legumin prepared from peas and beans, the following percentage of ash, phosphorus, and sulphur:

	Legumin.	Ash.	Phosphorus.	Sulphur.
From green peas		1.100	1.383	0.870
The same, precipitated with a small quantity of acetic acid			1.880	0.571
The same, precipitated with excess of acetic acid			2.180	0.851
From white peas		1.45	1.520	
From white French beans		0.71	1.780	0.590

Norton (Pharm. Centr. 1847, p. 466; 1848, p. 240) also found in legumin prepared from peas, sweet almonds, and oats, from 0.8 to 2.3 per cent. phosphorus. The large amount of phosphorus found by Völeker and Norton renders it probable that legumin contains, or is associated with, a compound of phosphoric acid, perhaps phosphoglyceric acid.

Decompositions.—When legumin is subjected to dry distillation, it swells, yields a yellowish distillate containing carbonate, sulphide, and acetate of ammonium, and leaves a residue of shining charcoal. (Braconnot.)

Legumin distilled with *acid chromate of potassium* and *dilute sulphuric acid* yields an acid liquid which smells of prussic acid and bitter almond oil, contains a considerable quantity of prussic acid, with a small quantity of formic acid, but does not give the reactions of the aldehydes with potash or with nitrate of silver. When rectified over mercuric oxide, the first portion of the distillate exhibited a more aromatic and ethereal odour than the original liquid; the second portion, which was covered with a thin layer of oil, contained benzoic acid (4 pts. to 1,000 of legumin) valericianic, butyric, propionic, acetic, caproic, and probably also caprylic acid (Fröhde, J. pr. Chem. lxxvii. 290). In a second series of experiments, Fröhde found among the products of oxidation of legumin, valerionitrile, acetonitrile (not distinctly recognised), and a third nitrile, probably propionitrile.

All *acids* coagulate the solution of legumin; the precipitates redissolve in excess of the acid.

When legumin is boiled with *dilute sulphuric acid*, leucine is formed. Dry legumin saturated with *concentrated sulphuric acid* dissolves slowly and forms a brown solution, but no glycocine is produced.

Concentrated *nitric acid* dissolves dry legumin, with evolution of nitrous fumes. Dilute *hydrochloric acid* precipitates legumin like acetic acid. The concentrated acid dissolves it with the characteristic blue tint.

When gelatinous legumin is placed in contact with concentrated *acetic acid* it absorbs the acid, and swells, becoming semitransparent. The product is completely soluble in boiling water. A gummy residue of legumin, soluble in water, is obtained on evaporation. A solution of legumin is immediately precipitated by dilute acetic acid, and the precipitate is redissolved by an excess of the acid, forming a perfectly clear solution. This is reprecipitated by adding ammonia; the precipitate dissolves in an excess of the acid (Dumas and Cahours). Liebig found legumin insoluble in weak acetic acid; Löwenberg's legumin, which is insoluble in water, dissolves in an excess of acetic acid.

Solution of legumin is precipitated by tribasic *phosphoric acid*, also by *oxalic, tartaric, malic, and citric acids*; the precipitates are readily soluble in excess of acid. Legumin is dissolved in the cold by *potash, soda, and ammonia*. Heated with fixed alkali, it evolves ammonia, and sulphide of ammonium is formed in the solution.

* The carbon and nitrogen in the other analyses of MM. Dumas and Cahours fall between these two analyses.

† Previously purified by Rochleder's method.

‡ The substance was redissolved in ammonia, precipitated by acetic acid, and exhausted by boiling alcohol and ether.

§ Purified by Löwenberg's process.

Baryta and *lime* form insoluble-compounds with legumin, as with casein. Like casein, solution of legumin precipitates many earthy and metallic salts, but does not precipitate sulphate of magnesium, or the acetate, or other salts of calcium in the cold; on applying a slight heat, the liquid rapidly coagulates. Braconnot attributes the hardening of vegetables cooked in selenitic waters to the formation of these lime-compounds.

A concentrated solution of legumin, to which rennet has been added, does not begin to coagulate for several hours; after 24 hours all the legumin is precipitated. The coagulation does not appear from this to be due to the free acid contained in the rennet (Dumas and Cahours). Putrefying legumin acts as a powerful ferment.

Dry beans, peas, lentils, &c., contain, on an average, about 25 per cent. of nitrogenised matter (legumin, albumin, &c.), and are the most nutritive of vegetables. At the same time, they are deficient in starch and fat. They are not generally a very wholesome food in large quantity, except for men enjoying robust health and engaged in severe labour. Legumin appears to be much more indigestible than insoluble casein, as casein is far more indigestible than the fibrin of meat.

C. E. L.

LEHMANNITE. Native chromate of lead (i. 934).

LEHRBACHITE. Selenide of mercury and lead from Tilkerode, near Lehrbach; probably a mechanical mixture of the two selenides, inasmuch as specimens from different parts of the same vein exhibits very different proportions of lead and mercury (see p. 558).

LEHUNITE. Syn. with NATROLITE.

LEIDENFROST'S PHENOMENON. This term is sometimes applied to the spheroidal state of liquids (p. 88), first observed by Leidenfrost.

LEMNA. *Duckweed*.—Plants of this genus are very rich in inorganic substances, and have accordingly been recommended for use as manure. In a specimen of *Lemna minor* growing in the river Eure, in France, Hervé Mangon (Institut. 1861, p. 107) found:

Combustible matter (without nitrogen).	Nitrogen.	Silica.	Lime.	Phosphoric acid.	Other mineral constituents.
61.1	3.6	6.7	8.2	1.1	19.3 = 100

Liebig (Ann. Ch. Pharm. cv. 109) obtained from *Lemna trisulca* growing in a marsh, 16.6 per cent. ash, and from a litre of the surrounding water 0.415 grm. of saline residue. 100 pts. of the slightly ignited plant-ash, *a*, and of the saline residue of the water, *b*, contained:

CaO	MgO	NaCl	KCl	K ² O	Na ² O	Fe ² O ³	P ² O ⁵	SO ³	SiO ²
<i>a</i> . 16.82	5.08	5.90	1.45	13.16	•	7.36	8.73	6.09	12.85
<i>b</i> . 35.00	12.26	10.10	•	3.97	0.47	0.72	2.62	8.27	3.34

LEMNIAN EARTH. *Sphragide*.—The *Ἀμυλία σφραγίς* of the Greeks. A yellowish-grey earth or clay frequently marbled with rusty spots. Dull. Fracture fine earthy. Meagre to the touch. Adheres slightly to the tongue. When plunged in water it falls to pieces, with disengagement of air-bubbles. Its constituents are, 66 silica, 14.5 alumina, 0.25 magnesia, 0.25 lime, 3.5 soda, 6 oxide of iron, 8.5 water (Klaproth). It has hitherto been found only in the Island of Stalimene (ancient Lemnos). It is reckoned a medicine in Turkey; and is dug up only once a year, with religious solemnities, cut into spindle-shaped pieces, and stamped with a seal. In ancient times it was esteemed an antidote to poison and the plague. U.

LEMON. See CITRUS (i. 1003).

LENTIL. *Ervum Lens*. The air-dried seed of this leguminous plant contains, according to Krocken (Ann. Ch. Pharm. lviii. 224), from 34 to 35 per cent. starch. Horsford (*ibid.* 199) found in 100 pts. of the seed, 30.4 pts. of non-azotised matter, to 2.6 ash and 13.0 water.

Poggiale (J. Pharm. [3]. xxx. 180, 255), and Fresenius found in 100 pts. of air-dried lentils, the following constituents:

Starch.	Gum.	Sugar.	Legumin.	Fat.	Cellulose, Pectin, &c.	Ash.	Water.	
44	•	•	29.0	1.5	7.7	2.4	15.4	Poggiale.
35.6	7.0	1.5	25.0	2.5	12.0	2.3	14.0	Fresenius.

Levi found in lentil-seeds from Worms 2.06 per cent. ash of the composition given below.

The straw of lentils contains 0.01 per cent. nitrogen (Boussingault); the air-dried straw contains 27 per cent. water and 34 per cent. substances soluble in dilute alkaline ley, 57 per cent. woody fibre, and 3.9 per cent. ash, having the following composition:

* With traces of alumina.

Composition of Lenzin-ash.

	Seed.	Straw.		Seed.	Straw.
Potash	34.6	10.8	Silica	1.3	17.6
Soda	9.5		Phosphoric acid	36.2	12.3
Lime	6.3	52.3	Sulphuric acid		1.0
Oxide of manganese	2.5	3.0	Chloride of sodium	7.6	2.1
Ferric oxide	2.0	0.9			

According to Schwarz, a hectare of ground yields about 1,360 kilogrammes of seed and 3,700 kilogrammes of straw; the former, therefore, containing 30, the latter 144, and the whole, 174 kilogrammes of mineral constituents (Handb. d. Chem. ii. [3] 832).

LENZINITE. A variety of kaolin from the pegmatite of La Vilate near Chanteloupe (Haute Vienne), of a clear brown colour, tender, but not plastic. Before the blowpipe it becomes reddish, but does not fuse. It is decomposed by hot sulphuric acid. Contains, according to Salvétat (Ann. Ch. Phys. [3] **xxi.** 102), 36.36 per cent. silica, 36.00 alumina, 1.95 ferric oxide, and 21.50 water (agreeing nearly with the formula $2\text{AlPO}_3 \cdot 3\text{SiO}_2 \cdot 3\text{H}_2\text{O}$), besides 0.18 magnesia, 0.50 alkalis, 2.0 gelatinous silica, and 1.64 quartz (= 101.62).

LEONHARDITE. A hydrated silicate of calcium and aluminium, occurring at Schemnitz in Hungary, and at Copper Falls, Lake Superior, in monoclinic crystals, in which $\alpha\text{P} : \infty\text{P} = 83^\circ 30'$ and $96^\circ 30'$; $\alpha\text{P} : \infty\text{P} = 114^\circ$. Cleavage parallel to αP , very perfect; basal imperfect. Also columnar and granular. Hardness = 3 to 3.5. Specific gravity = 2.25. Lustre on cleavage-faces pearly; elsewhere vitreous. Colour white, sometimes yellowish, seldom brownish. Subtranslucent. It usually whitens on exposure, like laumontite; but the variety from Lake Superior does not. Before the blowpipe it exfoliates, froths, and easily melts to an enamel. It dissolves in acids.

Leonhardite from Schemnitz has been analysed by Delffs and v. Babo (Pogg. Ann. **lix.** 336, 339), that from Copper Falls by Barnes (Sill. Am. J. [2] **xv.** 440):

	Schemnitz.	Copper Falls.
Silica	54.92	55.00
Alumina	22.49	21.36
Lime	9.05	10.50
Water	13.54	12.30
	100.00	102.16
		99.68

The analyses do not agree well together. The first analysis of the Hungarian mineral agrees approximately with the formula $(3\text{CaO} \cdot 4\text{SiO}_2) \cdot 4(\text{AlPO}_3 \cdot 3\text{SiO}_2) + 15\text{H}_2\text{O}$, which, however, is improbable; that of the American mineral may be represented by the much simpler formula $(\text{CaO} \cdot \text{SiO}_2) \cdot (\text{AlPO}_3 \cdot 3\text{SiO}_2) + 3\text{H}_2\text{O}$, or $2\text{CaAl}^2\text{Si}_2\text{O}_7 \cdot 3\text{H}_2\text{O}$, which is that of a metasilicate, and differs from the formula of laumontite (p. 472) only in the amount of water. According to Brooke and Miller, leonhardite agrees in form also with laumontite. Delffs found in the mineral 13.55 to 13.81 per cent. water; it gave off 11.64 per cent. at 100° . According to Kenngott, leonhardite is identical with caporicianite. (Dana, ii. 308; Rammelsberg, *Mineralchemie*, p. 800.)

LEOPARDITE. A spotted felspathic rock, occurring at Charlotta, Mecklenburgh County, and in the Steele Mine, Montgomery County, North Carolina, and recognised by Genth (Sill. Am. J. [2] **xxxiii.** 197), as a true porphyry, spotted with iron- and manganese-compounds. The crypto-crystalline felspathic base is interspersed with small crystals of orthoclase and quartz. Analysis gave:

SiO_2	Al_2O_3	Fe_2O_3	MgO	CaO	Na_2O	K_2O	Loss by ignition.
75.92	14.47	0.88	0.09	0.02	4.98	4.01	0.64 = 100.00

agreeing very nearly with the composition of Bunsen's normal trachytic substance.

LEPAMINE. A volatile base containing the elements of 1 at. diamylamine and 1 at. lepidine; $\text{C}^m\text{H}^{2m}\text{N} \cdot \text{C}^n\text{H}^n\text{N} = \text{C}^{2m+n}\text{H}^{2m+n}\text{N}_2$, produced by the action of iodide of amyl on lepidine (p. 673).

LEPARGYLIC ACID. Syn. with Anchoic Acid (i. 289). Arppe has lately shown (Ann. Ch. Pharm. **cxiv.** 86) that Laurent's *Azoëic acid* (i. 477) has the same composition as lepargylic or anchoic acid: it appears, however, to differ so much from the latter in melting point, solubility, and the properties of some of its salts, that the two acids can scarcely be regarded as identical (which is Arppe's view), but only as isomeric.

Azelaic acid is most easily obtained by heating castor-oil with 2 pts. of nitric acid,

of specific gravity 1.2—1.3, added by small portions, continuing the operation for 12 hours, then separating the acid liquid from the remaining oil, adding fresh acid, and continuing the oxidation for another day. The acid liquid is then to be separated from the oil and added to the former portion, the whole evaporated, with addition of water, and freed from oil, which then separates, by means of a tap-funnel. The clear acid solution duly concentrated yields a white granular mass, which, when freed from oxalic acid by washing with cold and recrystallisation from warm water, and from other more soluble acids by melting the crystals, pulverising the fused mass, and treating the powder with water, leaves a mixture of azelaic and suberic acids; and on treating this residue with cold ether, the azelaic acid is dissolved, while the suberic acid remains behind. The ethereal solution is evaporated, the residue is dissolved in hot water, and the solution, freed from any oil that may still remain, is evaporated to the crystallising point.—Azelaic acid is also obtained in a similar manner, together with several other acids, from almond-oil, spermaceti, and oleic acid (Arppe, *Ann. Ch. Pharm.* **cxix.** 288; *Jahresber.* 1861, p. 357).

Azelaic acid, prepared as above, has the composition $C^8H^{10}O^4$. It crystallises on cooling from a moderately concentrated aqueous solution, sometimes in large laminae, sometimes in long flattened needles several inches long; the crystals are transparent and colourless, with vitreous lustre, but of no determinate form. From a very dilute solution, it separates in smaller laminae, which under the microscope exhibit several forms, viz. oblique rhombic prisms with acute angles of about 22° , square tables, and thin flattened prisms. It dissolves in 700 pts. water at 15° (lepargylic or anchoic acid, according to Buckton, in 217.4 pts. at 18°); it is more soluble in ether, and still more in alcohol. It melts at 106° (lepargylic acid at 114 — 116° , Buckton; partially at 115° , completely at 124° , Wirz); and volatilises with partial decomposition at higher temperatures; the vapours excite coughing, but not so strongly as succinic acid. Heated with caustic baryta, it is resolved into carbonic anhydride and hydride of heptyl, C^7H^{14} , together with small quantities of other hydrocarbons; $C^8H^{10}O^4 = 2CO^2 + C^7H^{14}$. (R. S. Dale, *Chem. Soc. J.* xvii. 261.)

The azelaates of the alkali- and alkaline-earth-metals are soluble in water, the calcium-salt being the least soluble; those of the heavy metals are insoluble. They are all decomposed by dilute nitric acid, with separation of crystalline azelaic acid. The neutral salts form with chloride of calcium a copious crystalline precipitate, with ferric chloride a brick-red, and with cupric sulphate a blue-green precipitate.

Barium-salts.—The acid salt, $C^8H^{10}Ba^2O^4$, is obtained by neutralising a hot solution of the acid with carbonate of barium. [Buckton did not succeed in preparing an acid anchoate of barium.]—A warm concentrated solution of the acid neutralised with hydrate of barium yields a granular precipitate of the salt $2C^8H^{10}Ba^2O^4.C^8H^{10}Ba^2O^4$, which may be crystallised from water, but when washed with hot water is converted into the neutral salt, $C^8H^{10}Ba^2O^4$.

The calcium-salt, $C^8H^{10}Ca^2O^4$, is very sparingly soluble. The copper-salt, $C^8H^{10}Cu^2O^4$, is a blue-green precipitate; the lead-salt, $C^8H^{10}Pb^2O^4$, a white precipitate. The magnesium-salt, $C^8H^{10}Mg^2O^4.3H^2O$, is efflorescent, and separates from solution in warm water by evaporation in crystalline crusts. The manganese-salt, $C^8H^{10}Mn^2O^4$, is a white fusible precipitate; the nickel-salt, an apple-green crystalline precipitate; the silver-salt, $C^8H^{10}Ag^2O^4$, a white powder.—The strontium-salt, $C^8H^{10}Sr^2O^4.2H^2O$, separates by evaporation from its warm aqueous solution in crystalline crusts, which when dried in the exsiccator, give off half their water, leaving granular crystals containing $C^8H^{10}Sr^2O^4.H^2O$. (Arppe.)

LEPIDINE. C^8H^8N . (Gr. Williams, *Edinb. Phil. Trans.* **xxi.** [3] 377; *Gm.* **xiv.** 103.)—A volatile organic base homologous with chinoline, and obtained, together with that base, and several others of the series, by distilling quinine or cinchonine with water and hydrate of potassium (i. 809). The bases are first separated by fractional distillation,—the portion which distils above 199° , especially that between 216° and 243° , consisting of chinoline and lepidine, the latter being found chiefly in the portion boiling above 270° ,—and the separation is completed by fractional crystallisation of their platinum-salts.

A base isomeric, and originally supposed to be identical, with lepidine is contained in coal-tar oil, and may be separated by collecting and rectifying the portion which distils between 250° and 267° , and completing the purification by fractional crystallisation of the platinum-salt as above. This base, now called iridoline, is distinguished from lepidine by its lower boiling point, by certain differences in the characters of its salts, some of which crystallise less easily than the corresponding salts of lepidine, and in particular by the reaction of its amyl-derivative with ammonia (p. 573).

Lepidine is an oily base resembling chinoline, of specific gravity 1.072 at 15° , boiling at 266° and 271° (iridoline boils between 252° and 257°). Vapour-density, $d = 5.14$, calc. = 4.96.

Both lepidine and iridoline form crystallisable salts; the iridoline-salts smell of naphthalene. The hydrochlorates of both bases, $C^{10}H^{11}N.HCl$, form small colourless needles, which do not melt at 100° . They form, with chloride of cadmium, crystalline double salts containing $C^{10}H^{11}N.HCl.CdCl_2$; and with tetrachloride of platinum, the salt $2(C^{10}H^{11}N.HCl).PtCl_4$, which is insoluble in alcohol. The platinum-salt of iridoline crystallises less readily than that of lepidine.

Acid chromate of lepidine, $2\text{C}^{18}\text{H}^{16}\text{N}^{10}\cdot\text{H}^{12}\text{O}\cdot2\text{CrO}_3$, crystallises in long golden-yellow needles which decompose at 100° when moist, but not when dry, and leave chromic oxide when ignited.—*Acid chromate of iridoline* is an oily compound which does not crystallise.

Amyl-lepidine. $C^{15}H^{19}N = N \begin{cases} C^8H^{11} \\ C^{10}H^7 \\ H \end{cases}$.—The hydriodate of this base, or iodide of

$$2\text{C}^{15}\text{H}^{20}\text{NI} + \text{KHO} = \text{C}^{20}\text{H}^{30}\text{N}_2\text{I} + \text{KI} + \text{H}_2\text{O}.$$

Iodide of amyl- Iodide of
leucidal-ammontum. pelamine.

Diamyline-lepidine or Lepamine. $\text{C}^{10}\text{H}^{12}\text{N}^2 = \text{C}^{10}\text{H}^{12}\text{N}.\text{C}^{10}\text{H}^9\text{N}$, or perhaps $\text{C}^9\text{H}^{11}\text{N}^2$. (Gr. Williams, Chem. Soc. J. xvi. 375.)—When lepidine is cohobed

Hydrochlorate of Iepamine, $C^{10}H^{17}N$, $2HCl$, melts below 100° , is sparingly soluble in water, and must be dried in a vacuum before being heated over the water-bath.

Chloroplatinate.—On adding an excess of strong hydrochloric acid to a solution of the base, so as to obtain the hydrochlorate as an oil floating on the surface, and then a considerable excess of tetrachloride of platinum, an adhesive yellow mass is formed, which may be washed by agitation with cold water, dried over oil of vitriol for a day or two and then over the water-bath. It is perfectly soluble in alcohol, and has the composition, $2(\text{C}^{10}\text{H}^{17}\text{N}^{12}) \cdot 2\text{HCl} \cdot \text{PtCl}_4$.

Gold-salt.—On adding trichloride of gold to a solution of the hydrochlorate, a chocolate-coloured precipitate is formed, which quickly changes to bright green salt is soluble in alcohol, forming a green solution.

Lepamine dissolved in strong *nitric acid* yields a red solution, from which on dilution, a red oil separates, probably a nitro-compound.

By heating lepamine with *i*odide of ethyl in a sealed tube, a syrupy liquid is obtained which when distilled with potash, yields a volatile oily base, probably *le*pamine.

It dissolves readily in hydrochloric acid, forming a salt which is much more difficult to crystallise than hydrochlorate of lepamine.

Ethyl-lepidine. $C^{12}H^{11}N = C^{10}H^8(C^2H^3)N$.—The hydriodate of this base, or iodide of ethyl-lepidyl-ammonium, $[(C^2H^3)(C^{10}H^7)H^2]NI$, is obtained by heating lepidine with iodide of ethyl, in brown needles, which after recrystallisation, exhibit a beautiful canary-yellow colour, becoming transiently blood-red at 100° . Treated with moist oxide of silver, it yields the corresponding hydrate, which when treated with hydrochloric acid and tetrachloride of platinum, yields the platinum-salt, $2C^{12}H^{11}NCl$. $PtCl^4$, soft at first, but soon becoming crystalline.

Methyl-lepidine. $C^{11}H^{11}N = C^{10}H^8(CH^3)N$.—The hydriodate, or iodide of methyl-lepidyl-ammonium, $C^{11}H^{12}NI$, is obtained in crystals by heating lepidine with iodide of methyl.

LEPIDOCROCITE. *Needle Iron ore.*—A hydrated ferric oxide of the same composition as göthite, $Fe_2O_3 \cdot H_2O$ (ii. 940), occurring at Spring Mills, Montgomery County, Pennsylvania, in minute radiating crystals or granular scales, and feathery aggregations, imbedded in fibrous red oxide of iron, and in nodules of chalcodony.

LEPIDOLITE. Lithia-mica, found at Rogena and Iglau in Moravia, in the island of Utön, Sweden, and in other localities. (See Mica.)

LEPIDOMELANE. A variety of mica, so called from its scaly structure and black colour (*λεπίς* and *μέλας*), consisting, according to Soltmann's analysis (Pogg. Ann. l. 664) of 37.40 silica, 11.60 alumina, 27.66 ferric oxide, 12.43 ferrous oxide, 9.20 potash, 0.26 lime and magnesia, and 0.60 water, corresponding with the formula $(FeO; K_2O).(Al_2O_3; Fe_2O_3).2SiO_2$, which is reducible to that of an orthosilicate, $M^{1'}R^{1''}\}SiO^4$.

The mineral forms crude masses of granular scaly structure, consisting of small scales, sometimes exhibiting the form of six-sided tables; according to Wöhler, it is completely decomposed by hot hydrochloric or nitric acid, the silica separating in crystalline scales like those of the mineral. It is found only in one locality in Sweden, probably at Persberg, Wermland.

LEPOLITE. See ANORTHITE (i. 303).

LEPTYNITE. *Granulite* or *Eurite*. A granular compound of felspar with quartz, sometimes containing garnet.

LEUCANILINE. $C^{20}H^{21}N^3$. (A. W. Hofmann, Proc. Roy. Soc. xii. 2; Jahresber. 1862, p. 34.)—A base produced by the action of reducing agents on rosaniline, and related to it in the same manner as indigo-white to indigo-blue:

It may be obtained by leaving hydrochlorate of rosaniline in contact with metallic zinc, or more easily by digesting a salt of rosaniline (or commercial fuchsine or magenta) with sulphide of ammonium. A yellow resinous mass is then formed, which is to be finely pulverised, washed with water and dissolved in dilute hydrochloric acid. The solution forms with concentrated hydrochloric acid, a copious, crystalline, brown or yellow precipitate, of impure hydrochlorate of leucaniline, which may be purified by repeated solution in dilute, and precipitation by concentrated hydrochloric acid. It crystallises from boiling dilute hydrochloric acid in very small rectangular plates, which are obtained quite pure by recrystallisation from water, or by precipitation of the alcoholic solution with ether.

Leucaniline is precipitated from the solution of the hydrochlorate as a white powder, acquiring a faint rose tint on exposure to the air. It is nearly insoluble in cold, sparingly soluble in boiling water, whence it separates in small crystals, slightly soluble in ether, easily in alcohol. It turns red when heated, and melts at 100° to a dark-red transparent liquid, which solidifies to a lighter-coloured mass on cooling. By oxidising agents, such as peroxide of barium, ferric chloride, and especially chromate of potassium, it is easily converted into rosaniline. It unites with sulphide of carbon, chloride of benzoyl, and several other bodies, forming compounds which have not yet been examined.

The salts of leucaniline crystallise well, especially the sulphate; they are all soluble in water, and are precipitated by acids. The hydrochlorate, $C^{20}H^{21}N^3 \cdot 3HCl \cdot H_2O$, gives up its water only when heated for a long time in a stream of hydrogen. On boiling its solution with excess of leucaniline, the latter separates out in splendid crystals, without forming a less acid salt. The chloroplatinate, $2(C^{20}H^{21}N^3 \cdot 3HCl) \cdot 3PtCl^4 \cdot 2H_2O$, is sparingly soluble in cold water, decomposable by boiling water, and gives up its water with difficulty, even when heated above 100° . The nitrate, $C^{20}H^{21}N^3 \cdot 3HNO_2 \cdot H_2O$,

forms white needles soluble in water and in alcohol, but not in ether, only sparingly in nitric acid, and decomposing at 100°.

Triphenyl-leucaniline. $C^{20}H^{18}(C^6H^5)^3N^3$.—Obtained by the action of reducing agents on triphenyl-rosaniline. The blue solution of the hydrochlorate of this base is decolorised by zinc and hydrochloric acid, and the clear liquid treated with water yields a precipitate which may be purified by solution in ether. The same compound is obtained as a brittle, non-basic resin, by the action of sulphide of ammonium on hydrochlorate of triphenyl-rosaniline. It is anhydrous, and when treated with oxidising agents, is reconverted into triphenyl-rosaniline. (Hofmann, *Compt. rend.* lvii. 26.)

LEUCAZOLITMIN. See LITMUS.

LEUCHTENBERGITE. A variety of chlorite (i. 914) from Slatoust in the Ural. Breithaupt regards it as an altered chlorite. Komonen found in it only 8.62 per cent. water instead of 12.62, the percentage in normal chlorite. Kennigott regards it as a distinct species.

LEUCIC ACID. $C^8H^{12}O^3$. (Strecker, *Ann. Ch. Pharm.* lxxviii. 55; Gössman, *ibid.* xci. 135; Waage, *ibid.* cxviii. 295; Thudichum, *Chem. Soc. Qu. J.* p. xiv. 307; Frankland, *Proc. Roy. Soc.* xii. 396; Frankland and Duppa, *ibid.* xiii. 140.)—An acid, homologous with lactic acid, produced:—1. From *leucine*.—a. When nitric oxide gas is passed through a solution of leucine in strong nitric acid, nitrogen is evolved and leucic acid is formed (Strecker). The same reaction takes place when nitrous acid is passed through a solution of leucine in warm water (Thudichum), or water slightly acidulated with nitric acid (Waage):

Cahours had previously observed (*Compt. rend.* xxvii. 368) that a peculiar acid is formed when an aqueous solution of leucine is left to itself.—B. When chlorine gas not in excess is cautiously passed through a solution of leucine in caustic soda, leucic acid is formed and may be separated from the mixture in the same manner as benzo-glycollic acid (i. 548) from hippuric acid. (Gössmann.)

2. From *oxalate of ethyl*, by the action of zinc-ethyl. The direct product of this action is probably zincoleucic ether, a body not isolated, thus [$zn = 32.6 = \frac{1}{2} zn$]:

The zincoleucic ether is converted by the action of water into leucic ether:

and from this, the barium-salt, and thence the acid itself, is easily obtained. (Frankland.)

Preparation.—1. Pure leucine is dissolved in boiling water slightly acidulated with nitric acid; nitrous acid gas is passed through the warm solution as long as nitrogen continues to escape; the liquid, which turns brown and gradually deposits brown flakes, is left to cool, then agitated several times with ether; and the ethereal extracts are evaporated. The residue is a brown oily liquid not miscible with water, which gradually solidifies to a radio-crystalline mass. The aqueous solution, freed from leucic acid by repeated agitation with ether, left on evaporation a considerable quantity of nitro-leucic acid.—To purify the crude leucic acid thus obtained, it is dissolved in a large quantity of water (a smaller quantity dissolves it but imperfectly); the boiling liquid is mixed with an aqueous solution of acetate of zinc; and the precipitated leucate of zinc is washed on the filter with water (which dissolves but a small quantity of it), purified by recrystallisation from alcohol, then suspended in water, and decomposed by sulphuretted hydrogen. The filtered solution is but very slightly coloured, and when evaporated to a syrup and left to stand, yields leucic acid in colourless needles. If, on the other hand, the zinc-salt be suspended in alcohol and decomposed by sulphuretted hydrogen, the acid is obtained in hard, brittle prisms. (Waage.)

2. Thudichum passes nitrous acid gas through a warm aqueous solution of leucine; evaporates, with addition of leucine, to neutralise the free nitric acid, and prevent it from oxidising the leucic acid; agitates the syrupy residue with ether (or extracts the leucic acid from the aqueous solution by agitation with ether, without previous evaporation; in which case, however, the treatment with ether must be repeated a great number of times)—and purifies the crude leucic acid from adhering brown oil, either by solution in cold water, filtration and recrystallisation,—or by strongly pressing the coloured crystals between bibulous paper—or by precipitating the aqueous solution

with acetate of lead, decomposing the washed precipitate with sulphuretted hydrogen, and evaporating the filtrate either over the water-bath at a very moderate heat, or over sulphuric acid.

3. Oxalic ether is mixed with its own weight of zinc-ethyl, in a vessel surrounded by cold water, to prevent rise of temperature and the consequent occurrence of a secondary reaction, attended with the evolution of large quantities of ethylene and hydride of ethyl; towards the end, however, the reaction requires to be assisted by the application of a gentle heat. The mixture, which generally remains fluid, is mixed after cooling, with its own volume of water (whereupon torrents of hydride of ethyl, derived from excess of zinc-ethyl, are evolved), and subsequently distilled in a water-bath. Weak alcohol containing an ethereal oil in solution then passes over, and a further quantity of the oil may be obtained by adding water to the residue in the retort, and continuing the distillation on a sand-bath. The oil is precipitated from the alcoholic distillate by water, added to that which floats on the surface of the watery distillate, then dried over chloride of calcium, and rectified. The principal portion, which distils between 174° and 176° , consists of leucic ether. (Frankland.)

The process may be greatly simplified, and a larger product obtained, by generating the zinc-ethyl during the reaction, namely by heating a mixture of amalgamated zinc, iodide of ethyl, and oxalic ether to the necessary temperature. The operation may be considered complete when the mixture has solidified to a resinous-looking mass; and this, when treated with water as above, and distilled, yields a considerable quantity of leucic ether. (Frankland and Duppa.)

The leucic ether heated with hydrate of barium, is converted into leucate of barium, and this when decomposed by dilute sulphuric acid, yields a solution of leucic acid.

Properties.—Leucic acid forms colourless needles (Strecker); needles or hard, brittle prisms, of the trimetric or monoclinic system, according to the mode of preparation (Waage); radiary group of needles, having a mother-of-pearl lustre, with a beautiful variety of concentric markings, like those of some kinds of larch-agaric (Thudichum); it is heavier than water, and cuts like hard soap, almost like stearic acid (Thudichum); it has an acid taste, and reddens litmus (Thudichum); a bitter taste, and strong acid reaction (Waage). It melts below 100° and solidifies on cooling (Thudichum); melts at 73° , and sometimes solidifies at a few degrees below the melting point, sometimes remains liquid even when cooled to 0° (Waage). It is easily soluble in water and in alcohol, soluble also in ether.

Decompositions.—1. Leucic acid volatilises at 100° , apparently without decomposition. When it is placed on a watch-glass and heated over the water-bath, the sides of the glass become fringed with crystals of the sublimed acid, which dissolve easily in water, leaving, however, a few flocks, probably consisting of the anhydride. The mass which remains in the middle of the watch-glass is syrupy, dissolves in water only after prolonged boiling, but is easily soluble in alcohol and ether; it probably also consists of leucic anhydride (Waage). The acid heated for some time in the water-oven, continually gives off acid-smelling vapours, and does not afterwards solidify on cooling, but remains in the form of an uncrystallisable, dark-brown, smeary syrup; the anhydride, which has a very disagreeable odour, remains unchanged, even when left over oil of vitriol for weeks, and is nearly insoluble in water, separating from it like an oil and sinking to the bottom. A small quantity of this insoluble compound is likewise formed, when the aqueous solution, even if dilute, is heated to the boiling point or evaporated (Thudichum). Leucic acid may be boiled with water without decomposition, and traces only of it distil off with the water (Frankland).—2. Leucic acid strongly heated in the air, gives off thick fumes and blackens, then takes fire and burns with a yellow smoky flame, leaving a small quantity of charcoal, which is quickly and easily consumed. (Thudichum.)

Leucates. Leucic acid forms crystallisable salts, the composition of most of which may be represented by the formulae, $M^{\cdot}C^{\cdot}H^{11}O^{\cdot}$ and $M^{\cdot}(C^{\cdot}H^{11}O^{\cdot})^2$. They are analogous in composition to the lactates, the acid being diatomic and monobasic. An acid silver-salt has, however, been obtained, having the composition $C^{\cdot}H^{11}AgO^{\cdot}, C^{\cdot}H^{12}O^{\cdot}$. The leucates are for the most part obtained by boiling the aqueous solution of the acid with the corresponding carbonates (Thudichum). They are less soluble than the lactates in water, more soluble in alcohol. (Waage.)

Leucate of Ammonium.—The acid slightly supersaturated with ammonia, and evaporated, leaves a thick homogeneous residue, in which no trace of crystallisation can be observed, even after drying for several weeks over oil of vitriol. (Thudichum.)

Leucate of Barium, $Ba^{\cdot}(C^{\cdot}H^{11}O^{\cdot})^2$.—Obtained by digesting the aqueous acid with carbonate of barium, or by heating leucic ether with hydrate of barium, separating the excess of baryta by carbonic acid, filtering and evaporating (Frankland,

Waage, Thudichum). It dissolves with moderate facility in warm water and dilute alcohol, and separates from boiling alcohol in beautiful colourless, silky, lamellar crystals, which, like most leucates, retain something of the appearance of leucate. (Waage.)

Leucate of Calcium, $\text{Ca}(\text{C}^6\text{H}^{11}\text{O}_5)_2$.—An aqueous solution of the acid neutralised with chalk or milk of lime, and left to evaporate, yields the calcium-salt in fine needles, easily soluble in water and in alcohol.

Leucate of Cobalt, $\text{Co}(\text{C}^6\text{H}^{11}\text{O}_5)_2$.—The dilute aqueous acid boiled with excess of carbonate of cobalt, then filtered and evaporated, deposits light crusts of a pink colour while moist, but of a very pale rose-colour or almost white when dry. The salt is but sparingly soluble in cold water, and not much more soluble at the boiling heat. It crystallises in needles, which, under the microscope, appear to be arranged in globular masses. (Thudichum.)

Leucate of Copper.—When a dilute aqueous solution of leucic acid is treated with a dilute solution of ammonio-sulphate of copper, the colour of the copper-salt changes to light-green. On boiling the liquid, it becomes paler, and on cooling deposits light green granules of leucate of copper. Under high powers of the microscope, these granules appear as balls, formed by a radiary arrangement of needles (Thudichum). A solution of leucic acid mixed with acetate of copper, forms a green flocculent precipitate, very sparingly soluble in water, even at the boiling heat, but easily crystallised from boiling alcohol, from which it separates in very beautiful light blue, shining, bulky scales, which do not undergo any diminution in weight at 100° . (Waage.)

Leucate of Lead.—On adding acetate of lead to a solution of leucic acid or a leucate, a copious white flaky precipitate is formed, which on boiling dissolves almost entirely in the liquid. Any portion remaining undissolved melts into a white mass, which is soft like resin while warm, but becomes brittle and hard on cooling. This substance is insoluble in water and alcohol, even on boiling, and seems to be a basic salt.

If the solution of lead is added to a boiling solution of the acid, no precipitate ensues, acid vapours are evolved, and the liquid becomes milky on cooling. In a short time, it deposits the lead-salt as a light, granular, white mass, which, under the microscope, appears to be made up of a multitude of strongly refracting spherical masses, of the size of human blood-corpuscles. This salt is more easily soluble in an excess of the acetate than in water. It is easily soluble in spirit of wine, particularly in boiling spirit. Even in these solutions, basic salts are easily formed. The addition of water to these solutions produces a precipitate. (Thudichum.)

Leucate of Magnesium.—Sparingly soluble in water, deposited in crusts on evaporation. (Thudichum.)

Leucates of Mercury.—*Mercuric Leucate* may be prepared:—*a.* Directly, by dissolving freshly-precipitated moist mercuric oxide in aqueous leucic acid. A flaky precipitate gradually ensues, which on heating becomes red and granular, and adheres to the sides of the glass. On cooling, a new precipitate, consisting of whitish globules, is deposited.—*b.* By adding mercuric nitrate to an aqueous solution of leucic acid, a whitish-red precipitate is formed, which dissolves on boiling, and on cooling is again deposited in reddish granules.—*c.* By adding the mercurial solution to the leucate of an alkali-metal.

Mercurous Leucate.—When a solution of mercurous nitrate is added to a solution of leucic acid a slight turbidity ensues. The addition of carbonate of sodium produces a copious reddish-white precipitate, which, on boiling, becomes red, then dull grey, and deposits metallic mercury. (Thudichum.)

The leucates of mercury have a great tendency to become reduced. The mercuric salt easily passes into the mercurous salt. The mercuric salt, moreover, has a great tendency to become basic and insoluble. (Thudichum.)

Leucate of Potassium is produced by the action of aqueous potash on leucic ether, and separates as a semi-solid soap on the surface of the potash-solution, if the latter is concentrated. (Frankland.)

Leucates of Silver.—*a.* The neutral-salt, $\text{C}^6\text{H}^{11}\text{AgO}_5$, is obtained by adding nitrate of silver to the solution of the acid neutralised with ammonia, or by boiling the acid with oxide of silver, and may be rendered quite colourless by recrystallisation from boiling water, in which it is moderately soluble. It is anhydrous (Waage). Nitrate of silver added to a warm solution of leucate of ammonium, potassium, or sodium, forms a copious white crystalline precipitate, which increases as the liquid cools, and blackens if left in the mother-liquor (Thudichum). It contains 45.2 per cent. silver (Waage); 44.14 (Thudichum); calc. 45.19 per cent.

Acid salt, $\text{C}^6\text{H}^{11}\text{AgO}_5 \cdot \text{C}^6\text{H}^{11}\text{O}_5$.—A hot dilute solution of leucic acid decomposes recently

precipitated carbonate of silver, with effervescence. The excess of the carbonate of silver and undissolved portion of the leucate become blackish-grey, but the acid is not decomposed. The hot filtrate forms no deposit on cooling. The attempt to evaporate it over the water-bath produces a black precipitate of reduced silver. It must therefore, be evaporated in vacuo over oil of vitriol. After prolonged standing, a few crystals, of a glassy lustre and appearing under the microscope as groups of rhombic plates, are deposited at the margin of the dish. The liquid then becomes covered with a pellicle, and evaporation is impeded. At a later stage conglomerates of needles are deposited, which, when carefully dried over sulphuric acid in vacuo, appear a little blackened, like most silver-salts, but are not decomposed. Silver by analysis 26·97 per cent.; the formula requires 29·1 per cent. (Thudichum.)

Leucate of Sodium.—The aqueous acid neutralised with carbonate of sodium, and evaporated, leaves a syrupy residue covered with a crystalline crust. When this syrup is left over oil of vitriol, crystals form in it, which under the microscope exhibit a characteristic tub-shape, with rhombic plates interspersed here and there. (Thudichum.)

Leucate of Zinc, $\text{Zn}(\text{C}^6\text{H}^{11}\text{O}^3)^2$.—This salt is obtained by neutralising the dilute acid at the boiling heat with carbonate of zinc, and filtering at the same temperature. The solution deposits a thin crust on cooling. Evaporated over the water-bath, it soon becomes covered with a crust, and on cooling deposits bulky masses of needles, which must be separated by filtration, pressed between bibulous paper, and dried by exposure to the air or over the water-bath. The best crystals are obtained from a solution containing excess of leucic acid (Thudichum). For Waage's mode of preparation, see page 575.

The salt is snow-white, with splendid silky lustre; exhibits under the microscope the appearance of masses of needles (Thudichum); extremely light scales, of dazzling whiteness and silky lustre (Waage). It is sparingly soluble even in boiling water, less in cold water (Thudichum); dissolves in 300 pts. water at 16° , and in 204 pts. boiling water; more soluble in alcohol (Waage). The air-dried salt contains $\text{Zn}(\text{C}^6\text{H}^{11}\text{O}^3)^2 \cdot \text{H}_2\text{O}$, and gives off its water (5·1 per cent.) at 100° (Waage). The anhydrous salt gives by analysis, 43·87 per cent. carbon, 6·39 hydrogen, and 20·10 zinc, the formula requiring 44·01 carbon, 6·72 hydrogen, and 19·92 zinc (Thudichum). Sulphydric acid precipitates the zinc completely (Waage); according to Thudichum, on the contrary, the precipitation is only partial, even after the solution has been repeatedly saturated with the gas.

LEUCIC ETHER. *Leucate of Ethyl, $\text{C}^6\text{H}^6\text{O}^3 = \text{C}^6\text{H}^4(\text{C}^2\text{H}^5)^2\text{O}^3$.*—The formation and preparation of this compound by the action of zinc-ethyl on oxalic ether have already been described (p. 575). It is a colourless, transparent, somewhat oily liquid, possessing a peculiar penetrating ethereal odour, and a sharp taste. It is insoluble in water, but dissolves readily in alcohol and ether. Specific gravity 0·9613 at $18\cdot7^\circ$. Boiling point, 175° . Vapour-density, obs. = 5·241; calc. 5·528. Treated with hydrate of barium or potassium, it yields the corresponding salts of leucic acid. (Frankland.)

LEUCINDIN-SULPHURIC ACID. See INDIN-SULPHURIC ACID (p. 268).

LEUCINE. $\text{C}^6\text{H}^{11}\text{NO}^2$. Formerly called *Aposepedine* and *Caseous Oxide*. (Proust, Ann. Ch. Phys. [2] x. 40; Braconnot, *ibid.* xiii. 119; Mulder, J. pr. Chem. xvi. 290; Bopp, Ann. Ch. Pharm. lxi. 20; Laurent and Gerhardt, Ann. Ch. Phys. [3] xxiv. 321; Cahours, Compt. rend. xxvii. 265; Limpriecht, Ann. Ch. Pharm. xciv. 243; Gössmann, *ibid.* xc. 184; xci. 129; Streckger, *ibid.* lxxviii. 54; Gm. xi. 426.)—This substance was first observed by Proust, in 1818, as a product of the putrefaction of cheese; and Braconnot in 1820 found it among the products of decomposition of animal substances by sulphuric acid; Mulder, in 1838, showed that the two substances thus obtained were identical.

It is homologous with glycocine ($\text{C}^2\text{H}^3\text{NO}^2$) and alanine ($\text{C}^3\text{H}^5\text{NO}^2$), and may be regarded as lactamic acid, $\text{C}^6\text{H}^{10}\text{O}^2 \cdot \frac{\text{H}^2}{\text{H}} \left\{ \begin{smallmatrix} \text{N} \\ \text{O} \end{smallmatrix} \right.$, being related to leucic acid in the same manner as glycocine to glycollic acid, and alanine to lactic acid.

Occurrence.—In old cheese (Proust). In fresh calf's liver (Liebig, Chem. Briefe, 3 Aufl. 453); also, together with tyrosine, in the human liver, in certain cases of disease, but not in the healthy liver (Frerichs and Städeler, Jahresber. 1854, p. 676). According to later researches by these chemists (*ibid.* 1856, 702; 1858, 560), leucine and tyrosine are very widely diffused in the animal organism. Leucine also exists, together with taurine, inositol, and uric acid, in the tissue of the lungs (A. Cloëtta, Ann. Ch. Pharm. xcii. 289). According to Gorup-Besanez, Ann. Ch. Pharm. xxviii. 7, it occurs in many parts of the glandular system, viz., in the thymoid and thyroid glands, in the liver, and especially in the pancreas. It has been found also in

LEUCINE.

the brain of oxen (W. Müller, *Ann. Ch. Pharm.* ciii. 131); in the pancreas (Scherer, *Jahresber.* 1859, p. 610); in the stomach and intestines of the butterflies (Schwarzenbach, *ibid.* 1857, p. 538), and in the fly-agaric, *Agaricus carius*. (Ludwig, *ibid.* 1862, p. 516.)

Formation.—1. In the decomposition of gelatin, muscular flesh, legumin or wool (or white of egg, according to Mulder), by sulphuric acid (Braconnot); together with a small quantity of glycocine (Mulder). Goup-Besanes also (*Ann. Ch. Pharm.* cxviii. 230), by treating wool with sulphuric acid, obtained, together with volatile acids and a large quantity of ammonia, about 3 per cent. of tyrosine, and a rather large quantity of leucine containing sulphur. The leucine was obtained free from sulphur by dissolving it in rather dilute potash-ley, boiling it with a solution of lead-oxide in potash, filtering from sulphide of lead, neutralising the filtrate with sulphuric acid, evaporating to dryness, boiling the pulverised residue with alcohol, and leaving the solution to crystallise.

2. By heating horn with dilute sulphuric acid (Hinterberger), also together with tyrosine, by heating elastic tissue, especially the cervical ligament (Zollikofer), or feathers, hedge-hogs' spines, human hair, the wing-cases of cockchafers, or globulin and hæmatin from ox-blood (Leyer and Köller, *Ann. Ch. Pharm.* lxxiii. 332), or silk (Hinterberger, *Wien. Akad. Ber.* xi. 450) or conchiolin (Schlossberger, *Zeitschr. Ch. Pharm.* 1860, p. 424), with dilute sulphuric acid. Erlenmeyer and Schöffler (*Zeitschr. Ch. Pharm.* 1859, p. 315), by boiling 1 pt. of various albuminous and gelatinous substances with 5 pts. of a mixture of 1 pt. sulphuric acid (H^2SO^4) and $1\frac{1}{2}$ pts. water, obtained the following quantities of leucine and tyrosine: Cervical ligament yielded $\frac{1}{4}$ per cent. tyrosine and 38 to 45 per cent. leucine; blood-fibrin, 2 per cent. tyrosine (on evaporating the neutral liquid to about 1.08 to 1.10 specific gravity), then 14 per cent. leucine; flesh-fibrin, not quite 1 per cent. tyrosine, and about 18 per cent. leucine; white of hen's egg, 1 per cent. tyrosine and about 10 per cent. leucine; horn (treated with 10 pts. of the above acid mixture), 3.6 per cent. tyrosine, and about 10 per cent. leucine. The several substances were decomposed by three hours' boiling with the acid as completely as when the boiling was continued for 36 or 40 hours.

3. By the action of dilute acids upon indican. (Schunck, p. 247.)

4. By boiling white of egg, gelatin, or flesh, with potash-ley, glycocine being formed at the same time (Mulder). Hence also, when the juice of mangold-wurzel is boiled with lime. (Hochstetter, *J. pr. Chem.* xxix. 36.)

5. By melting albumin, fibrin, casein (Bopp), or horn (Hinterberger) with hydrate of potassium.

6. In the putrefaction of casein or gluten under water (Proust, Mulder); sometimes abundantly, sometimes only in traces (Cahours). Also, together with tyrosine, ammonia, butyric acid, and lactic acid, by the putrefaction of yeast (A. Müller, *J. pr. Chem.* lvii. 162, 447). But according to Hesse (*J. pr. Chem.* lxx. 34), the substance regarded by Müller as leucine contains 3 or 4 per cent. sulphur, and is more soluble in alcohol than leucine (see PSEUDOLEUCINE, p. 582).

7. By the action of hydrocyanic acid and dilute hydrochloric acid, with the aid of heat, on valerian-ammonia (Parkinson, *Ann. Ch. Pharm.* xc. 144; Limpricht, *ibid.* xciv. 243):

It was stated by Gössmann, that thialdine* is converted into leucine by the action of moist silver-oxide, according to the equation:

but according to Hofmann (*Chem. Soc. J.* x. 193), thialdine thus treated gives off the whole of its nitrogen in the form of ammonia.

Preparation.—1. Finely-chopped beef, washed with water and then strongly pressed, is mixed with an equal weight of oil of vitriol, and gently heated till it is completely dissolved; the fat is skimmed off after cooling; the mixture diluted with water amounting to $3\frac{1}{2}$ times the weight of the meat; the liquid boiled for 9 hours, with frequent renewal of the water; the sulphuric acid removed by chalk; the filtrate evaporated to an extract; this extract repeatedly boiled with alcohol of 34° Bm.; the resulting alcoholic tincture evaporated; the dry residue exhausted with cold alcohol; the residual mixture of leucine and a small quantity of matter precipitable by tannin dissolved in water; a solution of tannin carefully added to it by drops as long as any precipitate ensues; and the liquid filtered after a few seconds, then evaporated (Braconnot). The leucine prepared by Braconnot appears still to have contained glycocine. (Mulder.)

2. 1 pt. of dry albumin, fibrin, or casein, free from fat, is boiled with 4 pts. of oil of vitriol and 12 pts. of water, in an open vessel, the ebullition being continued for a day

and the water continually renewed. Or, better: 1 pt. of the substance is dissolved in 4 pts. of strong hydrochloric acid; the liquid mixed with 3 or 4 pts. of oil of vitriol and evaporated over the water-bath till the greater part of the hydrochloric acid is expelled, and the remaining black-brown pitchy or syrupy mass, in which minute crystals form, is dissolved in hot water. Either of these acid liquids is boiled with excess of milk of lime to expel ammonia, then strained through a linen bag; the clear filtrate treated with sulphuric acid to precipitate the lime which is held in a solution by a product of decomposition; the excess of acid precipitated by acetate of lead, and the excess of lead by sulphydric acid; and the filtrate evaporated to a syrup, from which in a few days leucine and tyrosine crystallise. The crystals are freed from the syrupy mother-liquor by digestion in 86 per cent. alcohol, and the leucine separated from the tyrosine and brown matter by treatment with water, hydrated oxide of lead, and animal charcoal, as in the fifth mode of preparation.

3. 1 pt. of cow-horn shavings is boiled with 4 pts. of oil of vitriol and 12 pts. of water for 36 hours, the water being renewed from time to time, the liquid then supersaturated with milk of lime; the whole boiled for 24 hours in an iron pot, then strained through a conical bag and squeezed, and the liquid mixed with a very slight excess of sulphuric acid, filtered, and evaporated; it then yields at first spherical crystalline masses of tyrosine, and afterwards laminated masses of leucine. The latter are pressed between paper, freed from brown matter by washing with absolute alcohol, and crystallised from solution in a small quantity of hot water, tyrosine then separating first, and the mother-liquor afterwards yielding leucine, tolerably pure but not quite white. It must therefore be dissolved in hot water; digested with a small quantity of hydrated oxide of lead; the liquid filtered; the filtrate freed from lead by sulphydric acid, and the crystallised leucine further treated with animal charcoal (Hinterberger, *Ann. Ch. Pharm.* lxxi. 72). H. Schwanert (*ibid.* cii. 221) boils 2 lbs. of horn-shavings with 5 lbs. sulphuric acid and 13 lbs. water for 24 hours, renewing the water as it evaporates, then supersaturates with lime, and, after filtering off the gypsum, evaporates the filtrate to 12 lbs. and mixes it with a quantity of oxalic acid sufficient to produce a slight acid reaction. The liquid filtered from calcic oxalate, and evaporated till a crystalline film forms upon its surface, deposits groups of yellowish laminae of leucine mixed with tyrosine, more of which crystals may be obtained by evaporating the mother-liquor. The crystalline mass is then dissolved in such a quantity of hot water that the solution on cooling yields crystals of tyrosine only; the leucine solution is then decolorised with animal charcoal, evaporated, and the leucine which separates is purified by pressure and recrystallisation from hot alcohol. Waage (*Ann. Ch. Pharm.* cxviii. 295) proceeds in the same way as Schwanert, excepting that, after precipitating the last portions of lime with oxalic acid, he mixes the filtrate with sulphate of copper, precipitates the copper with sulphydric acid; evaporates the filtered liquid which is then nearly colourless, to the crystallising point; recrystallises the separated leucine from water and dilute alcohol; and finally decolorises it by boiling with a small quantity of hydrate of lead, and removing the lead by sulphydric acid. The leucine thus prepared still retains 2 per cent. ash and a trace of sulphur.

4. White of egg, gelatin, or flesh, is boiled with potash-ley till it is completely decomposed; the liquid neutralised with sulphuric acid, and evaporated; and the leucine extracted with alcohol. (Mulder.)

5. 1 pt. of the powder of dry albumin, fibrin, or casein free from fat, is added to 1 pt. of hydrate of potassium, heated to fusion in an iron crucible of 25 times the capacity; and water carefully added after half an hour, when the violent frothing arising from the escape of water and ammonia has subsided, and the brown colour which the mixture at first exhibits, is changed to yellow; if the liquid be then saturated with acetic acid, filtered hot, and gradually cooled, it yields tufts of needles consisting of tyrosine. These crystals completely fill the filtrate, when the process is well conducted; on the other hand, they are less abundant the longer the fusion has been continued.—The liquid decanted from the crystals of tyrosine is evaporated till a crystalline film appears on the surface; then set aside for 24 hours and exhausted with strong alcohol, which leaves crystals of leucine and the still remaining tyrosine; the liquid is mixed with alcoholic sulphuric acid, and decanted from the crystallised sulphate of potassium; the alcohol separated from it by evaporation, the sulphuric acid by lead, and then the lead by sulphydric acid; and the solution finally evaporated, whereupon it yields crystals of leucine and a greasy syrup, the quantity of which is less in proportion as the fusion has been longer continued. To purify the leucine from tyrosine and a small quantity of brown colouring matter, it is dissolved in such a quantity of hot water that only a small quantity of leucine may separate on cooling, together with the tyrosine; the mother-liquor is digested with hydrated oxide of lead, which removes the colouring matter together with a small quantity of leucine; the filtrate is treated with sulphydric acid; and the filtrate thus obtained, which has merely a yellowish colour, is evaporated in a flask till a crystalline film forms on its surface. It then, on cooling, yields crystals

of leucine, which must be washed with cold water and alcohol, and decolorised by treatment with animal charcoal and recrystallisation.—If the object be merely to obtain leucine, and not tyrosine, it is sufficient to heat the potash-mixture till the strongest intumescence is over. At that stage of the process, the same quantity of leucine is formed, but no tyrosine. (Bopp.)

6. One pt. of cheese, muscular flesh, or white of egg, is left to putrefy with 5 pts. of water for six weeks at a temperature somewhat above 20°; the resulting turbid solution boiled with a small quantity of milk of lime; the lime precipitated by a very slight excess of sulphuric acid; the filtrate boiled down and precipitated by neutral acetate of lead; the decanted liquid treated with sulphydric acid; the filtrate evaporated to a syrup; and the leucine which crystallises therefrom, is freed from the remaining syrup by means of alcohol, and purified by solution in water, treatment with hydrated oxide of lead and sulphydric acid, crystallisation, and washing with cold water and alcohol. When the above-mentioned alcoholic solution of the syrup is evaporated to complete dryness, and the residue dissolved in absolute alcohol, the solution still deposits a small quantity of leucine. (Bopp.)

7. The cervical ligament of the ox, after being freed from the surrounding fibrous tissue by boiling with water containing acetic acid, and subsequent scraping with a knife, and (if necessary) from fat by digestion in ether, is boiled for 48 or 60 hours with dilute sulphuric acid (8 pts. oil of vitriol to 12 pts. water), the water being replaced as it evaporates. The resulting solution is mixed with a slight excess of thin milk of lime, and boiled for some hours; the filtrate exactly neutralised with sulphuric acid and evaporated; and the liquid, after filtration from the separated sulphate of calcium, is again evaporated: it then yields, especially on cooling, impure leucine, which may be purified by recrystallisation from hot alcohol. This process is peculiarly advantageous, as the acid mother-liquors crystallise to the last drop, yielding nothing but leucine. (Zollikofer, Ann. Ch. Pharm. lxxxii. 162; compare Güssmann, *ibid.* xci. 130.)

8. Valeral-ammonia is boiled in a retort with hydrocyanic and hydrochloric acids till the oily layer consisting of the fused ammonia-compound has completely disappeared; the solution is then left to itself till the greater part of the resulting chloride of ammonium has crystallised out; the hydrochloric acid removed by means of hydrated oxide of lead, and the lead by sulphydric acid; the filtrate is evaporated over the water-bath, and the residue dissolved in hot dilute alcohol: the solution thus obtained yields crystals of pure leucine. (Limpriecht.)

Properties.—Leucine crystallises from alcohol in soft nacreous scales, lighter than water and resembling cholesterin. It sublimes completely at 170°, in cotton-like flocks without fusion or decomposition (Mulder); according to Schwanert, on the contrary, it melts at 170°. It is sparingly soluble in cold, but dissolves easily in hot water; sparingly in alcohol of ordinary strength (in 658 pts. of cold alcohol of specific gravity 0.828 according to Mulder), very sparingly in absolute alcohol. According to Zollikofer, it dissolves in about 27 pts. of cold water, in 1040 pts. of cold alcohol of 96 per cent., and in 800 pts. hot alcohol of 98 per cent. It is insoluble in ether. Its solubility in water and alcohol is increased by the presence of acetic acid, or an alkaline acetate.

Decompositions.—1. Leucine heated to 180°, yields a yellow distillate having an ammoniacal odour, and solidifying in the cold, while a brown resinous mass remains in the retort. The alcoholic solution of the distillate has an alkaline reaction, and when treated with hydrochloric acid, gives off carbonic anhydride, and yields a solution containing hydrochlorate of amylamine, together with sal-ammoniac. The resolution of the leucine into carbonic anhydride and amylamine, which is the principal reaction, is similar to that of phenyl-carbamic acid into carbonic anhydride and phenylamine, and shows that leucine may be regarded as amyl-carbamic acid:

—2. Leucine heated in contact with the air burns readily, and with a white flame.

—3. An alkaline solution of leucine exposed to the action of ozone, yields carbonic acid, butyric acid, and other volatile fatty acids, ammonia, and probably also, in the earlier stage of the decomposition, cyanic acid and valeraldehyde (Görup-Besanez, Ann. Ch. Pharm. cxxv. 210).—4. Leucine is decomposed by chlorine, forming a hard brown body, similar to that obtained with glycocine (il. 903), and a red volatile liquid (Mulder). When chlorine is passed into water in which leucine is suspended, carbonic anhydride is evolved, and a turbid solution is formed, from which an oily liquid separates, consisting of a mixture of valeronitrile and chloro-valeronitrile ($\text{C}^5\text{H}^8\text{ClN}$): the solution contains hydrochlorate of leucine (Schwanert).—5. Sulphuric anhydride is rapidly absorbed by leucine, forming a brown viscid liquid, which at 100° gives off

carbonic and sulphurous anhydrides, and if then distilled with water, yields a fragrant liquid boiling at 97° , and forming crystalline compounds with the acid sulphites of the alkali-metals; probably, therefore, valeraldehyde (Schwanert).—6. Leucine heated for some time with a sufficient quantity of *nitric acid*, is completely resolved into gases, but so long as the decomposition is incomplete, the still remaining portion exhibits the characters of nitrate of leucine (Mulder).—7. When nitric oxide is passed into a solution of leucine in nitric acid, nitrogen is evolved, and leucic acid, $C^8H^{12}O^4$, is formed (Strecker, p. 675). The same acid is formed when chlorine is passed, not in excess, into a dilute solution of leucine in caustic soda (Gössmann).—8. Chlorine gas passed to saturation into a solution of leucine in carbonate of potassium, forms chloride of cyanogen, valerianic acid, and valeronitrile (Gössmann).—9. Leucine distilled with *peroxide of manganese* and dilute sulphuric acid yields valeronitrile and carbonic anhydride:

When stronger sulphuric acid is used, valerianic acid passes over, and the residue contains ammonia. When leucine is distilled with *peroxide of lead* and water, only a trace of valeronitrile passes over, but a large quantity of butyral and then ammonia, which crystallise together in the form of butyral-ammonia.—10. By *permanganic acid* it is resolved into ammonia, oxalic acid, and valerianic acid (Neubauer, Ann. Ch. Pharm. cvi. 59).—11. Leucine fused with *hydrate of potassium*, gives off ammonia and hydrogen and forms valerate of potassium (Liebig, Ann. Ch. Pharm. lvii. 127).—12. An aqueous solution of leucine emits a very offensive odour, and forms a peculiar acid, perhaps leucic acid (Cahours).—In a vacuum, the aqueous solution of leucine appears to remain undecomposed (Gössmann).—13. When a solution of 1 pt. of leucine in water is set aside for some weeks in contact with a quantity of moist fibrin, which in the dry state would weigh $\frac{1}{2}$ pt., putrefaction takes place, the greater part of the leucine is decomposed, and ammonia is produced, together with such a quantity of valerianic acid as cannot be wholly produced from the fibrin. (Bopp.)

Combinations.—1. With acids. Leucine dissolves easily in acids, forming crystallisable salts. The *hydrochlorate*, $C^8H^{12}NO^2.HCl$, forms crystals very soluble in water. The *nitrate*, $C^8H^{12}NO^2.HNO^3$, called also *nitroleucic acid*, forms colourless needles. *Nitrate of leucine and barium* contains 41.01 per cent. baryta (Mulder). *Nitrate of leucine and calcium* forms mammellated groups containing water of crystallisation. *Nitrate of leucine and magnesium* forms small granular crystals. Leucine also forms a crystalline salt with *nitrate of silver*. These salts have probably the formula $C^8H^{12}NO^2.MNO^3$.

2. With bases. Leucine dissolves readily in caustic *alkalis*, but without neutralising them. The aqueous solution of leucine does not precipitate the solution of any metallic salt excepting basic acetate of lead.

Cupric salts.—Recently precipitated cupric oxide dissolves readily in aqueous leucine, forming a bluish liquid, which, on cooling, deposits crystalline grains or laminae having the colour of ammoniacal sulphate of copper, and containing $CuO.2C^8H^{12}NO^2$

or $C^8H^{24}CuN^2O^4.H^2O$. (Gössmann.)

Lead-salts.—On cautiously adding ammonia to a boiling aqueous solution of leucine and neutral acetate of lead, nacreous scales are deposited containing $PbO.2C^8H^{12}NO^2$ or $C^8H^{24}PbN^2O^4.H^2O$ (Strecker, Ann. Ch. Pharm. lxxii. 89). Gössmann obtained a salt of the same composition; but in one experiment, perhaps in consequence of a peculiar degree of concentration, he obtained laminated groups of crystals resembling lepidolite, and containing $9PbO.2C^8H^{12}NO^2$.

Mercurio salt.—Recently precipitated mercuric oxide dissolves very readily, and in considerable quantity in aqueous leucine; and the solution, when evaporated, deposits first crystalline granules and afterwards laminae containing 47.3 per cent. mercuric oxide: therefore $HgO.2C^8H^{12}NO^2$ or $C^8H^{24}HgN^2O^4.H^2O$. (Gössmann.)

Aqueous leucine is not precipitated by mercuric nitrate or chloride; but on addition of potash or ammonia, a white bulky precipitate is formed, which dissolves in excess of potash: the precipitate gradually becomes gelatinous and decomposes during washing (Gössmann). According to R. Hoffmann, on the contrary (Ann. Ch. Pharm. lxxxvii. 123), pure leucine is precipitated by mercuric nitrate in white flakes, without red colouring of the supernatant liquid, the production of such a colour indicating the presence of tyrosine.

Aqueous leucine added to a solution of *mercurous nitrate* throws down an abundance of white flocks, the supernatant liquid acquiring a red colour. (Braconnot.)

Pseudoleucine. This name is applied by Hesse (J. pr. Chem. lxx. 34) to a sulphuretted compound nearly related to leucine, found by A. Müller among the products of the decomposition of yeast (p. 679). It contains 3 or 4 per cent. sulphur, and is perhaps $C^8H^{12}N^2O^4S$. It is more soluble in alcohol than leucine, and when

purified as completely as possible, forms a white spongy mass composed of shining laminae. When cautiously heated, it sublimes almost without decomposition. It melts at 210° , and when distilled in an atmosphere of carbonic anhydride, yields, together with more volatile compounds containing nitrogen and sulphur, a woolly mass of acicular crystals resembling phlorizin, having the composition C^4H^4NO , and dissolving in dilute soda-ley with evolution of ammonia; this substance is designated by Hesse, leuconitrile. The other products of the dry distillation of pseudoleucine are sulphydric acid, hydrocyanic acid, a brownish, tarry, fetid substance, and several volatile bases, including ammonia, methylamine, dimethylamine, tritylamine, and a considerable quantity of amylamine.

LEUCITE. A silicate of aluminium and potassium, $(KAl)Si^4O^6$, occurring in monometric crystals, the usual form being the ikosi-tetrahedron or trapezohedron, hence called leucitohedron (fig. 180, ii. 125). Cleavage cubic, very imperfect; surface of crystals even, but seldom shining. The mineral often occurs disseminated in grains, rarely in granular masses. Hardness = 5.5 to 6. Specific gravity = 2.483 to 2.49. Lustre vitreous. Colour ash-grey or smoke-grey, white. Streak uncoloured. Translucent to opaque. Fracture conchoidal. Brittle. Infusible before the blowpipe, except with borax or carbonate of calcium, with which it melts with difficulty to a clear globule. Gives a fine blue with cobalt-solution.

Analyses.—a. From Albano near Rome (Klaproth, *Beitr.* ii. 39).—b. From Pompeii (Klaproth, *ibid.*).—c. From Somma (Awdejew, *Pogg. Ann.* lv. 107).—d. From Vesuvius, eruption of 1811 (Rammelsberg, *ibid.* xlviii. 143).—e. From Vesuvius, eruption of 1845 (Rammelsberg, *ibid.*).—f. From Rieden on Lake Laach (Bischof, *Chem. Geologie*, ii. 2288):

	a.	b.	c.	d.	e.	f.
Silica . . .	54	54.5	56.05	56.25	57.84	56.22
Alumina . . .	23	23.6	23.03	23.26	22.85	23.07
Potash . . .	22	19.5	20.40	20.04	12.45	13.26
Soda	1.02	0.43	6.04	6.40
Lime	0.32	0.20	0.23
Ferric oxide	0.14	0.48
Loss by ignition	6.69	..
	99	97.5	100.50	100.30	100.11	99.66

The formula $(KAl)Si^4O^6$ or $K^2O.Al^2O^3.4SiO^2$ requires 55.58 silica, 23.16 alumina, and 21.26 potash. The potash is sometimes replaced to a considerable extent by soda, as in e. and f. Abich found in a specimen from Vesuvius a still greater amount of soda.

Leucite occurs in volcanic formations, both ancient and modern; it is abundant in trachyte between Lake Laach and Andernach on the Rhine; the finest and largest crystals are, however, obtained from Vesuvius. Near Rome, at Borghetta on the north, and Albano and Frascati to the south, some of the older lavas appear to be almost entirely composed of it. This leucitic lava is used to form millstones, and millstones made of it have been discovered in the excavations at Pompeii.

Leucite occurs altered to feldspar, nephelin, and kaolin. Leucite altered to glassy feldspar has been observed on Somma by Scacchi. (Dana, ii. 231; Rammelsberg, *Mineralchemie*, p. 645.)

LEUCOCYCLITE. Syn. with APOPHYLLITE.

LEUCOHARMINE. Syn. with HARMINE.

LEUCOLINE. An organic base obtained from coal-tar, isomeric with chinoline, C^4H^4N . The two bases having this composition, the one obtained by the dry distillation of quinine and cinchonine, the other among those of the distillation of coal, were formerly thought to be identical, and the name chinoline was applied to both. Subsequent researches, however, having pointed out important differences between the two, especially in their behaviour with iodide of amyl, the base obtained from cinchonine is now distinguished as chinoline, and the coal-tar base (originally called *leucol* by Runge, who discovered it) as leucoline (see i. 869).

Each of these bases has a series of homologues corresponding with it, and differing in a similar manner from their isomers in the other series. The following names have been proposed by Greville Williams (*Chem. Soc. J.* xvi. 377) to distinguish the isomeric bases of the two series:

Coal-series.		Cinchonine series.	
Leucoline . . .	C^4H^4N	Chinoline . . .	C^4H^4N
Iridoline . . .	C^6H^6N	Lepidine . . .	C^6H^6N
Cryptidine . . .	C^8H^8N	Dispidine . . .	C^8H^8N

The higher homologues of chinoline, as far as C^8H^8N , have also been obtained; the corresponding bases in the leucoline series are at present unknown. (*Proc. Roy. Soc.* xiii. 312.)

LEUCOLITE. Syn. with PYCNITE.

LEUCONE. $\text{Si}^{\text{H}}\text{O}^{\text{O}}$.—A white substance obtained by the decomposition of silicone, $\text{Si}^{\text{H}}\text{O}^{\text{O}}$, under the influence of light and water (Wöhler, *Ann. Ch. Pharm.* cxvii. 268). See **SILICIUM**.

LEUCONIC ACID. *Oxycroconic acid*, $\text{C}^{\text{H}}\text{O}^{\text{O}}$. (Will, *Ann. Ch. Pharm.* cxviii. 117; Lerch, *ibid.* xxiv. 20).—An acid produced from croconic acid (ii. 110) by oxidation and assumption of water:

When a solution of croconate of potassium is treated with chlorine or nitric acid, it is decolorised and converted into leuconate of potassium, in the latter case with evolution of nitric oxide.

The acid [? prepared by decomposing the barium-salt with sulphuric acid] forms a colourless syrup, which when heated above 100° turns yellow, and is converted into croconic acid. It is tribasic, and forms white or pale yellow salts, which are unstable, being easily converted into croconates, especially in presence of alkalis. (Lerch.)

The *barium-salt*, $\text{C}^{\text{H}}\text{O}^{\text{O}}\text{Ba}^{\text{O}}$, is obtained as a flocculent, yellowish-white precipitate by adding baryta-water to the solution of the potassium-salt, prepared as above, till it becomes alkaline. (Will.)

The *lead-salt*, $\text{C}^{\text{H}}\text{O}^{\text{O}}\text{Pb}^{\text{O}}$, and the *silver-salt*, $\text{C}^{\text{H}}\text{O}^{\text{O}}\text{Ag}^{\text{O}}$, are light-yellow precipitates.

Potassium-salt. When a solution of croconate of potassium decolorised as above with chlorine or nitric acid, is neutralised with caustic potash or carbonate of potassium, the liquid, just at the point of saturation, exhibits a transient play of colours, from colourless to purple-red, bluish-red and yellowish; and if the solution is concentrated, an abundant yellowish-white precipitate is formed at the same time, which redissolves in a large quantity of water. This precipitate was found by analysis to have the composition $\text{C}^{\text{H}}\text{O}^{\text{O}}\text{K}^{\text{O}}$, but the lead-salt obtained from it by precipitation with acetate of lead exhibited the normal composition $\text{C}^{\text{H}}\text{O}^{\text{O}}\text{Pb}^{\text{O}}$, whence it is probable that the sparingly soluble potassium-salt with 1 at. metal really consisted of the tripotassic salt mixed with free leuconic acid (Will). According to Lerch, the solution of the normal potassium-salt is decomposed by neutralisation with potash, yielding a small quantity of a black salt, probably dihydrocarboxylate of potassium (p. 190), together with oxalate and a colourless crystallised potassium-salt.

LEUCONITRILE. A product of the decomposition of pseudoleucine (p. 583).

LEUCOPHANE. A silicate of glucinum and calcium, occurring in syenite, together with albite, ekeolite and ytrotantalite, on a small rocky islet near the mouth of the Langesundfjord in Norway, where it was found by Esmark. It is trimetric, with imperfect cleavage in three directions inclined to one another at angles of $53\frac{1}{2}^{\circ}$ and $36\frac{1}{2}^{\circ}$, but usually occurs massive and columnar. Hardness = 3.5 to 4. Specific gravity = 2.974. It is more or less translucent, with pale dirty green or light wine-yellow colour, and yields a white powder, strongly phosphorescent when heated or struck. It likewise becomes electric when heated. It is optically biaxial. Before the blowpipe it melts to a clear bead with a tinge of violet, becoming turbid by flaming. Dissolves easily in borax to an amethyst-coloured glass; in phosphorus-salt it leaves a skeleton of silica; and with a small quantity of carbonate of sodium, it melts to a turbid bead, which, with a larger quantity of carbonate of sodium, sinks into the charcoal. With fused phosphorus-salt in an open tube, it gives the reaction of fluorine. According to an analysis by Rammelsberg (*Mineralchemie*, p. 764), it contains:

SiO^{O}	F	GO	Al^{O}	CaO	MgO	Na^{O}	K^{O}	
47.03	6.57	10.70	1.03	23.37	6.17	11.26	0.30	= 100.43

with traces of ferric and manganese oxides, a composition which may be represented by the formula, $4\text{NaF} \cdot 3(2\text{CaO} \cdot 2\text{GO} \cdot 3\text{SiO}^{\text{O}})$.

Melinophane, from the zircon-syenite of Norway, is nearly related in composition to leucophane.

LEUCOPHYLL. A colourless substance isomeric with chlorophyll, supposed by Sacc (Jahresber. 1869, p. 561) to be contained in those parts of plants which are capable of turning green, and to undergo this change under the influence of oxygen rendered active by the agency of light. The existence of such a substance is rendered probable, according to Sacc, by the fact that the plasma of those vegetable cells which quickly turn green on exposure to light, contains a substance which instantly assumes a bright verdigris-green colour when brought in contact with strong sulphuric acid, and that the same reaction is exhibited by the ready-formed light green granules of chlorophyll itself, whereas the plasma of cells which do not turn green in light, does not exhibit it.

LEUCOPYRITE. Native di-arsenide of iron, FeAs_2 , also called *arsenoiderite* (see p. 368).

LEUCORCEIN. An ammoniacal solution of orcein slightly acidulated with hydrochloric acid, is completely decolorised by immersing a piece of zinc in it. If ammonia be then added, a white precipitate called leucorcein is formed, which on exposure to the air becomes violet, and finally purple. (See ORCEIN.)

LEUCOTURIC ACID. Laurent's *Oximide*. (Schlieper, Ann. Ch. Pharm. lvi. i.)—Formed when an aqueous solution of alloxanic acid (i. 138) is rapidly boiled down to a syrup: cold water is then added, which leaves the leucoturic acid undissolved. It is a white crystalline powder, insoluble in cold water, slowly but rather abundantly soluble in boiling water, whence it crystallises on cooling. It is readily soluble in aqueous alkalis, whence it is precipitated by mineral acids, and by the aid of heat decomposes alkaline carbonates. The potash-solution is decomposed by keeping or by gentle heat, ammonia being evolved, and oxalic acid formed abundantly. The ammonia-solution yields on evaporation crystals of the ammonium-salt, whose solution precipitates nitrate of silver. Leucoturic acid is not decomposed by boiling with strong nitric acid. It appears to be monobasic. Schlieper found it to contain 31.15 per cent. carbon, 2.80 hydrogen, and 24.51 nitrogen, whence he deduced the formula $\text{C}_7\text{H}_4\text{N}_2\text{O}_3$, requiring 31.30 carbon, 2.61 hydrogen, 24.35 nitrogen, and 41.74 oxygen. Gerhardt pointed out the improbability of this formula, as it contains an uneven number of atoms of hydrogen and nitrogen. Baeyer suggests the formula $\text{C}_7\text{H}_4\text{N}_2\text{O}_3$, which requires 33.98 per cent. carbon, 1.89 hydrogen, 26.41 nitrogen, and 37.72 oxygen. F. T. C.

LEVULUSAN or LEVULOSAN. A product of the decomposition of cane-sugar by heat, having a laevo-rotatory power of 15° for the transition-tint (ii. 864).

LEVIGATION. The mechanical process of grinding the parts of bodies to a fine paste, by rubbing them between the flat face of a stone called the muller, and a table or slab called the stone. Some liquid is always added in this process. The advantage of levigation with a stone and muller over that of triturating in a mortar is, that the materials can more easily be scraped together and subjected to the action of the muller, than in the other case to that of the pestle; and, from the flatness of the two surfaces, they cannot elude the pressure. U.

A figure and description of a mill for levigating litharge are given under LEAD (p. 614).

LEVYNE. A hydrated silicate of calcium and aluminium, occurring in rhombohedral crystals truncated by the basal face oR , which greatly predominates, and always in twins compounded parallel to oR . Angle $\text{R}:\text{R} = 106^\circ 4'$; $\text{oR}:\text{R} = 136^\circ 1'$; ratio of principal to secondary axes = 0.8358 : 1. The crystals are often striated and often in druses. Hardness = 4 to 4.5. Specific gravity = 2.09 to 2.16. Lustre vitreous. Colourless, white, reddish or yellowish. Transparent to translucent. Before the blow-pipe it melts to an opaque blabby glass. When pulverised it dissolves in acids without gelatinising.

Analyses. a. b. from Faroö, by Berzelius; c. from Skye, by Connel; d. from Ireland, by Damour (Rammelsberg's Mineralchemie, p. 802):

	SiO_2	Al_2O_3	CaO	Na_2O	K_2O	Mg_2O	H_2O	
a.	48.00	20.00	8.35	2.86	0.41	0.10	19.30	= 99.32
b.	47.50	21.40	7.90	4.80	.	.	18.19	= 99.79
c.	46.30	22.47	9.72	1.55	1.26	.	19.51	= 100.81
d.	44.48	23.77	10.71	1.38	1.61	.	17.41	= 99.36

Berzelius' analysis gave the formula of chabasite. Damour's, which contains less silica than the rest, leads to the formula:

which is that of a hydrated orthosilicate.

Levyne is found in amygdaloid at Glenarm; on Hatfield Moss, Renfrewshire; at Dalnyfron, Faroö; at Godhavn, Disco Island, Greenland; and at Skagstrand in Iceland.

LEUCIOLITE. A variety of augite from Lake Lherz in the Pyrenees, where it occurs both crystallised and lamellar, and of a deep-green or olive-green colour.

LIATRIS. According to W. Procter, jun. (Am. J. Pharm. xxxi. 556), cumarin occurs in microscopic prisms on the dried leaves of *Liatria odoratissima*, a plant growing in the Southern States of North America.

LIBETHENITE. A native phosphate of copper, $4\text{CuO} \cdot \text{P}_2\text{O}_5 + \text{aq.}$ or $\text{Cu}_3(\text{PO}_4)_2 \cdot \text{CuH}_2\text{O}_2$, found at Libethen in Hungary, and other localities. (See PHOSPHATES.)

LICHENIC ACID. See FUMARIC ACID (ii. 741).

LICHENIN. $C_7H^{10}O_5$. (Gm. xv. 119.)—A substance isomeric with starch, occurring in several species of moss and lichen, especially in the so-called Iceland moss (*Cetraria islandica*), which is really a lichen. According to Maschke (J. pr. Chem. lxi. 7), it is formed from starch by the action of the free acid in the plant. It is extracted from Iceland moss by macerating the chopped lichen for twenty-four hours with a large quantity of cold water containing a small quantity of carbonate of sodium, and continuing the treatment till the liquid no longer tastes bitter. It is then boiled with water, and the boiling decoction is strained through a linen cloth. The liquid on cooling coagulates to a kind of jelly, which dries up to a hard brittle mass (Berzelius). Payen removes the bitter matter by washing the lichen successively with ether, alcohol of specific gravity 0.83 and 0.90, cold water, very weak solution of carbonate of sodium, aqueous hydrochloric acid of the strength of 1 per cent., and pure water. Davidson (Ed. N. Phil. J. xxviii. 260) macerates 112 lbs. of Iceland moss for a fortnight with potash-ley prepared from 4 lbs. of pearlash, or for six days with milk of lime prepared from 6 lbs. of lime, then washes with dilute hydrochloric acid, and finally with water. Chloride of lime may also be used for the maceration. Knop and Schnedermann (Ann. Ch. Pharm. lv. 164) treat Iceland moss with a large quantity of hydrochloric acid, and precipitate the solution, after dilution and straining, with alcohol. The precipitated lichenin is then freed from water and rendered friable by repeated treatment with absolute alcohol, and freed from adhering hydrochloric acid by immersion in running water.

Lichenin in the dry state forms a hard brittle mass, tasteless, but having a faint odour resembling that of lichens. In cold water it swells up without dissolving, dissolves in boiling water, and is deposited in the form of a jelly; by prolonged boiling, however, it loses the property of gelatinising, and is converted into a gummy substance, probably dextrin. When the solution in boiling water is left to evaporate, the lichenin separates as a rough pellicle on the surface. Lichenin is insoluble in alcohol and ether.

Dilute acids dissolve lichenin and convert it into glucose. Nitric acid heated with it converts it into oxalic acid. Pure lichenin is merely coloured yellow by iodine; but a green or blue colour is often produced, from admixture of starch.

LICHENS. The following enumeration of the proximate constituents of lichens is given by Rochleder in *Gmelin's Handbuch*, viii. 94:

Baeomyces roseus, Pers. See analysis by Brandes. (Berl. Jahrb. xxv. 1, 38.)

Biotaria lucida, Fr. Contains usnic acid. (Knop, Götting. gelehrte Anzeigen, 1843, 2 u. 3 Stück, 16; and Ann. Ch. Pharm. xlix. 103.)

Cetraria aculeata, Fr. Contains no cetrarin, but moss-starch (lichenin) and lichenic (fumaric) acid. (Weppen, Pharm. Centr. 1838, No. 12.)

Cetraria islandica, Ach. Contains: fumaric acid (Schödlér, Ann. Ch. Pharm. xvii. 87) and cellular substance; starch not deposited in granules, but uniformly distributed among the cells (lichenin); cetraric acid, lichenstearic acid, tallochlor, fat, sugar, gum, yellow extractive matter, a brown substance formed from cetraric acid, and a body not exactly determined (Knop and Schnedermann, lv. 144). This lichen always contains alumina (Knop, J. pr. Chem. xxxviii. 347). It contains a large quantity of a carbohydrate (lichenin) convertible into sugar. (C. Schmidt, Ann. Ch. Pharm. li. 29).

Cladonia digitata, Hoffm.

Cladonia macilentata, Hoffm. } contain starch. (Knop, loc. cit.)

Cladonia uncinata, Hoffm. }

Cladonia pyxidata, Spr. Contains a large quantity of a carbohydrate convertible into sugar. (C. Schmidt, loc. cit.)

Cladonia rangiferina, Hoffm. (*Lichen rangiferina*, L.) Contains usnic acid (Rochleder and Heldt, Ann. Ch. Pharm. xlviii. 13), and a large quantity of carbohydrate convertible into sugar. (C. Schmidt, loc. cit.)

Evernia furfuracea, Mann. (*Parmelia*, Ach.) Contains usnic acid (Rochleder and Helot, loc. cit.). See an analysis of this lichen grown on a pine-tree, by John. (Chem. Schr. vi. 41.)

Evernia ochroleuca, Fr. (*Parmelia sarmentosa*, Ach.) Contains usnic acid. (Knop, loc. cit.)

Evernia prunastri, Ach. Contains usnic and evernic acids (Stenhouse, Phil. Mag. [3] xxxii. 300). Rochleder and Heldt found lecanoric, but not a trace of usnic acid.

Evernia vulpina. The experiments of Bebert (Ann. Ch. Pharm. ii. 342) on the so-called vulpulin, seem to show that this lichen contains chrysophanic acid. (Berzelius, Jahresber. xii. 256.)

Gyrophora pustulata, Ach. (*Umbellaria*, Hoffm.) From Norway. Contains gyrophoric acid. (Stenhouse, Phil. Trans. 1849, p. 458.)

Isidium corallinum, Ach. Contains a large quantity of oxalate of calcium. (Braconnot, Ann. Ch. Phys. [2] xxviii. 319.)

Lecanora Parella, Ach. (*Parmelia*, Schaer.) Contains: three futs, tannin, parolic acid, lecanoric acid, chlorophyll, and gum, which gives a greenish-blue colour with iodine (Schunck, Ann. Ch. Pharm. liv. 257). The several species of *Lecanora* contain lecanoric acid. (Schunck, *ibid.* xli. 157.)

Lecidia candida, Ach. (*Psora*, Dec.) Contains a large quantity of oxalate of calcium. (Braconnot, *loc. cit.*)

Lecidia geographica, Schaer. From the Brocken. Contains usnic acid. (Knop, *loc. cit.*)

Parmelia ciliaris, Ach. (*Borreria ciliaris*.) See analysis by John. (Chem. Schr. vi. 39.)

Parmelia parietina, Ach. Contains chrysophanic acid, a yellow non-crystallisable colouring matter (Rochleder and Heldt, *loc. cit.*), and a carbohydrate convertible into sugar (C. Schmidt, *loc. cit.*) This lichen contains: a yellow and a red colouring matter, wax, crystalline stearin, chlorophyll, soft resin, gum, lichenin, vegetable mucilage, sugar, extractive matter, traces of volatile oil, and phosphate of calcium (Hesberger, Buchn. Report. xlvii. 179); compare Sander (*Ueber die Wandflechte*, Sondershausen, 1815; and Kastu. Arch. viii. 431); Monhardt (*Dissert. sist. Lobaria parietina Analysis chem.* Kilonie, 1818); Schröder (Berl. Jahrb. 1819, p. 44); Markowitz (Scher. Ann. i. 438); Thomson (Ann. Ch. Pharm. liii. 262 and 260).

Parmelia physodes, Ach. Contains crystallised physodin. (Gerding, *Arch. Pharm.* lxxxvii. 1.)

Parmelia saxatilis, Ach. Contains a small quantity of carbohydrate convertible into sugar. (C. Schmidt, *loc. cit.*)

Patellaria hematomata, Hoffm. (*Parmelia*, Ach.—*Patellaria rubra*, Hoffm.—*Parmelia*, Ach.—*Patellaria ventosa*, Dec.—*Parmelia*, Ach.) Contain large quantities of oxalate of calcium (Braconnot, *loc. cit.*). *P. hematoma* and *P. ventosa* contain usnic acid. (Knop, *loc. cit.*)

Patellaria tartarea, Dec. (*Parmelia*, Ach.) Contains large quantities of oxalate of calcium (Braconnot, *loc. cit.*) In a specimen from Norway, Stenhouse (*loc. cit.*) found gyrophoric acid. See analysis by N. v. Escherbeck (Ber. Arch. xvi. 135).

Peltigera canina, Hoffm. Contains a carbohydrate convertible into sugar. (C. Schmidt, *loc. cit.*)

Pertusaria communis, Dec. Contains a large quantity of oxalate of calcium.

Placodium ochroleucum, Dec. (*Parmelia saxicola*, Ach.) and *Placodium radiosum*, Dec. (*Parmelia radiosa*, Ach.) Contain very large quantities of oxalate of calcium. (Braconnot, *loc. cit.*)

Ramalina calicaris, Fr. var. *fustigiata*. Contains large quantities of starch, colouring matter and bitter substance, and a small quantity of saccharic acid (Berzelius, Scher. Ann. iii. 97). Contains usnic acid. (Rochleder and Heldt, *loc. cit.*)

Ramalina calicaris, Fr. var. *fraxinea*. The ash contains a large quantity of ferrio oxide, but scarcely a trace of potash (John, Chem. Schr. vi. 37); soluble and coagulable albumin (Berzelius, Scher. Ann. iii. 208); lichenin, and usnic acid (Rochleder and Helot, *loc. cit.*)

Rocella Montagnei, Belen. Contains erythric acid. (Stenhouse, *loc. cit.*)

Rocella tinctoria, Ach. This lichen (var. *fuciformis*, from Angola and Madagascar) contains erythric acid (Heeren's erythrin, Kane's erythrin, ii. 602), a fatty substance, roccellie acid, a brown substance extractable by potash, chlorophyll, and ash-constituents (Schunck, Phil. Mag. J. [3] xxix. 194). *Rocella tinctoria* from South America was found by Stenhouse (Phil. Mag. [3] xxxii. 300) to contain α -roccellie acid; the same lichen from the Cape of Good Hope contained β -roccellie acid and roccellinin. Stenhouse and Scouler are of opinion that the *Rocella tinctoria*, var. *fuciformis* analysed by Schunck, was really *R. Montagnei*.

Squamaria elegans, Fée. Contains chrysophanic acid. (Thomson, Ann. Ch. Pharm. liii. 266.)

Squamaria lentigera, Dec. (*Parmelia*, Ach.) Contains a very large quantity of oxalate of calcium. (Braconnot, *loc. cit.*)

Sticta pulmonacea, Ach. Contains lichenin and a bitter principle (Weppen, Pharm. Centr. 1838, No. 12) very near cetraric acid in composition, and named stictic acid by Knop and Schnedermann (J. pr. Chem. xxxix. 303); compare John (Chem. Schr. vi. 39).

Uloclaria esculenta, Ach. Contains a large quantity (13 per cent.) of gum. (Kirechhoff, Scher. Ann. iii. 213.)

Uloclaria scruposa contains a large quantity of oxalate of calcium (Braconnot, *loc. cit.*)

Usnea barbata, Fr. Contains usnic acid (Roshleder and Heldt, *loc. cit.*), and lichenin. (Berzelius, Scher. Ann. iii. 205.)

Usnea barbata, Fr. var. *florida*. (*Usnea florida*, Hoffm.) Contains usnic acid (Knop, *loc. cit.*), and a small quantity of carbohydrate convertible into sugar. (C. Schmidt, *loc. cit.*)

Usnea hirta, Hoffm. (*U. barbata* var. *plicata*, Fr.) Contains usnic acid (Knop, *loc. cit.*), bitter principle, gum-sugar, lichenin and a soft skeleton (Berzelius, Scher. Ann. iii. 203). Contains a large quantity of carbohydrate convertible into sugar. (C. Schmidt, *loc. cit.*)

Variolaria amara, Ach. Contains picrolichenin (Alms, Pharm. Zeit. 1832, No. 2, 17; Ann. Ch. Pharm. i. 61.) Contains chlorophyll, and a colourless, crystallisable, bitter substance, forming with ammonia a red non-bitter resin (Gregory, J. Pharm. Juin 1835, p. 314; Pharm. Centr. 1835, No. 39). Contains picrolichenin, two resins, chlorophyll, gum-sugar, bitter extractive matter, oxalate of calcium, silicic acid, iron and cellulose (A. Müller, Pharm. Centr. 1844, No. 47); compare Filhol and Boucharadt. (J. de Méd. de Toulouse, vii. 201, and Pharm. Centr. 1844, No. 39.)

Variolaria communis, Ach. (grown on a lime-tree). Contains waxy matter, green colouring matter, a bitter and acrid principle, uncrystallisable sugar, oxalate of calcium (4.7 per cent.), a substance resembling animal gelatin, &c. (Braconnot, Ann. Chim. Phys. [2] vi. 132.)

Variolaria dealbata, Dec. (*Lichen dealbatus*, Ach.) See analysis by Robiquet (Ann. Ch. Phys. [2] lxii. 236), who found variolarin in this lichen, and prepared orcin from it.

For the colouring matters of lichens, see ARCHIL, ERYTHRIC ACID, EVERNIC ACID, GYMNOCARPIC ACID, LECANORIC ACID, LITMUS, ORSELIC ACID, ORCIN, USNIC ACID, VARIOLARIN.

LICHENSTEARIC ACID. $C^{14}H^{24}O^2$. (Schneidermann, and Knop, Ann. Ch. Pharm. lv. 149.)—An acid existing in Iceland moss (*Cetraria islandica*), and probably also in the fly-agaric or toadstool (*Agaricus muscarius*) (Bolley, Ann. Ch. Pharm. lxxxvi. 50). To prepare it, Iceland moss is boiled for a quarter of an hour in alcohol containing carbonate of potassium; the strained decoction is mixed with excess of hydrochloric acid; and the whole is diluted with 4 or 5 volumes of water. The precipitate thereby formed is washed with water, and afterwards boiled three or four times with alcohol of 42 to 45 per cent. On cooling the alcoholic solution, a mixture of lichenstearic and cetraric acids with a third substance, is separated, from which the lichenstearic acid is taken up by boiling rock-oil, and again deposited on cooling, or more completely on partial distillation. Purification is effected by recrystallising from alcohol, with the help of animal charcoal.

Properties.—The acid forms a loose, white mass, consisting of delicate crystalline laminae having a pearly lustre. From a solution in very dilute alcohol it is obtained in small rhombic tables; on concentrating the solution, partly in oily drops. It is inodorous, has a rancid, harsh, not bitter taste, melts at about 120° without loss of weight, and solidifies to a crystalline mass; is not volatile.

It is perfectly insoluble in water, but dissolves readily in alcohol, ether, and oils, both fixed and volatile.

The salts of lichenstearic acid are permanent in the air, and are decomposed by acids, with separation of lichenstearic acid. Their solutions froth up on boiling.

Ammonium-salt.—The easily prepared solution of the acid in warm aqueous ammonia forms, on cooling, a white, elastic jelly, appearing under the microscope to contain a quantity of long, extremely delicate crystals. The salt, when dry, is white and silky, and only partially soluble in warm water, with loss of ammonia.

The *barium-salt*, $C^{14}H^{22}Ba^2O^4$, is obtained, on precipitating the aqueous lichenstearate of sodium with a soluble barium-salt, as a greyish-white precipitate, which cakes together in boiling water.

The *lead-salt*, $C^{14}H^{20}Pb^2O^4$, is obtained, by precipitating the aqueous sodium-salt with neutral acetate of lead, in white flakes, which, on boiling the liquid, melt to a yellow, semi-fluid mass. It is brittle, softens between the fingers, and becomes semi-fluid at 100° , at which temperature also it appears to decompose.

Potassium-salt.—A solution of the acid in aqueous carbonate of potassium throws down, when concentrated by evaporation, yellowish flakes, which are soluble in water, but insoluble in alkaline liquids. If the solution be evaporated to dryness, and the residue extracted with boiling absolute alcohol, a part of the salt is obtained, on cooling, as an indistinctly crystalline powder; and the remainder, on concentrating the solution, in the form of a syrup. It dissolves easily in water, forming an alkaline liquid, which tastes like soap, and froths up on boiling.

The *silver-salt* is thrown down from a solution of the sodium-salt, by nitrate of silver, as a greyish-white precipitate, turning violet on exposure to light, and caking together in boiling water. It decomposes below 100° .

The *sodium-salt* is obtained in the same manner as the potassium-salt. A concentrated aqueous solution throws down white granules on standing.

LIEBENERITE. A silicate found in a red felspar porphyry on Mount Viesena, Fleimser valley, Tyrol, crystallised in six-sided prisms, without distinct cleavage. Hardness = 3.5. Specific gravity = 2.18. Colour greenish-grey. Fracture splintery. Before the blowpipe it whitens and intumesces, but does not fuse. Contains, according to Marignac (Bibl. univ. iv. 157), 44.66 per cent. silica, 36.51 alumina, 1.94 ferric oxide, 1.40 magnesia, 9.90 potash, 0.92 soda, and 5.05 water (= 100.38). Marignac regards it as pinité (q.v.); according to Blum, Breithaupt, and Haidinger, it is a pseudomorph of nephelin. It has also been regarded as an altered dichroite. (Dana, ii. 226; Rammelsberg's *Mineralchemie*, p. 837.)

LIEBIGITE. Calcio-uranic carbonate. See CARBONATES (i. 798).

LIEBIN. A substance containing 53.71 per cent. carbon, 8.95 hydrogen, 4.82 nitrogen, and 32.52 oxygen, found by Scherer (Jahresber. 1851, p. 697) in the fluid of the spleen.

LIEVRITE. *Ivaite. Yenite.*—A silicate of iron and calcium, occurring in trimetric crystals in which $\alpha P : \beta P = 110^\circ 12'$; $\alpha P : P_\infty = 146^\circ 20'$; ratio of principal axis, brachydiagonal and macrodiagonal = 0.66 : 1 : 1.46. Observed combination, $\alpha P, P, \beta P, \alpha P_2, \alpha P_3, \alpha P_4, \alpha P_\infty, \beta P_\infty, P, 3P_\infty, 2P_\infty, \frac{1}{2}P_\infty, 2P_2$. Lateral faces usually striated longitudinally. Cleavage parallel to the longer diagonal, indistinct. Also columnar or compact massive. Hardness = 5.5 to 6. Specific gravity = 3.8 to 4.2. Lustre submetallic. Colour black, of various shades. Streak black, inclining to grey or brown. Fracture uneven. Brittle. Before the blowpipe it melts to a magnetic globule. It is easily and completely decomposed by hot hydrochloric acid.

Analyses: 1. Stromeyer (*Rammelsberg's Mineralchemie*, p. 740). — 2. Rammelsberg (*ibid.*). — 3. Wackernagel (*ibid.*):

	SiO ²	Fe ² O ³	FeO	MnO	[CaO]	Al ² O ³	H ² O	
1. Elba.	29.28	23.00	31.90	2.43	13.78	0.61	1.27	= 101.27
2. „	29.83	22.56	32.40	1.50	12.44	„	1.60	= 100.32
3. „	29.45	25.79	28.60	0.94	15.49	„	„	= 100.27

These results do not agree very closely with any simple formula, but they may be approximately represented by $9MO.2Fe^2O^3.6SiO^2$.

Lievrite occurs in the Island of Elba, in large solitary crystals and aggregated crystallisations in compact augite. It is also found at Fossum and Skoen in Norway; in Siberia; near Andreasberg in the Hartz; near Predazzo, in the Tyrol, in granite; at Schneeberg, in Saxony; and near Bytown, Canada.

Kobell's *Wehrlite*, a massive granular mineral from Szuraskö in Hungary, containing 34.60 per cent. silica, 0.12 alumina, 42.38 ferric oxide, 15.78 ferrous oxide, 0.28 manganous oxide, 5.84 lime, and 1.00 water, is sometimes regarded as lievrite. It is, however, harder (hardness = 6 to 6.5), fuses with difficulty and only on the edges, and is but imperfectly soluble in acids. (Dana, ii. 263.)

LIGHT. Light is the agent which makes us acquainted with the existence of bodies through the organ of sight. It is likewise one of the most important agents of chemical change. Plants, with few exceptions, are absolutely dependent upon it for their existence and development; the greater number of animals are incapable of living in health and vigour unless subjected to its influence; and a variety of chemical processes both natural and artificial depend in great measure upon its agency.

The several views which have been entertained respecting the nature of light may be ranged under two heads, the system of emission, and the system of undulations. The former, suggested in ancient times by Empedocles and Democritus, afterwards adopted by Gassendi, and brought to the utmost degree of completeness of which it is susceptible by Newton, supposes light to consist of minute particles emitted from luminous bodies, and travelling through space with immense rapidity till they reach the eye. The latter theory, the germ of which may be found in the writings of Aristotle, supposes that objects are rendered visible by vibrations excited by luminous bodies in an elastic medium, called the *ETHER*, pervading all space, and filling up the intervals between the molecules of ponderable bodies. Ideas similar to this were advocated by Descartes, Mallebranche, and Grimaldi; but it was in the hands of Huyghens that the theory first assumed a definite shape, and was rendered capable of affording an exact explanation of known facts; and by the subsequent labours of Young, Fresnel, Cauchy, and others, it has been brought to such a state of perfection that it is capable of accounting for most of the phenomena of light in their minutest details, and has even anticipated many important results, subsequently confirmed by observation; whereas the theory of emission, though it gave a satisfactory account of

most of the phenomena known in Newton's time, is altogether unable to account for a vast number of facts which have since been discovered. The wave-theory is therefore now universally accepted as the true representative of the phenomena.

The existence of a fluid or medium, such as the theory supposes to exist in the celestial spaces, may be regarded almost as a matter of certainty: for the motions of comets are found to be retarded in a manner which cannot be accounted for on any other hypothesis. This phenomenon has been particularly studied in the case of Encke's comet, which revolves about the sun in a period of three years. Now this period is found to be continually diminishing, showing that the comet is gradually approaching the sun, an effect which can only be accounted for by supposing its motion to be retarded by the action of a resisting medium. Moreover, as the light-waves are transmitted freely, not only through the celestial spaces, but also through air, water, glass, and other transparent media, we must likewise suppose that the spaces between the molecules of these bodies are filled up by the ether. It will hereafter be shown that the elasticity of the ether is different in different media.

In the present article, after speaking of the sources of light, we shall endeavour to show how the wave-theory is applied to explain the several phenomena of Radiation, Interference, Reflection, Refraction, Absorption, and Polarisation.

The chemical action of light will be treated in a separate article.

Sources of Light.

The sun, the fixed stars, certain meteors, and terrestrial bodies in the states of incandescence and phosphorescence, shine by their own light; all other bodies, terrestrial or celestial, are visible only when the light of a self-luminous body falls upon them. Our knowledge of the peculiar conditions which render bodies self-luminous is not very exact; but assuming that vision is produced by undulations in an all-pervading elastic medium, we must suppose that these undulations are excited by vibratory movements in the particles of luminous bodies. This supposition is moreover in accordance with the conclusions deduced from the phenomena of heat (p. 131). The particles of all bodies are supposed to be in a state of constant motion, and it depends upon the intensity and rapidity of this motion whether the effect produced on our senses by the undulations thereby excited in the surrounding ethereal medium, is that of heat alone, or of heat accompanied by light. We shall see hereafter that the non-luminous heat-waves are of less rapid vibration than those which likewise produce light. Accordingly when the temperature of a body is gradually raised, it first gives out heat unaccompanied by light; but at a certain temperature, the vibrations become rapid enough to excite in the ethereal medium, waves which produce in our organs the sensation of red light, and at still higher temperatures vibrations are produced of a rapidity corresponding to those which excite the sensation of yellow and of blue light, which, together with the red, produce the combined sensation of white light. (See RADIATION OF HEAT.)

A body may be raised to the temperature necessary to render it luminous, either by chemical action (combustion) going on within its own mass (*e.g.* the burning of metals, wood, hydrocarbons, &c.), or by heat imparted to it from without, as by the combustion of a neighbouring body, by the electric current, by mechanical agency such as friction or percussion, or by the sun's rays concentrated upon it by a lens or mirror. Matter in either of the three states of solid, liquid, and gas, may be brought to the incandescent or self-luminous state; flame, indeed, is merely incandescent gas; but, as explained in the article COMBUSTION (i. 1094), solids become luminous at a much lower temperature than gases, and give out much more light at any given temperature: hence the brightest flames are those which contain suspended particles of solid matter raised to a very high temperature by the heat of the combustion.

The light of the sun and of the fixed stars is in all probability due to incandescence; indeed recent observations have shown that the luminous atmosphere of the sun contains many of the metals which exist in our own globe, and similar observations have been made on several fixed stars.

Phosphorescence.—Many bodies, under peculiar circumstances, are thrown into such a state of vibration that they emit light without perceptible evolution of heat. Phosphorus, in the state of slow combustion which takes place on exposing it to the air at ordinary temperatures, gives off acid vapours, which shine in the dark with a faint bluish light: hence the term *phosphorescent* has been extended to all bodies which exhibit a similar luminosity, from whatever cause it may arise. The phosphorescence of decayed bodies of plants and animals, as of dead wood and putrid sea-fish, is familiar to every one. The flowers of certain living plants, especially those of a bright yellow or red colour, as *Calendula officinalis*, *Tropeolum majus*, *Helianthus annuus*, and

Papaver orientale, have been observed to emit a sudden flashing light on fine summer evenings, a little after sunset. Some plants also emit in the dark a faint continuous light, probably arising from the combustion of some substance, such as a hydrocarbon, emitted from them; this phenomenon has been observed in the leaves of *Phytolacca decandra*, which shine at night, sometimes with bluish-green, sometimes with yellowish-green light. The acrid milky juice of *Cipo de Cananum* (a Brazilian plant, probably of the euphorbiaceous order) emits light for several hours, after flowing from a wound in the plant. *Rhizomorpha subterranea*, a plant which grows in mines, emits light from its whole surface, but especially from the whitish growing points, and a similar phenomenon has been observed in other subterranean plants.

A more familiar kind of phosphorescence is that exhibited by many living animals, as by the glow-worm and fire-fly, and the numberless small marine animals, such as crustacea, medusæ, polypora, and infusoria, which give rise to the phosphorescence of the sea at night. In many animals the phosphorescence is an act of the will; in others it takes place at a particular period of life.

In nearly all phosphorescent plants and animals, the phosphorescence appears to be due to chemical action, in fact to a slow combustion: for it increases in brightness in pure oxygen gas, and ceases altogether in a vacuum or in nitrogen or carbonic acid gas; the phosphorescence of decaying fish, however, takes place in nitrogen as well as in air or oxygen.

Phosphorescence may be excited artificially in a large number of bodies by any cause which sets their particles in rapid vibration; viz., by heat, by the electric discharge, by mechanical action, and by insolation.

1. Many solid bodies become phosphorescent when thrown upon a heated surface; such is the case with diamond, chalk, certain varieties of fluor-spar, oyster-shells, paper, flour, especially that of maize, and indeed with most well-dried organic substances. This effect is not to be confounded with incandescence, for it takes place at temperatures much below an ordinary red heat; and the light emitted is generally of a blue or violet tint, instead of the dull red of incipient incandescence.

2. A lump of sugar through which a powerful electric discharge is passed, shines for several seconds afterwards with a beautiful violet light; and a similar effect is produced on many non-conducting minerals, but not on metals or other substances of good conducting power. Substances which have lost the faculty of becoming phosphorescent by heat or by insolation, recover it after they have been subjected to repeated electric discharges. There can be but little doubt that the immediate effect of the discharge is to throw the particles of the body into a state of rapid vibration, which is then communicated to the surrounding ethereal medium.

3. The phosphorescence produced by friction, percussion, and other mechanical actions, generally lasts only as long as the disturbing cause continues to act. In many cases a development of electricity takes place at the same time, and to this the light may be partly or in some cases wholly due; sometimes, however, the light emitted appears to be a direct consequence of the vibratory motion communicated to the particles by the mechanical disturbance. *Adularia* struck with a hammer so as to split it, emits at each crack a light which may last for several minutes; and when ground in a mortar, it appears all on fire. Quartz, fluor-spar, rock-salt, and sugar likewise exhibit light when broken or pounded.

Light is often emitted during the change of state of bodies, especially in the passage from the amorphous to the crystalline state, and the separation of crystals from a solution (i. 200).

4. *Insolation*, or exposure to the sun's rays, develops phosphorescence most easily in substances which are bad conductors of heat. Most calcareous substances are capable of becoming phosphorescent by insolation: e.g. carbonate and sulphate of calcium, fluor-spar, petrifications, shells, and pearls.

Canton's phosphorus, prepared by heating calcined oyster-shells with sulphur, emits after insolation a yellow light bright enough to show the time by a watch. The phosphorescence may even be excited by exposure to the light of a candle. The *Bolonyian phosphorus*, prepared by strongly igniting heavy spar with gum-tragacanth, emits, after insolation, a bright light which lasts for more than a day. *Baudouin's phosphorus* (fused nitrate of calcium) emits a white light. Diamonds sometimes remain phosphorescent for an hour, after exposure to the sun for a few seconds only. Certain organic substances, e.g. flour, sugar, gum, white wax, and resin, also shine after insolation.

From recent researches by E. Becquerel, it appears that the number of bodies rendered phosphorescent by insolation, is much larger than has hitherto been supposed, phosphorescence, lasting for a few seconds, or rarely for a few minutes, being exhibited by numerous minerals and salts, chiefly with alkaline or earthy bases. (See *Daguin's Traité de Physique*, iv. 260.)

For numerous details relating to phosphorescence, see *Gmelin's Handbook* (i. 181—209).

The Electric Light.—The passage of electricity, when it meets with a certain resistance, is accompanied by light, more or less bright in proportion to the strength of the charge and the degree of resistance. As the discharge in all cases, even in the most highly rarefied atmospheres, such as Gassiot's tubes (ii. 391), takes place through the medium of material particles, we may suppose in this case also that the light owes its origin to vibrations excited in these particles by the electric action.

Radiation.

To understand the manner in which the vibrations of luminous bodies are transmitted in waves or undulations through the surrounding ether, it will be necessary to consider shortly the nature of undulations in general. A *wave* or *undulation* is a disturbance excited in one part of a body, and communicated to the other parts in regular succession. For example, a stone thrown into water depresses the water at the part where it is thrown in; the portion so depressed exerts a lateral pressure on the immediately surrounding it; and these again exert an upward pressure on the particles external to them, and form a raised circle; afterwards these portions fall, and in falling, push up other particles, situated external to them, and thus the undulation continually spreads outwards in concentric circles till it extends to the whole surface of the liquid. Now it is important to notice that these particles have no progressive motion; they merely move up and down, as may be seen by observing the motion of a light body floating on them: there is an appearance of progressive motion, but it is only an appearance, arising from the same form or state of motion being successively communicated to the different parts of the liquid. The wave travels onwards, perhaps for miles, or, as in the case of the ocean tide-wave, all round the globe; but the individual particles of water merely move in vertical lines through spaces not exceeding a few feet. Again, in the case of the waves in air which produce sound, the individual particles of air merely move backwards and forwards through small intervals, the motion being first excited in the particles immediately in contact with the sounding body, afterwards communicated by these to the next, and so on, and this communication of the vibratory motion from particle to particle constitutes a wave of sound. Here again the progress of the wave must be carefully distinguished from the motion of the individual particles. Sound travels through the air at the rate of about 1100 feet in a second; now if the individual particles of air whose vibration produces the sound were to rush onwards at that rate, every sound would be accompanied by a disturbance of the air amounting to a hurricane.

Thus it is also in the case of light. The motions of the individual particles of the ether take place through immeasurably small spaces, but are communicated with immense rapidity to the next; from these to those beyond them, and so on, even through the vast distances between the heavenly bodies. So long as the ether through which the light-wave travels is of uniform density—as we must suppose it to be in free space, and in media of uniform constitution, such as water, glass, and other uncrystallised bodies—the wave spreads with equal velocity in all directions; consequently, all the particles to which the motion extends at the same instant are situated on the surface of a sphere having the luminous body in its centre, and the illumination extends in lines at right angles to this wave-surface, that is to say, in straight lines radiating from the luminous body: these lines are called rays of light. When any change of density takes place in the medium, the wave-surface is no longer perfectly spherical, and the rays are broken or curved according as the change of density is sudden or gradual.

The vibrations of the particles of an elastic medium may be of two kinds: 1. *Direct* or *longitudinal*, when the line of vibration coincides with, or is parallel to, the direction in which the wave travels onwards, as in the case of sound-waves in air.—2. *Transverse* or *normal*, when the particles vibrate in directions at right angles to the motion of the wave, as is the case with waves in water, and with the vibrations of a stretched cord set in motion by drawing a bow across it.

Suppose a particle of an elastic medium to be disturbed in any direction whatever. This direction will in general be oblique to the line joining this particle with the next, and the actual velocity of the particle may be resolved into three others, one in the direction of the line of junction between the two particles, that is to say, in the direction in which the wave-motion proceeds, the other two in a plane at right angles to it. The first component determines the longitudinal, the other two the lateral motion or vibration of the particle; and the relative distances to which these two kinds of vibration are propagated depends upon the peculiar constitution of the medium. When the air is set in motion by the vibrations of a sounding body, it is the longitudinal vibrations which travel onwards, producing a series of compressions and

dilatations of the air along the line of the wave, and these motions ultimately reaching the ear, produce the effect of sound: the lateral vibrations, on the other hand, appear to be quickly extinguished; at all events, they produce no effect upon the ear. With the vibrations of the luminiferous ether, however, the case is exactly reversed; for, as will be seen hereafter, the phenomena of polarised light show plainly that the transverse vibrations of the ether are the only ones which affect our visual organs. With regard to many phenomena, however, the particular directions of the vibrating particles may be left out of consideration.

To explain more clearly the mode of transmission of the transverse vibrations of the ether-molecules, suppose that a row of these particles, a, b, c, d (fig. 640), situated in a homogeneous medium, is brought by any disturbing force into the position $a' b' c' d'$. The sum of the forces which hold the particles m, n , of the contiguous rows in their places will then be altered. If the displacement itself is small in comparison with the distances between the molecules, the forces at right angles to the line of displacement will remain unaltered; but the repulsion exerted by b upon n in the direction of displacement has increased, while that of d upon n is diminished. The same is true with respect to m , and all the particles in the same horizontal row, which, therefore, soon move in the same direction as a, b, c, d . This latter row of particles is, however, urged back to its original position, with a force equal to that with which it set the other particles in motion; so that its velocity in the primary direction is gradually destroyed, and it returns to its original position, which, however, it passes beyond, in consequence of the momentum which it has acquired, thus performing a succession of small oscillations like those of a pendulum. Similar oscillations are performed successively by the second, third, and other rows of particles; and if by the time that the first row of particles, a, a' (fig. 641), has completed a single oscillation, backwards and forwards, the vibratory motion has extended as far as b , the rows of particles between a, a' and b, b' inclusive will exhibit all possible phases of the movement. The distance a, b between two layers of corresponding phase is the length of a complete wave; the ray r, s , or the wave-surface normal to it, traverses this distance in the time in which the row of particles a, a' performs a complete oscillation. The greatest distance attained by any particle from its position of equilibrium during the time of a complete oscillation, is called the amplitude of the vibration. It is proportional to the greatest velocity of the particle during its passage through its position of equilibrium. The intensity of the light is proportional to the *vis viva* of the vibratory particles, and therefore to the square of the amplitude of the vibration.

Fig. 640.

Fig. 641.

Velocity of Light. The rate at which a wave travels through an elastic medium is a function of its elasticity and density, and when these are known, as in the case of sound, the rate of propagation may be calculated *a priori*, by the formula $v = \sqrt{\frac{c}{d}}$ (see p. 41). But, in the case of light, these elements are unknown, and therefore the velocity can only be determined by observation. The following methods have been adopted:—

1. *By Observations of the Eclipses of Jupiter's Satellites.*—This method was proposed and carried out by the Danish astronomer Römer in 1676. He found that, when the earth is between the sun and Jupiter, that is to say, at its least distance from that planet, the nearest of Jupiter's four moons enters the shadow of the planet at intervals of 42 h. 28' 35". Now, calculating from this the time at which the 100th eclipse should take place, observation showed a retardation of 15 minutes behind the calculated time. But in the same interval, the earth had travelled about half round its orbit, and had therefore increased its distance from Jupiter by nearly half the diameter of that orbit. This then was the distance which the light from Jupiter had passed over in 15 minutes; and thence the velocity of light was found to be 77,000 leagues, or 187,600 geographical miles per second. At this rate it takes 8' 13" to reach us from the sun, 4 h. 10' from Neptune, and about 10 years from the nearest fixed star (61 Cygni).

2. *By the Aberration of the Fixed Stars.*—The motion of the earth in its orbit, combined with that of the light coming from the stars, causes them to appear, not in their

true places, but in the direction of the resultant of these two motions. The apparent positions of all the stars are, accordingly, shifted in the direction in which the earth is moving. Each star, in the course of the earth's annual revolution, describes a small ellipse round its true place; for a star in the pole of the ecliptic, this ellipse is nearly a circle of $20'445''$ apparent diameter. The tangent of this angle gives the ratio between the velocity of light and that of the earth in its orbit; and the latter being known by independent observation, the velocity of light is thence found to be 166,072 geographical miles per second, a result differing from that of Römer by less than 1 per cent. It must also be observed that Römer's method gives the velocity of reflected light in free space, whereas the aberration method gives the velocity of direct light in air.

3. *Measurement of the velocity of light by small distances.*—*a. Fizeau's method.* A toothed wheel having its teeth of the same width as the intervals between them is made to revolve rapidly, so that its teeth may pass through a beam of light proceeding from a lamp or other source, the light being thus intercepted by the teeth, and passing through only at intervals. The light which passes between the teeth of the wheel is reflected perpendicularly from a plane mirror placed at a great distance; it then returns along the same path, and again passes between the teeth of the wheel. Now, during the time occupied by the light in travelling twice over the space between the wheel and the mirror, the wheel will have performed a certain part of its revolution; and if it turns with a due degree of velocity, the light which has passed in the first instance between two of the teeth will strike, at its return, on the face of a tooth instead of a space between two teeth, so that an observer looking through the wheel in the direction of the mirror, will not, in that case, perceive any light. The time which the light takes to pass from the wheel to the mirror and return, is therefore equal to that in which a tooth of the wheel moves into the place previously occupied by the space immediately preceding it, which time is easily calculated from the known velocity of the wheel and the number of its teeth. If, for example, the wheel has n teeth and makes t revolutions per second, each tooth will pass into the place of the preceding tooth in $\frac{1}{nt}$ of a second, and into the place of the space next preceding, in $\frac{1}{2nt}$ of a second. Fizeau's experiments, in which the wheel and mirror were placed at a distance of 8633 metres (between Turesnes and Montmartre), gave, as the velocity of light in air, 78,841 leagues of 4 kilometres each per second. Römer's method gave 77,000 leagues.

Fizeau's method might be applied to show that rays of light of all colours (like waves of sound of every pitch) travel with the same velocity. This conclusion may, however, be regarded as established by the fact that all the stars, whatever may be their colour, exhibit equal aberration, which could not be the case if rays of different colour travelled with different velocities.

B. By means of a Revolving Mirror.—This method, proposed by Arago, and carried out independently by Foucault, and by Fizeau and Breguet, is similar in principle to that by which Wheatstone determined the velocity of electricity, and affords the means

Fig. 642.

of measuring the velocity of light in a space not exceeding four metres. A line of light, S (fig. 642), proceeding from a very narrow rectangular aperture at right angles to the plane of the figure, after passing through the converging achromatic lens K, which would form an image of it at S', falls upon a plane mirror, mn , capable of revolving on a vertical axis passing through o on the line SS' , which reflects it to s' , a point symmetrical with S', as regards the mirror. At this point is placed a concave spherical mirror, M, whose

centre of figure o . The light falling on this mirror is reflected back again, along the same path, $s'o$, to the plane mirror, mn , which again reflects it to S in a beam coinciding with the incident light. This will be the case in all positions of the mirror mn , provided the light is reflected from it to M . As the image thus sent back to S would be confounded with the incident beam, an unsilvered plate of glass, ab , is placed in such a position, that the light falling upon it in the direction of oS may be partly reflected to s , where it may be observed by an eye-piece furnished with a vertical wire. If the mirror mn be made to revolve slowly, an eye placed at s will see the image of the line of light at intervals, but if the mirror makes more than 10 turns in a second, the image will be seen continuously; and if the eye-piece be adjusted, so that the image shall coincide with the wire, when the mirror makes from 20 to 30 revolutions per second, it will be seen to deviate in the direction of the rotation when the rate is increased to several hundred turns per second; if, for example, the mirror turns in the direction of the arrow, the image will be displaced from S to R , or from s to r . The cause of the displacement is that the mirror mn has time to revolve through a sensible angle, during the time occupied by the light in travelling from o to s' and from s' to o , so that the beam of light, at its second reflection from mn , is deflected from its first direction, forming, with the incident beam So , an angle equal to twice the angular displacement of the mirror.

The mode of calculating the velocity of light from the observed deviation is as follows:—Let $Sc = r$; $co = l$; $os' = l'$; the arc of deviation SR or $sr = d$; also let n be the number of turns performed by the mirror mn in a second, and V the velocity of the light. The mirror mn having moved into the position $m'n'$, by the time that the ray reflected from M returns to it, the deviation would be equal to the angle SoR , if the ray were not deflected by the lens cK , or, which comes to the same thing, if the point c coincided with o . Suppose, first, that this is the case; then the angle SoR is equal to twice the angle α , through which the mirror revolves during the time occupied by the light in passing over the space $2os' = 2l'$. This time is $\frac{2l'}{V}$, and since the mirror makes n turns in a second, the angle $\alpha = \frac{2nl'}{V}$. The angle of deflection of the ray is therefore $\frac{4nl'}{V}$, and the corresponding arc, whose radius is $oS = r + l$, is

$$d = 2\alpha \cdot 2\pi \cdot oS = \frac{8\pi nl'(r+l)}{V}.$$

But the reflected ray is actually deflected by the lens K . Draw $R'o$ through the optic centre c and the point R' , which is the image of s' in the mirror $m'n'$. The image of R' , formed by the lens K , will then be at E , and the angle of deviation will be $ScE = \delta$. Now the triangles $oR'S'$, $cR'S'$, give $\sin R'oS' = \sin \delta = \frac{R'S'}{S'o} = \frac{R'S'}{l+l'}$; and $\sin R'oS' = \sin 2\alpha = \frac{RS'}{r}$. Hence, replacing the angles (which are very small) by their sines, and substituting for 2α its value $\frac{4nl'}{V}$, we find $\delta = \frac{4nl'^2}{V(l+l')}$; and for the arc $SE = D = 2\pi r\delta$:

$$D = \frac{8\pi l'^2 nr}{V(l+l')}; \text{ whence } V = \frac{8\pi l'^2 nr}{D(l+l')}.$$

a formula which gives the velocity of light as a function of the deviation.

The same method serves also to measure the velocity of light in water or any other liquid, a tube T containing the liquid, and closed at the ends with flat glass plates, being interposed between the mirror mn and M' . As, however, the light would be refracted by the liquid, and therefore the focus would not fall on M' , a diverging lens is placed at L to compensate for the deviation thence arising.

Moreover, as the column of water does not occupy the entire space between the mirrors, the velocity calculated as above from the observed deviation is only the mean velocity of light in a space occupied partly by water and partly by air. Let U be this mean velocity; w and a the spaces occupied by the water and air respectively; V and V' the corresponding real velocities. The times occupied by the light in traversing the

spaces a and w are $\frac{a}{V}$ and $\frac{w}{V'}$, and the whole time is $\frac{aV' + wV}{VV'}$. Hence, dividing the total space $a + w$ by the time, we find for the mean velocity:

$$U = \frac{VV'(a+w)}{aV' + wV},$$

whence

$$V' = \frac{wUV}{(a+w)V - aU}.$$

By this method it is found that the velocity of light in water is less than in air, a

result which, as will be seen hereafter, is in accordance with the wave-theory, while it is directly opposed to that which would follow from the theory of emission.

Intensity of Light. The intensity of the light received by a surface from any given source—that is to say, the quantity of light received by a unit of the surface—depends partly on its distance from that source, partly on the obliquity at which the light falls upon it.

1. *The intensity of light emanating from a point varies inversely as the square of the distance.* For, as the undulations excited by the luminous source travel with equal velocity in all directions—supposing the medium uniform—they may be regarded as spreading out in concentric spherical surfaces of continually increasing magnitude; and as these surfaces are to one another as the squares of their radii, it follows that the quantity of light received by a unit of surface will vary inversely as the square of the radius of the sphere of which it forms a part—that is to say, as the square of its distance from the luminous point.

If the luminous body is of finite dimensions, the preceding law, being applicable to the light emanating from each point of its surface, must likewise hold good with regard to the whole, provided the body is sufficiently distant to admit of all its points being regarded as equally distant from the illuminated surface; and since the apparent diameter varies inversely as the distance, *the intensity of the light will vary in direct proportion to the square of the apparent diameter or to the apparent surface of the luminous body*, understanding by this last term the conical angle of a cone enveloping the body and having its vertex at the luminous point.

2. *The intensity of the light received by any surface varies as the cosine of the angle which the incident rays make with the normal to that surface.* For suppose AB (fig. 643) to be a portion of the illuminated surface, so small that the rays falling upon it may be regarded as parallel. The quantity of light received by AB , is the same as that which would fall on its projection BC , on a plane perpendicular to the direction of the rays, and therefore exposed to their full effect; hence the intensity of the light falling on these two surfaces is inversely as their areas; but $BC = AB \cdot \cos ABC = AB \cdot \cos SBN$, the angle which the incident rays make with the normal BN .

3. *The intensity of the light emanating from a self-luminous surface, is proportional to the cosine of the angle which the rays make with the normal.* This proportion may be demonstrated in a similar manner to the preceding, and the result may be verified by looking through a small aperture at an incandescent surface, as that of red-hot iron, and inclining it more and more to the direction of the rays proceeding from it to the eye. In accordance with this law, it is found that the brightness of a luminous surface is independent of its form and of its position with regard to the visual rays, the impression produced by it on the eye being the same as that produced by a plane surface of equal intrinsic lustre, which is the projection of the original surface on a plane perpendicular to the visual rays: a red-hot ball, for example, seen from a distance looks just like a flat disc.

Comparison of the Intensity of two Luminous Sources: PHOTOMETRY.

The eye is not capable of judging directly, with any great approach to accuracy, of the relative intensity of two lights, but it can perceive with great nicety whether two contiguous surfaces or portions of the same surface are equally illuminated, or whether two contiguous shadows have or have not the same depth. On this principle are constructed most of the instruments called *Photometers*, for measuring the relative intensity of different sources of light.

Rumford's *Photometer*, which is very easily constructed, consists of a small wooden cylinder set upright in front of a sheet of white paper, also placed vertically. The two lights to be compared (a candle and gas-flame, for example) are placed at the same height in front of the paper, and in such a manner that the two shadows of the wooden cylinder which they cast, shall fall on the paper close together, and that the rays from both of them shall meet the paper at the same angle. Each shadow will then be illuminated by only one of the lights, while the rest of the surface will receive the rays from both, and the two shadows will be of the same depth when the surface of the paper is equally illuminated by both lights. If then the stronger light be moved farther off till the shadows are equally dark, the intensities of the two will be directly as the squares of their distances from the screen when that condition is fulfilled.

Fig. 643.

This photometer gives very exact results in many cases; but in applying it to determine the relative illuminating power of a gas-flame and a candle, a difficulty arises from the different colours of the two shadows, that of the gas being bluish-brown, while that of the candle is yellowish-brown. In all such cases, Bunsen's photometer, whose indications do not depend on depth of shadow, is much more convenient.

Bunsen's *Photometer* consists of a screen of thin writing paper stretched on a frame, and saturated with a solution of spermaceti in oil of turpentine, except a spot in the centre about the size of a shilling. A light of constant intensity being placed at a fixed distance behind the screen, the ungreased spot appears darker than the rest of the screen. One of the lights to be compared is then placed in front of the screen, so that its reflected rays may be added to the light transmitted from behind, and adjusted so that the ungreased spot shall be illuminated just as much as the rest of the surface, and shall therefore be no longer visible. This will be the case when $T + r = t + R$, denoting by T , t , the quantities of light transmitted by the uncovered part of the screen, and the part covered by the disc respectively, and by R , r , the quantities reflected. A precisely similar experiment being then made with the other source of light, the intensities of the two will be to one another as the squares of their distance from the screen at which the disappearance of the disc takes place. Sometimes the grease is applied only to a small circular spot in the centre of the screen, which then transmits more light than the rest of the surface.

Masson's *Electro-photometer*. This apparatus has the advantage of admitting of the comparison of lights of different colours. It consists of a circular disc divided into white and black sectors of equal size, and set in motion by clock-work at a uniform rate of 250 to 300 revolutions in a second. If it be then illuminated by a constant source of light, such as a lamp, it appears of a uniform grey tint, in consequence of the duration of the visual impression on the eye. But if it be illuminated by an instantaneous light, such as the electric spark, the black and white sectors become distinctly visible, and appear as if they were fixed, because they have not time to move through a sensible angle during the extremely short interval for which the spark continues. If now the intensity of the light afforded by the spark be gradually diminished, as by removing it to a greater distance, the source of constant light still remaining, the increase of illumination which the spark affords to the disc ultimately becomes too feeble to render the sectors visible, so that the disc still continues to exhibit a uniform grey tint. The relative intensities of the constant and instantaneous lights at which this limit is attained, evidently depend upon the number of the sectors and the velocity of revolution.

The relative intensities of two electric sparks are as the squares of the distances to which they must be removed from the disc to cause the sectors to disappear, while the disc is illuminated by a constant light. On the other hand, to use the instrument for comparing the intensities of two continuous lights, a succession of electric sparks is made to pass in front of the disc, and one of the constant lights is made to approach it till the sectors cease to be distinguishable. The same experiment being then made with the other light, the intensities of the two are as the squares of the distances thus determined.

By means of this instrument, M. Masson has demonstrated the following laws relating to the intensity of the electric light. 1. *It is proportional to the coated surfaces by the discharge of which, at a constant distance, the spark is produced.* 2. *It is inversely as the distance between those surfaces, or as the thickness of the jar.* 3. *It is proportional to the square of the striking distance.* 4. *The quantities of light in the spark are proportional to the quantities of heat developed in a wire forming part of the same circuit.*

General results of photometric observation.—1. By comparing the quantities of light emitted by the same number of flames in different relative positions, it is found, that flame is perfectly transparent; in fact the luminous effect of a series of candles placed side by side, is the same whether they are arranged in a line perpendicular or parallel to the direction of the rays. In like manner, a flat gas-flame, like that of a bat's-wing burner, gives the same amount of light in all directions.

2. It appears from observations by Bouguer, made with Rumford's photometer, that one of the shadows thrown by lights of equal brightness disappears when one of these lights is placed 8 times as far from the screen as the other—that is to say, when the nearer light illuminates the screen 64 times as strongly as the other. Hence it appears that light emanating from any source becomes imperceptible in presence of another 64 times as strong; the disappearance of the stars in daylight shows, therefore, that the diffused light of the earth's atmosphere must be at least 64 times as strong as that sent to us from any of the stars.

3. When the flames of two lamps or candles touch one another, the intensity of the

combined flame is greater than the sum of the intensities of the separate flames. This effect, first observed by Franklin, appears to be due to the increased temperature at the part where the flames overlap. Rumford found that a number of flat cotton wicks impregnated with oil, gave a much greater amount of light when they were placed together nearly in contact, than when they were separated. On the same principle, Arago and Fresnel have constructed lamps for light-houses, in which a number of concentric wicks are arranged with small spaces between them, through which a current of air is made to pass by the draught of a chimney. The flame being transparent, a considerable amount of light is thus obtained within a small space.

4. The photometric method serves also to determine the illuminating equivalents of different light-giving materials. Rumford found that 100 pounds of wax burnt in the form of a taper, were equal in light-giving power to 101 lbs. of tallow, if the candles were well snuffed, and 229 lbs. if the wicks were allowed to grow long; to 100 lbs. of olive oil burnt in an Argand lamp, and 129 in a lamp burning without smoke; also to 125 lbs. of rape oil, and 120 lbs. of linseed oil in a common lamp. Péclet calculated the following table of the expense per hour of various modes of illumination, yielding a quantity of light equal to that afforded by a gas-jet burning at the rate of 6 centimes per hour:

	Centimes.		Centimes.
Carcel lamp	5·8	Wax taper of 100 grm. . .	48·6
Candle of 82 grm.	9·8	Stearine candle	18
Candle of 10 grm.	12·0		

It appears from this comparison that gas is the most economical of all illuminating materials. The results depend, however, in a great measure on the facility of access of air to the flame, the form of the wick or burner, and the length of the flame. For numerous determinations of the illuminating equivalents of various kinds of gas, and other light-giving substances, see *Ure's Dict. of Arts, &c.*, articles COAL-GAS (i. 734) and ILLUMINATION (ii. 493).

Interference.

When two or more waves pass over the same part of a medium, each of them affects the particles of the medium disturbed by the other just as it would have affected the same particles in a state of rest. Consequently, the state of any particle affected by the two waves at once, will be the same as that which would have resulted if it had been first disturbed by the one wave, and then the second had acted upon it while in that disturbed state. Thus the height of the tide is found by calculating the heights to which it would be raised by the sun and by the moon acting separately, and taking the sum or difference as the case may be.

Suppose now two waves of equal breadth and intensity (equal height in the case of water) to proceed from the same, or nearly the same point, and travel onwards one after the other; then, if they meet in such a manner that the phases or alternations of the one coincide with the phases or alternations of the other, the result will be a compound wave, having the sum of the intensities of the separate waves; this will be the case if the paths along which they travel before meeting are of equal length, or if one exceeds the other by any exact number of whole undulations, as in *fig. 644*; but if the phases of the one are exactly opposed to the phases of the other, which is the case

Fig. 644.

when the one wave is behind the other by any odd number of half-undulations, as in *fig. 645*, a wave will be produced whose intensity equals the difference of the intensities

Fig. 645.

of the separate waves, and if these are equal, the vibratory motion will be completely destroyed and the particles of the medium brought to rest along the whole line of the combined waves. If the paths of the two waves do not differ by any exact number of half undulations, even or odd, the result will be intermediate between the two just considered, the intensity of the combined wave being always less than the sum and

greater than the difference of the separate waves. This composition or superposition of oscillations is called Interference. In order that it may take place along a whole line of wave, it is clear that the component waves must be of the same breadth, and that they must proceed from points very near each other, otherwise their paths will intersect only at isolated points.

Let us now enquire whether these principles are applicable in the case of light. If light consists of undulations, and these undulations are governed by ordinary mechanical laws, it must follow that two rays of light may meet one another in such a manner as to counteract each other's action and produce darkness; and such, in fact, is found to be the case.

Suppose s, s' (fig. 646) to be two radiant points very close together, and producing in the luminiferous ether, waves of the same length (of red light, for example) and always in the same phase of vibration at the instant of starting from these points. Imagine also two series of spherical wave-surfaces having the points s, s' for centres, and with radii increasing successively by half the length

of a wave = $\frac{\lambda}{2}$. These sur-

faces will cut the plane of the figure in two systems of arcs, which will intersect one another in the manner shown in the figure, in which each two consecutive arcs, one represented by a full, the other by a dotted line, are separated by the interval $\frac{\lambda}{2}$, and each pair of alternate arcs (both full or both dotted) by the interval λ , or a whole undulation.

Consider now the point a , situated on the line Aa , drawn perpendicular to ss' , through its middle point A . The two rays $sa, s'a$, being of equal length, are in the same phase of vibration: consequently their intensities will be added to one another and will produce increased light, and the same effect will be produced at c, e , and at all the intersections of the continuous arcs, where the difference in length of the rays proceeding from the points s, s' is equal to any multiple of λ or to any even multiple of $\frac{\lambda}{2}$. But at n, n' or any other intersections of a continuous and a dotted arc, where the difference in length of the rays $sn, s'n$, &c., is equal to $\frac{\lambda}{2}$, or any odd multiple

thereof, the rays are in opposite phases, so that their vibrations act against one another, and the amount of light at those points is less than it would be if only one of the rays arrived there. The distance between the points s, s' being very small compared with Aa , the surface anc is very nearly plane, so, that if a white screen be placed there, a succession of luminous points, a, c, e , &c., will be formed upon it separated by dark spaces, n, n' , &c.

If the sources s, s' , instead of being luminous points, are lines of light perpendicular to the plane of the figure, a series of alternate light and dark bands, or fringes, will be produced parallel to those lines.

The conditions essential for exhibiting these effects are, that the two luminous sources s, s' shall be very near one another, and that the waves emanating from them shall always be simultaneously in the same phase. These conditions are most easily fulfilled by the following arrangement devised by FRESNEL:—

A beam of light entering through a rectangular slit in the shutter of a darkened room, and passing through a plate of red glass, is condensed at S to a very fine line of light, by a cylindrical lens L (fig. 646) of very short focus. The rays there cross each other, and fall upon two plane mirrors lm, lm' , placed together at a very obtuse angle, and having their line of intersection parallel to the line of light. The rays, after reflection from these mirrors, proceed as if they had originally issued from two points s, s' , situated symmetrically to the point S , behind each of the mirrors. The mirrors being

placed nearly in one plane, the points $s s'$ are very close together, so that all the conditions are fulfilled for the production of light and dark fringes on the screen, as above described.

Instead of reflecting the light diverging from S from two plane mirrors, it may be made to pass through a glass prism having a very large refracting angle. The fringes also, instead of being received on a screen, may be viewed through a telescope, and their angular breadths estimated by micrometrical measurement.

If the beam of light proceeding from one of the points s, s' , be intercepted, the whole of the fringes disappear, and the light from the other source produces a uniform illumination on the screen, plainly showing that the fringes are produced by the combination or interference of the rays proceeding from the two sources.

Measurement of the lengths of the waves of light.—The breadths of the fringes having been ascertained, as above described, an easy calculation gives the lengths of the waves of the particular light by which they are produced. In fig. 646, the length of the wave λ is equal to the distance za . Now the curvilinear triangle azo may be regarded as a right-angled triangle, whose hypothenuse $ac = b$ is the distance from the centre to the first bright lateral fringe. Moreover, the angles zca and $sas' = \omega$ are equal, because their sides are respectively perpendicular to one another: hence

$$\lambda = b \sin \omega.$$

Hence to obtain the value of λ , it is sufficient to measure the angle sas' with a repeating circle, and the distance ac with a micrometer. A more exact mode of determination will be described hereafter.

The length λ is proportional to the distance ac . Now the breadth of the fringes is found to be greatest in red and least in violet light, and of intermediate breadths for the intermediate colours of the spectrum: hence also it follows that the lengths of the waves are greatest in red and least in violet light.

The formula $\lambda = \frac{v}{n}$, in which v is the velocity of light, and n the number of vibrations per second, shows that the vibrations are most rapid in violet, and least rapid in red light.

The length of the wave and the rapidity of vibration of the particles of the ether determine the colour of the light, just as the length of the sound-wave and the rate of vibrations of the particles of the air, determine the pitch of sound.

The following table exhibits the wave-lengths and the number of vibrations per second of the mean rays of the several colours of the spectrum, and of the principal fixed lines:

Fixed lines and colours.	Values of λ in ten-thousandths of a millimetre.	Number of vibrations per second in millions of millions.	Fixed lines and colours.	Values of λ in ten-thousandths of a millimetre.	Number of vibrations per second in millions of millions.
Line B . . .	6.88	. .	Mean green . .	5.12	601
Line C . . .	6.56	. .	Line F . . .	4.84	
Mean red . .	6.20	497	Mean blue . .	4.75	648
Line D . . .	5.89	. .	Mean indigo . .	4.49	686
Mean orange .	5.83	528	Line G . . .	4.29	
Mean yellow .	5.51	529	Mean violet . .	4.23	728
Line E . . .	5.26	. .	Line H . . .	3.93	

The expression $b = \frac{\lambda}{\sin \omega}$, which gives the breadth of the fringes in terms of the wave-length and the angle ω , shows that for each colour they are broader in proportion as that angle is smaller. If it is too large, that is, if the distance $s s'$ is too great in proportion to Aa , the fringes disappear altogether; they are still visible, however, when this angle has a magnitude of several degrees.

The fringes being of different breadths in the different coloured lights, and white light, as will hereafter be shown, being a mixture of all the colours of the spectrum, it follows that when the preceding experiment is made with white light (sun-light, the electric light, or the lime-light), the bands produced are not simply bright and dark alternately, but exhibit a succession of colours produced by the combination of the simple colours in various proportions, and not separated by any absolutely dark bands. Moreover, these coloured fringes are much less numerous than the simple light and dark bands produced by homogeneous light, because the breadths of the simple-coloured fringes of which they are composed do not vary proportionally to one another, as their distance from the centre increases; hence, they ultimately become

mixed, and reproduce white light. Even the simple fringes formed in homogeneous light become less and less distinct as they recede from the centre, and ultimately disappear when the difference between the lengths of the rays which form them becomes equal to a certain number of half-undulations. The cause of this disappearance is, that the light used in the experiment is never absolutely homogeneous, and that the want of perfect equality between the lengths of the waves which compose it, ultimately makes itself perceptible, the fringes of different breadths overlapping and effacing each other in the same manner as when white light is used, though at a much greater distance from the centre. Whatever kind of light is employed, the fringes are more distinct and numerous in proportion as the line of light is narrower, provided it be wide enough to give the required amount of illumination; for it is evident that a broad aperture may be regarded as a number of narrow ones placed side by side, each producing its own set of fringes, which, as they do not coincide in position, will overlap and efface each other more or less completely.

If a very thin plate of glass, mica, selenite, or other transparent substance be placed in front of one of the mirrors (fig. 646), so that the rays proceeding from one of the points, s, s' , shall be obliged to pass through it before reaching the screen or telescope, the whole of the fringes will be displaced towards the side on which the transparent plate is situated, so that the central fringe a will no longer be opposite to A . Suppose the displacement to be towards the right of the figure; then the line $s'a$ will be shorter than sa . Now, as the two rays forming this central fringe must contain the same number of wave-lengths, it follows that these wave-lengths are less in the more highly refracting substance (glass, &c.) than in the air. The velocity of the light is, therefore, diminished in the more highly refracting medium; and experiment shows that the retardation thus produced is greater as the refracting power is greater. This result is in accordance with the direct measurement of the velocity of light in air and water (p. 596), and likewise, as we shall presently see, with the law of refraction. Moreover, as the velocity of transmission of vibrations in an elastic medium is related

to its elasticity and density by the equation $v^2 = \frac{e}{d}$, it follows also that the elasticity of the ether is least, or its density greatest, in the most highly refracting media.

The transparent plate used in the experiment just described must be extremely thin; otherwise the fringes will disappear altogether, just as if an opaque screen had been interposed. A thicker plate would, in fact, shift the fringes beyond the space in which the two systems of waves meet each other, namely, the space bounded by the two straight lines passing through s, s' and the intersection, I , of the mirrors.

Diffraction. The principle of interference serves to explain some very remarkable and beautiful phenomena which are observed when light passes by the edge of an opaque body, or through a small aperture. The effects thus produced consist in this, that the light bends to a certain extent within the geometric shadow bounded by straight lines drawn from the luminous point through the edges of the opaque body, just as a wave in water will turn the angle of a wall, or spread itself through a hole in any fixed obstacle. The result is the formation of a number of alternate bright and dark bands or coloured fringes, sometimes within the shadow, sometimes beyond it, sometimes in both places at once. These effects, formerly known as *Inflection*, but now called *Diffraction*, admit of complete explanation on the wave-theory of light, but are quite inexplicable on the theory of emission.

The explanation of diffraction on the undulatory theory depends upon the general principle first enunciated by Huyghens, that—*The vibrations of a wave of light, at each of its points, may be regarded as the resultant of the elementary movements which would be communicated to it, at the same instant, by all the parts of the same wave in any one of its previous positions.* For it is evident, from the elasticity of the ether, and the facility with which vibratory movements are transmitted through it, that its particles do not vibrate independently of each other, but that each may be regarded as a centre of disturbance with regard to all around it. Consequently, each point of a spherical wave, mn (fig. 647), will produce by its vibration, a number of secondary spherical waves, which, spreading out with the same rapidity, will have for their enveloping surface—that is to say, for the general surface of the wave as it spreads outwards—another spherical surface, $m'n'$, concentric with the former. Hence the vibration imparted to any point P , by the wave mn ,

Fig. 647.

when it reaches that point, may be regarded as the resultant of all the secondary disturbances emanating from the several points of mn .

To determine the manner in which the movement of P is affected by the several points of the wave in any of its previous positions, draw sP , cutting the wave mn in A (fig. 648), and designating the distance AP by γ , describe, from P as a centre, and

Fig. 648.

with the radii γ , $\gamma + \frac{1}{2}\lambda$, $\gamma + 2 \cdot \frac{1}{2}\lambda$, $\gamma + 3 \cdot \frac{1}{2}\lambda$, &c., a number of arcs cutting the wave in the points a , b , c , d , . . . and draw the straight lines Pa , Pb , Pc , &c., which evidently differ from another by half a wave-length. Then it will be found that the intervals Aa , ab , &c. are not equal, but continually diminish from A towards m . Further, for every point in ab , there exists a point in Aa , such that the lines drawn from these points to P differ by $\frac{1}{2}\lambda$, and consequently the waves emanating from these points to P will be in complete discordance. Hence, if Aa were equal to ab , its effect on P would be completely neutralised by ab ; but this not being the case, ab can only neutralise part of Aa , and there remains a portion of the arc Aa , which produces a certain degree of illumination at P . There is a further reason why ab neutralises only part of Aa , and that is, that it acts more obliquely. Similarly, cd will neutralise a part, but only a part, of the action of bc . Hence, it will be seen that the illumination produced at P by the half-wave Am is the sum of the effects of the arcs of uneven order over those of even order, counting from A . In all cases, however, it

is only necessary to take account of that part of the wave which is very near to the line sP : for at a greater distance, as at m , the arcs kl , lm become very nearly equal, and, moreover, their action on P is very oblique—for both of which reasons their effect on P may be neglected. The arc An acts exactly like Am , so that if the illumination produced by Am be denoted by 1, that of the entire wave mn will be equal to 2.

The arcs Aa , ab , &c. are called elements of interference, and the point A is called the pole of the point P .

The direction of vibration of the ether-molecule P at any instant is determined by that of the first element Aa , of the half-wave Am ; and if this portion were intercepted, the point P would then vibrate in the direction determined by the movement of ab , which is opposite to that of Aa . Hence, it appears that the action of Aa on P is greater than the resultant actions of all the remaining elements, ab , bc , &c.: for the motion of P changes its direction according as the element Aa acts upon it or not. The same is true with regard to each of the elements ab , bc , &c., the action of each one of them on P being greater than the resultant of all beyond it.

Now, suppose part of the half-wave Am to be intercepted by the interposition of an opaque screen; then the arc ab , which destroyed a great part of the effect of Aa , is removed, and the point P receives more light than it did before: for the effect of ab is greater than that of all the rest of the wave, from b outwards, taken together.—Next suppose the screen to terminate at b ; then, since ab destroys the greater part of Aa , and the rest of the wave is intercepted, P will now receive less light than it would if the screen were not there. In the same manner, it will be found that whenever the screen is so placed as to leave an odd number of elements of the wave free, the point P will be more illuminated than it would be if the screen were not there, and the contrary if an even number are left free.

These principles lead immediately to the explanation of the phenomena of diffraction.

1. *Fringes produced by rays passing along the edge of a screen.*—Suppose a beam of homogeneous light proceeding from a luminous point S (fig. 649), or better from a fine line of light passing through S at right angles to the plane of the figure, to pass by the opaque screen AB , of indefinite extent towards B , and fall upon another screen CD , covered with white paper. The boundary of the geometrical shadow will be determined by the straight line SAP . The light received at P will proceed from the half-wave Am , and may be represented by 1; and from the preceding explanations it follows that the points c , c' , &c., so situated that $Ac - ac = \frac{1}{2}\lambda$; $Ac - d'c' = \frac{3}{2}\lambda$, will receive more light than if the screen were not there, and will therefore be the centres of bright fringes; and on the contrary, the points n , n' , &c., for which $An - bn = \lambda$

$As' - b'n' = 2\lambda$, &c., will receive less light than if the screen were away, and will therefore be the centres of dark fringes. The general result may be thus stated: The presence of a screen increases the intensity of the light at every point so situated that the broken line (SA, Ac for example) passing to it from the source of light by the edge of the screen exceeds the straight line (Sc) drawn to it directly from the luminous source, by an *odd* number of half undulations, and diminishes the intensity of the light at every point so situated, that the broken line (SA, An) proceeding to it from the luminous point by the edge of the screen, exceeds the straight line joining it with the luminous point, by an *even* number of half-undulations.

In this manner, a succession of bright and dark fringes are produced beyond the geometrical shadow of AB; they may either be received on the screen CD, or viewed by a telescope directed to the edge A, the latter being of course the better method for exact measurement. They become less and less distinct as their distance from the edge of the shadow increases, because the successive arcs Aa, ab, bd, &c. do not neutralise each other's action completely, so that a small quantity of light always mixes with the dark fringes, increasing in amount as they are more distant from P. Finally, at points situated so far from P that the portion of the half-wave intercepted by the screen is too far from the pole *b'* to produce a sensible effect, the fringes disappear altogether, and the surface of the screen becomes uniformly illuminated with light of intensity = 2.

The fringes are broadest in red, and narrowest in violet light; and in white light fringes of compound colours are formed, as in the experiment with the mirrors.

The locus of each fringe, light or dark, considered at different distances from the luminous source, is a hyperbola, having the points A, *s* for its foci. The dark fringe *n*, for example, of the *m*th order, gives $An - bn = m \cdot \frac{1}{2}\lambda$; and subtracting these equal magnitudes from $sb = sA$, we have $sb - An + bn$, or $sn - An = sA - m \cdot \frac{1}{2}\lambda$. The difference $sn - An$ is therefore constant, whatever may be the length of ΔP ; consequently, the locus of the point *n* is a hyperbola whose foci are A and S.

There is also a certain quantity of light *within the geometrical shadow*. For any point *p* situated to the right of P (Fig. 649) receives light from a certain portion of the wave Aab; but this portion is smaller and farther from the corresponding pole, as *p* is more remote from P: hence the brightness of the light diminishes rapidly from the edge of the shadow inwards; but the diminution is continuous and no fringes are produced.

Fringes at the edge of a Mirror.—Rays reflected from the edge of a plane mirror inclined to their direction, proceed as if they had originally issued from a line of light situated symmetrically behind the mirror. The space beyond the mirror may therefore be compared to the opaque screen in the experiment last described: hence the fringes are produced towards the surface of the mirror, whilst a continuous light is visible for a short distance beyond it.

2. Fringes produced by narrow rectangular apertures.—Light passing through such an aperture may form fringes in the beam of light itself and in the shadow, separately or together, according to the width of the slit and the distance at which the fringes are viewed. They may be observed by means of a very simple apparatus, consisting of two thin plates of copper fixed in a small frame, one of them being capable of sliding backwards and forwards, so as to vary the width of the aperture at pleasure. On looking at the flame of a candle or other source of light through the slit, brilliant coloured fringes are seen parallel to the edges of the slit. These fringes are also very distinctly seen on viewing the flame of a candle between two fingers held up so as to leave a very narrow space between them.

Internal Fringes.—Let AB (Fig. 650) be the slit, S the source of light, rendered homogeneous by passing through a coloured glass; and suppose in the first place that the screen AB', on which the light is thrown, is placed at such a distance that $AP - oP$ and $BP - oP = \frac{1}{2}\lambda$; then all the points of the part AB of the wave-surface will be in accordance with each other, and there will be a bright band at P. The same will be the case *a fortiori*, if the screen AB' is still farther removed, as to A'B'. But if the screen be moved to a shorter distance from the slit, such that $AP - oP$ is

Fig. 649.

more than $\frac{1}{2}\lambda$, and equal to n times $\frac{1}{2}\lambda$, then if n is even, each half of the wave AB may be divided into an even number of elements of interference, whose actions

Fig. 650.

destroy each other two by two. There will then be a dark band at the central point P. If, on the other hand, n is odd, there will remain one element whose action is not neutralised, and the central band will be bright. Hence, as the screen is gradually removed farther from the aperture, the central band will be alternately bright and dark, until the distance is such that $AP - BP = \frac{1}{2}\lambda$, at and beyond which it will be always bright. The same alternations may be produced by diminishing the width of the aperture AB, while the distance OP remains constant.

There are also fringes in the beam of light to the right and left of P. Suppose that the distance of the screen is such that the central band is bright, and $AP - BP = \frac{1}{2}\lambda$, and let n be a point such that $Bn - An = 2 \cdot \frac{1}{2}\lambda$. The arc AB may then be divided in a , so that $nB - na = na - nA = \frac{1}{2}\lambda$. The vibrations communicated to n by the two arcs An, nB will then destroy one another to a great extent, so that there will be a dark band at n . At c , so situated that $cB - cA = \frac{3}{2}\lambda$, there will be a bright band, because the arc AB may then be divided into three elements of interference, and so on.

A precisely similar explanation applies to the case in which the central band is dark.

The interior fringes recede farther from the central point P, as the distance of the screen is greater in proportion to the width of the aperture; and when the screen is placed at such a distance that $BA'' - AA'' = \frac{1}{2}\lambda$, the first dark band will be at A'' , and consequently there will be no fringes within the beam of light passing through the aperture; the distance of the screen at which they cease to be produced is less as the aperture is narrower.

External Fringes.—The mode of production of these fringes is similar to that of the internal fringes just considered. Any point N, within the shadow on either side, will be a centre of a dark or a bright band, according as $NB - NA$ is equal to an even or an odd number of times $\frac{1}{2}\lambda$. These external fringes rapidly lose their distinctness as they recede from the edge of the geometric shadow, and disappear altogether when the slit is so wide that the vibrations emitted from the point B are no longer sensible at A. For the simultaneous production of external and internal fringes, therefore, the aperture must be neither too wide nor too narrow.

The loci of both the external and internal fringes are hyperbolas having their foci in A and B. All the fringes are broadest in red and narrowest in violet light, and in white light are made up of bright bands of various colours.

3. *Fringes produced by two narrow slits very close together.*—The two beams of light interfere and produce fringes, precisely as in Fresnel's experiment with the mirrors. This, which is Young's form of the experiment, is similar to that by which Grimaldi originally showed that light added to light may produce darkness.

4. *Fringes produced by very narrow screens.*—In this case also fringes are produced both within and without the shadow. A hair or a thin wire held between the eye and the flame of a candle or a bright line of light, exhibits these fringes very distinctly. Suppose that the screen AB, instead of being of indefinite extent towards B, as in fig. 649, is so narrow that the light passing by each of its edges A, B (fig. 651), goes beyond the middle of the geometric shadow AB' ; the rays will then act upon each other so as to produce fringes within the shadow, independently of those beyond it. The latter are also modified, because the points at which they are formed likewise receive light from the opposite edge of the narrow screen, which contributes to their formation; in fact, on interposing an opaque body so as to cut off the light from one edge of the screen, the external fringes immediately alter their appearance, and the internal ones disappear altogether.

Formation of the internal fringes.—If the screen AB (fig. 651) is not extremely narrow, the internal fringes differ but little from those which would be formed by two slits placed at A and B; for the direction of vibration at any point n within the shadow is then determined by the action of the two elementary portions of the wave immediately contiguous to A and B. When the screen is extremely narrow, the result is the same, excepting that the effect of the first elements of interference Aa, Ba, of the arcs Ad, Bd', being modified by the other portions of these waves, which partly neutralise their action, the points, o, o' , from which the resultant actions of these waves

may be considered as proceeding, are situated somewhat closer to A and B than they would be if the portions of the wave beyond a and a' were cut off. At any point n within the shadow, there will be a light or a dark band (in homogeneous light), according as $on - on'$ is equal to an odd or even number of half-undulations. The point P in the middle of the geometric shadow, being perfectly symmetrical with regard to the arcs Ad, Bd , receives from them accordant impulses, and is therefore the centre of a bright band.

Fig. 651.

The fringes are wider apart in proportion as AB is smaller, because in order, to obtain a given difference of length in the rays on, on' , the point n must then be taken farther from P. This may be verified by viewing a needle held parallel to a bright line of light; the fringes are then much broader near the point than near the eye.

5. *Fringes produced by screens or apertures which are very small in all directions.*—The effects in this case are much more complicated than in those above considered, where the edges of the screen or aperture are supposed to be straight, and so much elongated that it is sufficient to consider the effect of the cylindrical wave situated in a section at right angles to the screen or aperture. But in the case now under consideration it is necessary to consider the actions resulting from all the points of the free surface of the wave, and the problem becomes too complicated to be treated without the aid of the higher analysis. We shall therefore merely enumerate the effects produced in a few of the more simple cases.

When rays proceeding from a luminous point pass through a small circular aperture circular fringes are formed, both within and beyond the geometric image. The circular aperture may in fact be regarded as a number of very narrow rectilinear apertures radiating from the centre. In homogeneous light the rings are equidistant, and their diameters are inversely as that of the aperture, excepting that the distance from the centre to the first ring is less than that between two consecutive rings. The centre is bright or dark, according to the proportion between the size of the aperture and its distance from the screen, and either the external or internal rings may disappear according to these dimensions.

A small circular screen also produces fringes similar to those of the linear fringes formed by a narrow rectangular screen. At certain distances, the centre of the shadow is as bright as if the screen were not there.

A small rectangular aperture forms two series of fringes at right angles to its sides; their distances being inversely as the widths of the aperture in all directions. There is also a great number of small spectra, regularly distributed in the angular spaces formed by the two series of fringes.

Two small circular apertures placed at a certain distance from one another, form two series of rings just as if each of them existed alone; but if they are close enough to make the rings overlap, the rays proceeding from the two likewise produce, by their interference, a series of very close rectilinear fringes at right angles to the line joining the centres of the apertures, together with two sets of oblique fringes passing through the middle point between these centres. This is the original experiment of Grimaldi already referred to (p. 604).

6. *Diffraction through Gratings or Networks.*—When light, instead of passing through one or two small apertures, passes through a great number of them very close together and regularly distributed, some very remarkable diffraction phenomena are produced, which were discovered by Fraunhofer. Such a system of apertures is called in optical language a grating (*résseau*, Fr.; *Gitter*, Germ.).

Fraunhofer formed his gratings:—1. By winding a very fine wire round two parallel screws of equal diameter and very fine thread.—2. By tracing very fine parallel lines on a film of gold-leaf fixed on a plate of glass.—3. By tracing lines with a diamond on a plate of glass, the lines thus formed being opaque, while the intermediate spaces are transparent. This is the method now generally adopted, a dividing engine being used to ensure regularity in the lines. Sometimes the lines are traced on glass covered with a thin coat of varnish, and etched with hydrofluoric acid. When great regularity is desired, the number of lines in a millimetre must not exceed 300, and 25 in that space are sufficient for the complete manifestation of the phenomena.

Effects of Parallel gratings.—A line of light viewed through a grating formed by parallel lines, appears just as it would to the naked eye, excepting that it is somewhat

fainter; while on either side is seen a dark space *N* (fig. 652), followed by a spectrum, *S*, *S*, having the violet within, and its colours so pure that the principal fixed lines can

Fig. 652.

be easily distinguished in it. Then comes another dark space narrower than the former, then several other spectra more and more extended, but overlapping each other more and more, so that their colours become paler and finally disappear. These spectra may however be separated by viewing them through a prism, the fixed lines then appearing. In homogeneous light, nothing is seen but isolated bands of the colour of the light employed, being in fact the corresponding portions of the several spectra.

Masson has observed that the electric light viewed through a grating exhibits bright lines, as when seen through a prism.

To measure the breadth of these spectra, the grating *o* is placed in front of two parallel slits *e*, *e'* (fig. 653), the distance between which admits of variation. Two

Fig. 653.

systems of spectra *ee*, *ee'* are then seen, which are partly superposed, but may be distinguished by placing one of the slits a little higher than the other. To find the position, or angle of deviation, of any given fixed line, the slits must be separated, or the grating moved farther back, till this line *a*, belonging to the right-hand spectrum formed by the slit *e*, coincides with the same line *a'* in the left-hand spectrum of the same order formed by the slit *e'*. The angle *coe*, is then equal to twice the angle of deviation sought, viz. $\angle coe = D$;

and the right-angled triangle *aco* gives $\tan D = \frac{ac}{ao}$, or $D = \frac{ec}{2ao}$,

taking the angle for its tangent. The angle of deviation is therefore given by the distance between the slits and their distance from the grating.

By observations thus made it is found that:—1. The middle points of the successive spectra are equidistant, or in other words, the deviations of these middle points are to one another as the numbers 1, 2, 3, 4, &c.

2. The lengths of the successive spectra, or the distances between two of their corresponding fixed lines, are to one another as the same numbers.

3. The difference of thickness of the opaque and transparent lines has no influence on the position of the spectra, but merely modifies their brightness.

4. The lengths of the spectra depend upon the sum of the widths of an opaque and transparent space taken together; this sum is called an element of the grating. The deviation of any given line is inversely as the distance between two elements, or it is proportional to the number of elements in a millimetre. When this number is 100, the first spectrum has the same width as that produced by a flint-glass prism of

Fig. 654.

60°. Moreover the spaces occupied by the several colours of the spectra are sensibly equal, so that the spectrum thus formed may be called a *normal spectrum*, and may serve as a standard of comparison for the irregular spectra produced by prisms.

The preceding laws may be comprised in the general formula, $D = m\lambda N$, where *D* is the deviation of a fixed line in the spectrum of the *m*'th order, *N* the number of the elements of the grating in a millimetre, and *k* a constant depending upon the colour in which the line is situated.

To explain the mode of formation of these diffraction spectra, let *Ae* (fig. 653) be the surface of the grating, *a*, *b*, *c*, *d*, *e* the opaque spaces. Suppose the eye placed at *C*, and the distance *CS* of the line of light to be so great, that all the rays proceeding from it to the grating may be regarded as parallel, and the surface of the wave passing by the point *A*, as coinciding with *Ae*. If the grating were removed, the slit *a* would be seen in the direction *CS*, and no light at all would be seen in any other direction, the elements of interference on the wave *Ae*, neutralising one another by pairs. The presence of the grating does not impede the view of the slit, or alter its apparent position, and on each side of the slit there is a dark space, just as if the grating were not there. But at a certain distance *Ad*, such that an opaque line of the grating exactly

covers the element of the wave which would counteract the action of the preceding element, light will be seen in the direction Cd , the distance Ad being greater in proportion as the eye is farther from the grating. If, for example, the angle ACd is of such a magnitude that $dC - oC = oC - cC = \frac{1}{2}\lambda$ of the violet, the vibrations communicated to the point C by the element co , will not be destroyed, by od , and violet light will be seen in the direction Co , brighter in proportion as the edge of the dark space is nearer to o .

To calculate the deviation $dCA = d$, describe the arc cr having its centre at C ; the triangle der gives $dr = \lambda = \overline{cd} \sin d$; and supposing cd to be contained N times in a millimetre, we have then $1 = N \cdot \overline{cd}$, and the preceding equation gives $\sin d = N\lambda$, or taking the angle for the sine, $d = N\lambda$, which is in fact the general formula of the diffraction-spectra ($D = m\lambda N$) applied to the case of the first spectrum. It shows that the deviation is independent of the difference between the opaque and the transparent spaces, and that the constant k is the length of an undulation corresponding to the colour under consideration. For the other colours, we find in like manner $d' = N\lambda'$, $d'' = N\lambda''$, &c., λ being greater than λ' , and λ'' greater than λ' &c. The colours will therefore appear one after the other, at angular distances sensibly proportional to $\lambda, \lambda', \lambda'',$ &c.

Consider, in the next place, another element of the grating at such a distance from A that the difference $dC - cC = 2\lambda$, or in general to $m\lambda$, m being a whole number. The interval may then be divided into $2m$ elements of interference corresponding to differences of distance from C , equal to $\frac{1}{2}\lambda$, and these elements being of even number, the actions resulting from their several points would counteract one another two by two, if there were no opaque spaces. But if the opaque spaces cover an uneven number of elements, so that an uneven number also remains free, one of these latter will act unopposed, and there will be light in the corresponding direction. The triangle cdr , then gives $d = m\lambda N$, which is the general formula above given.

It remains to be seen why the light of any particular colour is wanting between the luminous band which corresponds to the difference of distance $m\lambda$ from C , and that which corresponds to $(m + 1)\lambda$. Now between the lines of the grating corresponding to these two bands, two zones may be found in which the differences of distance from the point C increases from $m\lambda$ to $m\lambda + \frac{1}{2}\lambda$, then from this latter to $m\lambda + 2 \cdot \frac{1}{2}\lambda = (m + 1)\lambda$. The rays emanating from the corresponding points of these two zones differ in length of path by $\frac{1}{2}\lambda$, and destroy one another on reaching the point C . Dark bands will therefore occur in the direction of these zones. In white light, however, the colours, by overlapping one another, obliterate all these dark bands, excepting the first two on either side.

If the source of light is too near the grating to allow the rays to be regarded as parallel, the same mode of explanation is still applicable, only it becomes necessary to take account of the difference of path of the contiguous oblique rays at the moment when they reach the grating.

The formula $\sin d = mN\lambda$, shows that when $N\lambda$ is greater than 1, that is to say when $\frac{1}{N}$, or an element of the grating, is less than λ , $\sin d$ becomes greater than 1, which is impossible; in this case therefore no spectra can be formed, and in fact gratings which have their bars too close do not form any.

If the spectra are observed in any other medium, as when the slit and grating are placed at the opposite ends of a tube filled with water or other liquid, then, if l is the length of an undulation of violet light in that liquid, the deviation will be $d_1 = N\lambda$, which combined with the equation $d = N\lambda$, for the deviation of the same part of the spectrum in air, gives $d_1 : d = l : \lambda$, which is the ratio of the indices of refraction in the medium and in air.

Measurement of λ . The equation, $\sin d = N\lambda$, gives the means of measuring with great accuracy the wave-lengths corresponding to the several fixed lines of the spectrum, which cannot be done with the interference-fringes in Fresnel's experiment (p. 599), because the lines are not distinct. It is by this method that Babinet determined the values given in the table on p. 600.

Irregular Gratings.—Gratings whose bars are totally destitute of regular arrangement produce nothing but a whitish train of light at right angles to the bars; but if the irregularities are subject to a certain law and recur periodically, spectra are produced, whose deviation is expressed by the formula $\sin d = \frac{m\lambda}{L}$, in which L denotes the space comprising one complete set of bars. The successive spectra then differ greatly in brightness; some are very pale, and, occurring by the side of very bright ones, partly overlap them, but do not perceptibly alter their colours: hence lines may be distinguished in some of these spectra of the higher orders, which cannot be seen in the spectra of the correspond-

ing orders formed by regular gratings, because they are obliterated by superposition. By looking at a candle with the eyes nearly closed, so that the eye-lashes form a grating, a horizontal line of whitish light is generally seen, because the eye-lashes are for the most part at unequal distances; frequently, however, very distinct spectra are produced. Very fine spectra may be seen by looking at the sun or a bright flame through the plume of a crow's feather.

Gratings or Network with square or round bars or meshes.—Gratings with square apertures may be formed of two sets of parallel bars crossing one another. A piece of muslin or riband exhibits such a structure. Such gratings form a great number of small spectra, some disposed along the arms of a cross parallel to those of the squares, others distributed obliquely in the four right angles. The appearance is very brilliant, and varies with the size of the meshes and the distance of the luminous point.

Reflecting Gratings or Striated Surfaces.—When light is reflected from surfaces covered with striæ alternately bright and dull, the same spectra are produced as when it is transmitted through a grating: for the reflected rays are in the same state as if they had been transmitted through the striated surface from a point as far behind as the actual luminous point is before it; the spectra are not, however, quite so bright as those produced by transmission. The iridescence of mother-of-pearl is produced by very fine striæ resulting from its foliated structure; a cast taken of it in soft wax, mastic, or fusible metal, exhibits a similar iridescence. Fibrous gypsum exhibits colours due to the same cause. The feathers of certain birds likewise owe their brilliant colours to diffraction of the light reflected from the very fine filaments of which they are composed.

Half-polished metals sometimes exhibit iridescent colours, due to the parallel striæ produced by the hard powder used in polishing them; but as these striæ are seldom regular, the usual effect is merely a whitish line of light, at the points from which the rays are reflected to the eye. *Barton's buttons*, which are metallic buttons having very fine lines engraved on their surfaces by a peculiar machine, exhibit magnificent diffraction spectra.

Reflection and Refraction.

When a wave of light reaches the surface of separation of two media of different densities, its vibrations are not only propagated onwards into the second medium, but likewise reflected back into the first, each particle of the ether at the surface of separation then becoming a centre of disturbance from which fresh waves spread out in all directions. To find the directions of the reflected and transmitted waves, let *MN* (fig. 655) be the separating surface of two media (air and water, for example), and *SabS'* an incident beam of light of infinitely small section, so that the rays composing it may be regarded as parallel, and the wave-surface, *bc*, perpendicular to their direction, as plane. Now the several points of this wave-surface, *cb*, do not all meet the surface *MN* at the same instant, but each point, as it reaches that surface, becomes a centre of disturbance from which elementary waves are excited in both the media bounded by *MN*. Moreover, the velocity of propagation of the waves in the two media is different; because the density of the ether in the one is greater than in the other (pp. 595, 601). Suppose the lower medium to be the one in which the ether has the greater density, and that the velocity of transmission of the light-waves in it is $\frac{2}{3}$ as great as in the upper. Then, by the time the point *c* of the incident-wave has travelled on to *a*, a wave will have spread out from *b*, in each medium, of a radius $bd = ac$ in the first, and $bf = \frac{2}{3} ac$ in the second; also from any intermediate point *e* (*ea* being a portion of wave-surface parallel to *bc*), a wave will spread out of radius $ed = aa$ in the first, and $ef' = \frac{2}{3} aa$ in the second. Now each of these elementary waves produces no perceptible effect by itself, a sensible disturbance of the ether or production of light taking place only where a number of them act together, that is to say, in the first medium, along the plane surface *ad*, and in the second along *af*; and straight lines *ar*, *ar'*, *aq*, *bq*, &c., drawn at right angles to these surfaces from the several points between *a* and *b*, will give the direction of the reflected and transmitted rays.

In the first medium, the triangles *abc*, *abd* being equal in every respect, the angle *abd* = the angle *bac*, that is to say, the incident and reflected rays make equal angles with the reflecting surface, and therefore also with the normal *Pa*. The angles which these rays make with the normal are called the angles of incidence and reflection respectively.

The symmetry of the figure with respect to the plane of incidence, i.e. the plane passing through the incident ray and the normal, shows also that the reflected ray is contained in the plane of incidence.

The ray which passes on into the second medium is also contained in the plane of incidence, but is bent or refracted out of its previous direction, and does not make the same angle with the normal as the incident ray does. The angle of incidence $\angle Pas = i$ is equal to the angle *cba*, and the angle of refraction $\angle Paq = r$ is equal to *baf*;

and the right-angled triangles abc , abf give $ac = ab \sin i$; and $bf = ab \sin r$; therefore,

Fig. 655.

$\sin i : \sin r = ac : bf$. But the spaces ac , bf traversed by the ray in the same time, are to one another as the velocities v , v' of light in the two media: hence

$$\frac{\sin i}{\sin r} = \frac{v}{v'}.$$

That is to say, the sines of the angles of incidence and refraction are to one another in a constant ratio, namely, that of the velocities of light in the two media. This ratio, which is also that of the lengths of the waves $\lambda : \lambda'$ in the two media, is called the index of refraction, absolute or relative, according as the ray passes from a vacuum into a ponderable medium, or from one ponderable medium to another. The absolute index of refraction of a medium, usually denoted by the letter μ , is the reciprocal of the velocity of light in that medium referred to the velocity in a vacuum as unity; it is always greater than 1. If μ , μ' are the absolute indices of two contiguous media, say water and glass, the deflection of a ray passing from the one to the other will be determined by the equation

$$\frac{\sin i}{\sin r} = \frac{\mu}{\mu'},$$

which likewise holds good if μ , μ' are the indices of refraction of the ray in passing from any one medium, as air, into two others, as water and glass.

When μ is greater than μ' , that is to say, when the velocity of transmission, or the length of the wave is less in the second medium than in the first, the ray is refracted towards the normal; when μ is less than μ' , it is refracted from the normal.

In the latter case, the angle of incidence may be such that the sine of the angle of refraction would be equal to or greater than 1; under such circumstances, the ray does not pass into the second medium at all, but undergoes total reflection into the first. The value of the limiting angle, θ , at which refraction ceases to take place, is given by the equation, $\sin \theta = \frac{\mu}{\mu'}$, $\sin 90^\circ = \frac{\mu}{\mu'}$.

Limitation of the reflected and refracted rays.—The preceding explanations show that there must be reflection and refraction in the directions above determined, but they do not show why the reflected and refracted rays are confined to these directions; for as each point of the surface ab (fig. 655) is a centre of disturbance, from which waves spread out in hemispheres, it would seem as if rays should be reflected and transmitted in all directions. And such is in fact the case; only, as Fresnel has shown, all the rays oblique to the reflected and refracted beams $rabr'$, $qabq'$, destroy one another by their mutual interference.

Suppose an , en' (fig. 654) to be two parallel refracted rays, very close together, but not in the direction determined by the law of the sines. Draw ca and $a\beta$ perpendicular

to sa and en' ; then a vibration of the ray sa , in reaching the surface ab , will have travelled over a space greater by aa than the corresponding vibration of the ray te but when the two arrive at the surface ab of the refracted wave, te will have moved over a space which, expressed in wave-lengths, is greater, by $\mu \cdot e\beta - aa$, than that passed over by sa . Let i be the angle of incidence, α , and ρ the angle of refraction, $e\alpha\beta$, of the ray an . Then the right-angled triangles $e\beta a$, caa give $e\beta = ae \cdot \sin \rho$;

$aa = ae \cdot \sin i$; therefore $\mu \cdot e\beta - aa = ae (\mu \cdot \sin \rho - \sin i)$; and $ae = \frac{\mu \cdot e\beta - aa}{\mu \cdot \sin \rho - \sin i}$.

Now the rays an , en' will destroy one another by interference when the difference $\mu \cdot e\beta - aa = \frac{1}{2}\lambda$; therefore, when $ae = \frac{\frac{1}{2}\lambda}{\mu \sin \rho - \sin i}$. This shows that ae is smaller, or the interfering rays are closer together, the more the ratio $\frac{\sin i}{\sin \rho}$ differs from μ ; but when it is equal to μ , that is, when the refracted ray is in the direction indicated by the law of the sines, ae becomes infinite, and therefore there is no interference.

A precisely similar construction and demonstration, applied to the reflected rays an'' , en''' (fig. 655), shows that the contiguous reflected rays destroy each other in all

Fig. 655.

cases excepting when $\sin \rho = \sin i$, that is to say, when the reflected and incident rays make equal angles with the normal. If, however, the point a is very close to the left-hand edge of the mirror, the reflected ray en' will not exist, and an will not be destroyed. Hence if the mirror is very narrow, the rays reflected obliquely to the beam $rabr$ are not completely destroyed, and the reflected beam becomes divergent. Fresnel verified this theoretical deduction by blackening the surface of a mirror, with the exception of a very narrow triangular space. The beam of light reflected from this space was broadest at the narrowest part of the reflecting surface, so that the image which it formed on a screen was a triangle with truncated summit, in a position the reverse of that of the reflecting triangle.

The reflected and refracted beams are always less bright than the incident beam. In fact, they would be together equal in intensity to the incident beam, were it not that part of the light is scattered in all directions, by reflection from minute irregularities on the surface of the medium; and secondly, that a portion of it, often very considerable, is apparently lost by absorption. This process doubtless consists in a communication of the vibratory motion of the ether to the particles of the ponderable body itself, the particles thus set in motion again acting as centres of vibration, and exciting fresh undulations in the surrounding ether, thereby rendering the body visible. The vibrations excited in the particles of a ponderable body by the movements of the ether likewise produce numerous changes in the state of the body itself, raising its temperature, and setting up certain chemical actions within it, which will be afterwards more fully considered. It is true that the ether transmits vibratory movements which render bodies hot, and others which determine chemical changes

in them without directly rendering them visible; but it is probable that the luminiferous waves themselves likewise alter the thermic and chemical conditions of a body, that is to say, excite in the molecules of the body, vibrations which result in thermic and chemical changes, and do not again excite luminiferous waves in the ether. In other words, a certain amount of light is lost in producing heat and chemical change. In passing through a transparent medium, such as glass or water, with polished surface, and very little colour, the amount of light lost by absorption is but small; coloured media transmit certain rays and reflect or absorb others. When light falls on the surface of an opaque body, such as a metal, the path of the refracted ray cannot be followed, inasmuch as it is completely absorbed by an extremely thin stratum of the surface.

The general laws of reflection and refraction having been established, the application of them to determine the path of a reflected or refracted ray under any given circumstances is a problem of pure geometry, into which we do not propose to enter in this article, further than to speak of refraction through prisms, which is of special importance in the determination of indices of refraction.

A prism, in optical language, is a transparent medium, bounded by plane surfaces, not parallel to one another. The edge in which these surfaces meet, or would meet, if produced, is called the refracting angle of the prism. Solid prisms for optical use are generally made either of glass or of rock-crystal, and with triangular section. Such a prism has three refracting angles, which may be either equal or unequal. The face of a triangular prism opposite the refracting angle is called the base. Liquid prisms are made by inclosing a transparent liquid in a wedge-shaped glass, having its inclined sides formed of plate glass. One of the sides may be made to move on a hinge so as to vary the refracting angle.

Let us now trace the course of a ray of light through a prism. If BAC (fig. 656) be a prism of glass or any transparent material of greater refracting power than the surrounding medium, a ray SI , entering at I , and making an angle i with the normal, NI , will be refracted within the prism in the direction IE , making with the normal an angle r less than i . This ray emerging at E , will pass on in the direction ER , making with the normal to the face AC , an angle e greater than the angle r which IE makes with the same normal. The final result is to bend the ray away from the refracting angle, or towards the base of the prism; accordingly an eye placed at R will see an object S in the direction RE , as if it had been moved upwards towards the summit of the prism. The angle $SoR = D$ contained between the incident and emergent rays is called the angle of deviation. It is evidently equal to the sum of the angles IEO , EIO ; that is, $D = i - r + e - r'$. But the triangle IEF shows that $r + r' = IFN$, the angle contained between the two normals, and therefore to the refracting angle of the prism, a . The deviation is therefore given by the formula:

$$D = i + e - a.$$

For a given angle of incidence i , it increases with the refracting angle of the prism for suppose a to be increased by δ , then since r is constant, and $r + r' = a$, r' must also increase by δ , and therefore e by $\mu\delta$, μ being greater than 1; that is to say, e increases more than a , and consequently D increases.

When the refracting angle is constant, the deviation varies with the angle of incidence, and attains a *minimum* value when the incident and emergent rays make equal angles with the refracting surfaces. To show, in the first place, that this latter condition is possible, suppose that an incident ray coinciding with the normal NI (fig. 657) is gradually inclined into the position SI ; the angle r , which is at first equal to 0° , will also increase continually, and therefore r' must diminish, since $r + r' = a$; moreover since a must be less than 180° , and r may increase to 90° , the incident ray must eventually come into a position in which $r = r'$, and therefore $i = e$.

Now let SI and ER (fig. 657) be the rays which make equal angles with the normals; and suppose that SI moves into the position $S'I$ closer to the normal; r will then diminish,

Fig. 656.

and therefore r' must increase by the same quantity; e will therefore also increase, and become greater than i . But $\frac{\sin i}{\sin r} = \frac{\sin e}{\sin r'}$; and since $\sin e$ and $\sin r'$ are greater than $\sin i$ and $\sin r$, the difference between $\sin e$ and $\sin r'$ must be greater than that

Fig. 657.

are equally inclined to the surfaces of the prism, or to the normals.

In this case, the expression for the deviation becomes $D = 2i - a$, which gives $i = \frac{a + D}{2}$; also, since r and r' are equal, we have $r = \frac{a}{2}$; hence also:

$$\mu = \frac{\sin i}{\sin r} = \frac{\sin \frac{1}{2}(a + D)}{\sin \frac{1}{2}a};$$

an expression which gives the index of refraction of the medium forming the prism, as a function of the refracting angle of the prism and the angle of minimum deviation. This affords one of the best means of determining indices of refraction.

Measurement of the Index of Refraction of Solids and Liquids.—1. To measure the angle of the prism: the prism ABC (fig. 658) is fixed in such a manner that its edges

Fig. 658.

may be perpendicular to the divided circle of a theodolite o ; and a mark S , placed at such a distance that the rays proceeding from it may be regarded as parallel, is viewed through the telescope, first by reflection from AB , then directly, and the angle $Soi = d$ is measured. The theodolite is then moved to o' , and the same mark is viewed directly and by reflection from AC , and the angle $S'o'i = d'$ is measured. Half the sum of these two angles is the measure of the angle A . To show this, draw AD parallel to the direction of the incident rays, and dividing the angle A into two parts, α and β . Then $\alpha = S'iA = oiB$, and therefore $2\alpha = 180^\circ - S'io$. But $Soi = d = 180^\circ - S'io$; therefore $d = 2\alpha$. In like manner it may be shown that $d' = 2\beta$; consequently $\alpha + \beta = A = \frac{1}{2}(d + d')$.

2. To measure the minimum deviation, the prism is fixed on a support capable of turning on a vertical axis. A very distant mark m (fig. 659) is viewed with the theodolite o , first directly in the direction om , then through the prism in the direction om'' ; and

Fig. 659.

the prism is turned round till the angle mom'' between these two directions is reduced to its smallest possible magnitude. The angle so determined is the angle of minimum deviation, provided the mark is so distant that the rays proceeding from it may be regarded as parallel. A distant lightning-conductor forms a very good mark for the purpose in the day-light; a slit in the shutter of a dark room, provided the room be large, may also be used.

Observations are made by artificial light, with a lamp surrounded by a jacket of tin plate having a vertical slit.

In this last case, the mark is seldom far enough off to allow the divergence of the rays to be neglected. Let a be the angle of divergence, and o the angle nom . The triangle moo gives,

$$180^\circ = a + o + (180^\circ - m'cm) = a + o + 180^\circ - (2i - a).$$

This gives $i = \frac{1}{2}(a + o + a)$, and therefore

$$\mu = \frac{\sin \frac{1}{2}(a + o + a)}{\sin \frac{1}{2}a}.$$

The angle a may be measured by transporting the theodolite to m . But as a is very small, it is generally considered sufficient to measure the length of the perpendicular nP and the distance mP , by stretching a cord from o to m ; then $\tan a = \frac{nP}{mP}$.

A very convenient method of obtaining parallel rays is by the use of the collimator, an instrument consisting of a telescope-tube blackened inside, and having two wires, one vertical, the other horizontal, fixed within it, and crossing in its axis. When the tube is directed towards a window, the wires, being illuminated by a beam of parallel rays, form a shadow which may be regarded as an object placed at an infinite distance. If a convex lens be placed at one end of the tube, and the cross-wires in its principal focus, the collimator may be used in the same manner for observations with artificial light: for when the other end of the tube is directed towards a lamp, the rays crossing each other at the intersection of the wires will issue parallel after passing through the lens, and will therefore be brought to a focus by another telescope just like those proceeding from a celestial object.

In all observations of indices of refraction, it is necessary to specify the colour of the light to which the observation refers. Solar light, and lamp, candle, or gas light are in fact of composite nature, and separable by refraction into coloured rays of unequal refrangibility; consequently, any line of light viewed through a prism appears widened and fringed with bands of colour parallel to its edges. It is usual to make the observations on the yellow rays, which are situated towards the middle of the coloured image, or spectrum, and possess the greatest brightness. But as each colour occupies a certain breadth in the spectrum, and the boundaries of the several colours are not very well defined, it is by no means certain that two observations made on the same colour will refer to exactly the same part of the spectrum. The difficulty thence arising is however completely removed by the observation of certain fine dark lines, discovered by Fraunhofer, in the solar spectrum (p. 620), which are parallel to the lines of separation of the different colours, and are always disposed in the same manner in each colour, whatever may be the nature of the prism. The spectra of flames and of the electric light exhibit bright bands, likewise of fixed position for each particular source of light.

A very sharply defined mark may be obtained without recourse to the fixed lines, by replacing the vertical wire of the collimator with a sewing needle. The coloured bands parallel to the edges of the needle overlap one another towards the point, forming a well-defined line of separation between two very distinct colours, a bluish-green and a deep rose tint. (H. Deville.)

Determination of Refractive Indices by Interference.—The displacement of the fringes in Fresnel's experiment (p. 600) furnishes a very delicate method of determining indices of refraction. A thin film of the transparent substance being placed before one of the mirrors (fig. 645), so as to intercept part of the pencil of rays reflected from it, the number of ranks through which the central fringe is displaced is observed. Let R be this number, e the thickness of the film, m and m' the number of wave-lengths, λ and λ' , included within the thickness e of the air and the transparent film: then

$$e = m\lambda = m'\lambda'; \text{ whence } \frac{m'}{m} = \frac{\lambda'}{\lambda} = \frac{v'}{v} = \mu.$$

But, since the central band is displaced through R ranks, we have also $m' = m + R$, each additional wave-length in the film displacing the central band one rank further. Consequently,

$$\mu = \frac{m'}{m} = \frac{m + R}{m} = \frac{e + R\lambda}{e},$$

a formula which gives the index of refraction in terms of the thickness of the film and the wave-length.

This method is especially applicable to gases and vapours (p. 618).

Determination of the Index of Refraction of Liquids.—1. By the method of least deviation. The liquid is inclosed in a wedge-shaped vessel, of which *fig. 660* represents a transverse section. The sides are formed of thin plate-glass, and it is essential to

Fig. 660.

the accuracy of the observations that the two faces of each of these plates should be parallel. As, however, this condition is seldom completely fulfilled, it is necessary to measure the deviation produced by the prism when empty, previous to making the observation with the liquid to be examined. The first deviation is then to be deducted from, or added to the second, according as it is in the same or in the contrary direction.

As liquids are very expansible by heat, their indices of refraction may be sensibly affected, even by variations of temperature not exceeding those of the surrounding atmosphere. It is necessary, therefore, to make the observations at a constant temperature, to agitate the liquid briskly before making the observation, and to avoid using the direct rays of the sun, which might heat it unequally in passing through it.

2. *By total reflection.*—This method is especially applicable to very small quantities of liquid; also to imperfectly transparent liquids and pasty substances, such as the crystalline lens of the eye. A small drop of the liquid is attached to the lower surface of a right-angled prism *BAL* (*fig. 661*), resting on a horizontal rule *LL*, in which a

Fig. 661.

hole *o* is made to receive the drop. The prism must be formed of a substance of known refractive index, greater than that of the liquid. The drop of liquid is viewed through the prism by means of a small telescope *l*, turning on the centre of a graduated circle which slides up and down a vertical rule *L'l'*, fixed to the table. The telescope is at first fixed at such a height, that objects below the drop are seen through it; but on gradually lowering the divided circle, the angle *ion* continually increases, and at last the rays coming from the other side of the prism at *m* are totally reflected at *o*. The telescope observed. The angle *noI* is then equal to the

is then fixed, and the angle α is the limiting angle θ , and $\sin \theta = \frac{\mu'}{\mu}$, μ being the refractive index of the prism, and μ' that of the liquid. Now the angle $\theta = 90^\circ - r$; therefore $\sin i = \cos \alpha = \mu \sin r = \mu \cos \theta$; hence $\cos \theta = \frac{\cos \alpha}{\mu}$, and $\sin \theta = \frac{1}{\mu} \sqrt{\mu^2 - \cos^2 \alpha} = \frac{\mu'}{\mu}$; therefore

$$\mu' = \sqrt{\mu^2 - \cos^2 \alpha}.$$

Wollaston devised a modification of this method by which the refractive index may be determined without calculation (see *Miller's Elements of Chemistry*, 3rd ed. i. 155; and *Daguin, Traité de Physique*, 2^{me} ed. iv. 160).

Fig. 662.

the trouble of calculation from the preceding formula is not, however, a serious objection to the method. A more important objection arises from the difficulty of making the prism exactly rectangular. To obviate this difficulty, Malus uses an acute-angled prism (*fig. 662*), the angle *b* of which is known. The observation being made as above described, we have, as before, $\beta = 90^\circ - \alpha$ and $\sin \theta = \frac{\mu'}{\mu}$. Let the normal *In* be produced to meet the normal *nn'* the angle *b* of the prism, and the triangle *Ino* gives $\theta = r + b$; whence $\sin \theta = \frac{\mu'}{\mu} = \sin(r + b) = \sin r \cos b + \sin b \cos r$. But $\mu \sin r = \sin i$; and the triangle *In'n* gives $n'In = i + \beta = 90^\circ - b$; whence $i = 90^\circ - (b + \beta)$: therefore

$$\sin r = \frac{1}{\mu} \cos(b + \beta);$$

and

$$\cos r = \frac{1}{\mu} \sqrt{\mu^2 - \cos^2(b + \beta)}.$$

This gives; $\mu' = \mu \sin \theta = \cos(b + \beta) \cos b + \sin b \sqrt{\mu^2 - \cos^2(b + \beta)}.$

This method may also be applied to solids. Soft bodies like wax, or gelatinous organic bodies may be at once attached to the lower surface of the prism. Hard

bodies may be attached by means of a liquid of *greater refracting power* than the prism: the total reflection will then take place just as if the solid were immediately attached.

The same method also gives the index of refraction of the prism itself, the observation being made without applying any liquid to the lower face. In this case, since the medium below the prism is air, we have $\mu' = 1$, and the formula gives

$$\mu = \frac{1}{\sin \delta} \sqrt{1 + \cos^2 (b + \beta) - 2 \cos \delta \cos (b + \beta)}.$$

The following tables contain the indices of refraction of several solids and liquids, determined by the preceding methods. They all relate to the yellow rays of the spectrum, excepting those of Wollaston, which relate to the extreme red:

Indices of Refraction of Solids.

Name of substance.	Index of refraction.	Observer.	Name of substance.	Index of refraction.	Observer.
Chromate of lead	2.50 to 2.97	Brewster.	Sugar	1.535	Wollaston.
Diamond	2.47 to 2.75	Br.; Roehon.	Phosphoric acid	1.534	Brewster.
Phosphorus	2.224	Brewster.	Sulphate of copper	1.531 to 1.552	"
Glass of anti-mony	2.216	"	Canada balsam	1.532	Young.
Sulphur (native)	2.115	"	Citric acid	1.527	Brewster.
Zircon	1.95	Wollaston.	Crown glass	1.525 to 1.534	"
Borate of lead	1.866	Herschel.	Nitre	1.514	"
Carbonate of lead	1.81 to 2.08	Brewster.	Plate-glass	1.514 to 1.542	"
Ruby	1.779	"	Spermaceti	1.503	Young.
Felspar	1.764	"	Crown glass	1.500	Wollaston.
Tourmalin	1.668	"	Sulphate of potassium	1.500	Brewster.
Topaz, colourless	1.610	Biot.	Ferrous sulphate	1.494	"
Beryl	1.598	Brewster.	Tallow; wax	1.492	Young.
Tortoise-shell	1.591	"	Sulphate of magnesium	1.488	Brewster.

Oil of almonds	1.469	"	Saliva	1.339	Young.
Oil of lavender	1.467	Brewster.	Water	1.336	{ Wollaston; Brewster.
Sulphuric acid (specific gravity 1.7)	1.429	Newton.			
Nitric acid (specific gravity 1.48)	1.410	{ Young; Wollaston.			

The indices of refraction assigned to the same substance by different observers often exhibit considerable diversities, arising partly from imperfection of method, but especially from want of chemical or physical identity in the substances examined.

A comparison of the indices of refraction of different substances leads to but few general conclusions. One of the most remarkable is that inflammable substances are strongly refractive: *e. g.*, sulphur and phosphorus among solids; oils and hydrocarbons among liquids; it was the observation of this fact that led Newton to infer that the diamond would be found to contain an inflammable principle.

Generally speaking, the refracting power of *any one substance* increases with its density; though it is by no means true that the refracting powers of different substances are proportional to, or even follow in the same order as their densities. Jamin found, by a method presently to be noticed, that the refracting power of water is increased by compression. On the other hand, the refracting power of liquids is diminished when they are expanded by heat. Brewster found that the index of refraction of common ether, which, at ordinary temperatures, is equal to 1.358, is reduced to 1.057 when the volume of the ether is tripled by heat. Numerous experiments on this subject have been made by Dale and Gladstone (Phil. Trans. 1858; Ann. Ch. Phys. [3] lviii. 117), who operated on twelve different liquids between the temperatures of 3° and 50°, using the method of minimum deviation. The prism was placed horizontally and heated by a spirit-lamp or cooled by a freezing mixture. The temperature was indicated by a thermometer with which the liquid was stirred. The following table contains a portion of the results (see also page 625); they relate to the line D of the solar spectrum, excepting those with phosphorus, which relate to the line C:

Temperature.	Sulphide of carbon.	Water.	Ether.	Alcohol, absolute.	Methyl-alcohol.	Phosphorus, liquid.	Oil of Cassia.
0°	1.6442	1.3330					
10	1.6346	1.3327	1.3592	1.3658	1.3379		
20	1.6261	1.3320	1.3545	1.3615			
30	1.6182	1.3309	1.3495	1.3578		2.0741	
40	1.6103	1.3297	.	1.3536	1.3297	2.0677	1.5796
50	.	1.3280	.	1.3491	.	2.0603	
60	.	1.3259	.	1.3437	.	2.0515	1.5690

The refractive index of water diminishes continuously between -1.3° and $+5.2^{\circ}$, the direction of the variation not changing in the passage through the point of maximum density. (Arago. Jamin. Dale and Gladstone.)

In the passage of a body from the solid to the liquid state, the refractive index sometimes diminishes, as in the case of *phosphoric acid, wax, and tallow*. Sometimes it increases, as with *water and borax*; sometimes again it does not change perceptibly, as is the case with *sugar*.

H. Deville (Ann. Ch. Phys. [3] v. 129) has measured the index of refraction of *alcohol, wood-spirit, and acetic acid*, mixed with water in different proportions. These substances exhibit the greatest degree of contraction, or of density, when united with $\frac{2}{3}$ at. water (*e. g.*, $2C^2H^4O.3H^1O$). It is also with this proportion of water that wood-spirit and acetic acid exhibit the highest degree of refractive power, whereas with alcohol this is the case when it contains $\frac{1}{2}$ at. water ($2C^2H^4O.H^1O$). At 16° the refractive index of absolute alcohol is 1.3663; that of $2C^2H^4O.H^1O$ is 1.3662; that of anhydrous methylic alcohol, CH^3O , is 1.3358; of $2CH^3O.3H^1O$, 1.3462; that of anhydrous acetic acid, $C^2H^3O^2$, is 1.3753; and of $2C^2H^4O^2.3H^1O$, 1.3781.

Index of Refraction of Gases. Refractive Power. Biot and Arago determined the refractive index of atmospheric air, by the method of minimum deviation, using a hollow glass prism, called a *Borda's prism*, consisting of a glass tube (fig. 663) 4 or 6 centimetres in diameter, and having its ends *a, b* cut in a slanting direction and closed with very thin plates of parallel glass. The prism was mounted, with its refracting angle vertical, on a brass tube connected with a stop-cock and screwed on to the plate of an air-pump. The pressure of the air in the tube was measured by connecting it with a siphon-gauge. The tube having been exhausted, filled with dry air several times, and again exhausted, observations were made with it similar to those described at p. 612; with this exception however, that as the refracting power of the exhausted prism was less than that of the surrounding air, the *maximum*, instead of the *minimum* deviation was observed. The deviations being extremely small, the thickness of the prism prevented the mark from being viewed directly. To obviate this difficulty, after the mark had been viewed through the prism represented in section at AB, and the maximum deviation of the ray *meio* observed, the prism was moved half round into the position

AB, and the same mark again observed. The image *m* was thereby thrown to the opposite side of the ray *no* proceeding directly from the object, so that the angle *ios'* was equal to twice the angle *noi*. This method gave for the index of refraction of air at 0° C. and 0.76 met. barometric pressure, referred to a vacuum as the unit, the number 1.00294.

Fig. 663.

In like manner, the indices of refraction of other gases were determined, referred to that of air as unity.

Now on measuring in this manner the refraction produced by air or other gases at different densities, it was found that, at pressures not exceeding that of the atmosphere, the quantity $\mu^2 - 1$, which is called the refractive power, is proportional to the density of the gas—in other words, that $\frac{\mu^2 - 1}{d}$, which may be called the specific

refractive power, is a constant quantity. The law was not verified for pressures greater than that of the atmosphere, on account of the difficulty of retaining condensed gases within the hollow prism.

Dulong determined the refractive powers of a considerable number of gases and vapours by the following method, founded on the proportionality of the refractive power to the density. A distant mark is observed by a telescope through a Borda's prism filled with dry air, at a pressure *h*. The prism and telescope are then fixed, and the prism is filled with another gas, the pressure of which is varied till the image of the mark again coincides with the wire of the telescope. The refractive index of the gas under the pressure *h'*, is then equal to that of the air under the pressure *h*. If then μ' and μ are the indices of refraction of the gas and of air at the same pressure *h*, and at the same temperature, we have, since the index of the gas under the pressure *h'* is equal to μ ,

$$\mu'^2 - 1 : \mu^2 - 1 = h : h',$$

whence μ' is easily found.

Refractive power of Gases.

By this method Dulong has shown: 1. That the refractive power of a mixture of gases is equal to the mean of those of the constituent gases calculated for the pressure to which each gas is actually subjected in the mixture. 2. That the refractive power of a compound gas is not equal to the mean of those of the component gases, but is sometimes greater and sometimes less. The third column of the following table exhibits the differences between the actual refractive powers of certain compound gases, and those which would be obtained by adding together the refractive powers of the several components, and dividing by the volume of the compound gas. The refractive power of atmospheric air is found to be exactly the mean of those of its two constituent gases, a fact which shows, together with others, that the air is a mixture, and not a compound of oxygen and nitrogen.

The numbers in this table show that there is no simple relation between the refractive powers of different gases and their densities; hydrochloric acid gas, for example, has a lower density, but much higher refractive power than sulphurous anhydride, and ether-vapour has about the same density as chlorine, but double the refractive power.

The interferential method, the principle of which has been already described, is very well adapted to the measurement of the refractive indices of gases, and gives results more exact than those of the preceding methods. Arago and Fresnel applied it to the comparison of the refractive indices of moist and dry air. The interfering rays were made to pass through two copper tubes, each a metre in length, and closed at the ends with glass plates having exactly parallel faces, the one being filled with moist and the other with dry air. The fringes were then found to be displaced to the amount of one band and a quarter on the side of the dry tube, showing that moist air is rather less refractive than dry air. *Precipitated vapour* was found to produce a very slight increase in the refracting power of the air.

An improved apparatus for experiments of this kind has been constructed by Jamin, but we must refer for the description of it to his memoir (Ann. Ch. Phys. [3], xlix. 382), or Daguin's *Traité de Physique*, iv. 402. By means of this apparatus, Jamin has shown that vapour of water, at the temperature of 0° and at 0.76 met. barometric pressure, supposing it could exist under those circumstances, would have an absolute index of refraction equal to 1.00261, which is less than that of air at the same temperature and pressure. The refractive power of aqueous vapour calculated by the formula $\mu^2 - 1$ is therefore = 0.000521.

By adding to the refractive index of dry air that of aqueous vapour in the saturated state, under the pressure which it possesses at 20° , Jamin finds that the difference between the refractive indices of dry air and air saturated with aqueous vapour is only 0.000000726, a quantity which is too small to produce any sensible effects with Borda's prism, and may be safely neglected in the calculation of atmospheric refraction for astronomical purposes.

Refractive power of vapours produced at high temperatures. Leroux (Ann. Ch. Phys. [3], lxi. 386) has measured the refractive indices of a few of these vapours by the method of least deviation, using a hollow prism of iron having part of its opposite faces replaced by flat glass plates, and provided with proper appliances for heating, and for keeping the pressure of the vapour equal to that of the atmosphere. The indices and refractive powers of the vapours examined are as follows:

Substance.	Absolute index of refraction.	Refractive power $\mu^2 - 1$.
Sulphur . . .	1.001679	0.003258
Phosphorus . .	1.001361	0.002728
Arsenic . . .	1.091114	0.002228
Mercury . . .	1.000556	0.001112

Dispersion.

When a narrow beam of the sun's rays is passed through a glass prism (*fig. 664*) and received upon a screen, an elongated image or spectrum is formed, exhibiting a series of brilliant colours in the following order:

Red. Orange. Yellow. Green. Blue. Indigo. Violet.

the red occupying the lowest or the highest place, according as the refracting angle of the prism is turned downwards or upwards. The different coloured rays are therefore refracted by the prism in different degrees, the red exhibiting the least, and the violet the greatest deviation. Moreover, if a small hole be made in any part of the screen so as to allow a narrow beam of the rays of any one colour to pass, and this beam be transmitted through another prism, it will not again be elongated and split up into

different colours, but will form upon a second screen an image of the same shape as the aperture, and of the same colour as the beam before passing through the second prism. In this second refraction also, the red exhibits the least, the violet the greatest deviation.

Fig. 664.

Fig. 665.

It was by observations of this kind that Newton made the grand discovery, that *Solar light may be separated by refraction into a number of rays of different colours, and that to each colour there corresponds a distinct degree of refrangibility, the red rays being the least, the violet the most refrangible, and the intermediate colours increasing regularly in refrangibility from the red to the violet.*

This result is confirmed by the fact that the reunion of the colours of the spectrum produces white light. This may be shown by receiving the beam of light *s*, refracted by a prism *P* (fig. 665), on a second prism *P'* of the same substance and having the same refracting angle. The rays are thus brought back to parallelism and form a beam of white light. A very simple apparatus for exhibiting this recombination of white light is a rectangular glass trough divided in halves by a diagonal glass partition. On pouring water into one of the divisions and passing a beam of sunlight through it, a coloured spectrum is formed; but on pouring water into the second division, the rays are brought back to parallelism, and the emergent beam is white.

Another mode of demonstrating the recombination is to colour a circular piece of card-board in sectors with the tints of the spectrum, and give it a rapid rotatory motion. If the disc revolves in less than the tenth of a second (the time during which an impression remains on the retina) the whole surface appears of a uniform greyish-white tint, the deviation from perfect whiteness arising from the impossibility of exactly imitating the colours of the spectrum by pigments.

To obtain a complete separation of the colours of the spectrum, the prism should have a large refracting angle, and the aperture should be as narrow as possible: for a wide aperture may be regarded as a number of narrow ones side by side, each of which produces its own spectrum, the colours of the several spectra thus formed overlapping each other and producing compound tints; indeed, if the aperture exceeds a certain width, the middle of the image will receive rays of all colours and will appear white. For the same reason, the beam of light must not be divergent, and the apparent diameter of the luminous body from which the light proceeds must be as small as possible: for the incident light passing through a very small aperture is more divergent as the apparent diameter of the source of light is larger; the sun's rays passing through such an aperture form a cone having a vertical angle of 30 minutes. Newton obtained a

Fig. 666.

very bright and pure spectrum by passing a broad and thick rectangular beam of light through a convex lens *L* (fig. 666) of long focus, placed very near the prism *P*, and receiving the light on a white screen placed in the focus of the lens. Each colour is then brought to a focus on the screen, forming a bright narrow spot, the whole producing a very pure spectrum *ru*. An improvement on

this arrangement is to use a cylindrical lens parallel to the edges of the prism, whereby the rays of each colour are collected into a thin focal band well separated from the rest. Foucault has made a further improvement by interposing, between the lens and prism, a diaphragm, to stop the rays which would pass too near the edge of the lens, and diminish the sharpness of the coloured images. The spectrum is more elongated in proportion as the lens is placed nearer to the prism, which is then farther from the screen, the latter being placed at a determinate distance from the lens.

To obtain a beam of perfectly homogeneous light, a coloured beam passing through a small hole in the part of the screen on which the spectrum produced as above is received, is transmitted through a second prism; and if the deflected image thus formed is at all elongated, showing that the original coloured beam was not quite homogeneous, the light of a portion of it must be passed through an aperture in a second screen placed to receive it. A ray thus separated will be found to be perfectly homogeneous in colour, and of uniform refrangibility.

Instead of receiving the spectrum on a screen, it may be viewed directly by holding the prism between the eye and the source of light, the red rays then appearing in the highest or lowest position according as the refracting angle of the prism is held downwards or upwards. The spectrum may also be magnified by viewing it through a telescope. These methods enable us to view the spectra of sources of light not bright enough to throw a visible image on a screen, such as the light reflected from a strip of white paper on a dark ground.

The spectra of the moon and planets, and of white terrestrial objects illuminated by solar light, are similar to that obtained with the direct rays of the sun. The spectra of the fixed stars exhibit the same colours and nearly in the same proportions. Those of ordinary flames (hydrocarbon flames) likewise exhibit the same colours, but with a larger proportion of yellow. That of an alcohol flame consists mainly of yellow light, and if a little common salt be mixed with the alcohol, the flame gives a perfectly monochromatic yellow light. The flame of a Bunsen's burner in which a salt of lithium is ignited, gives a spectrum consisting almost wholly of red light; and when a salt of thallium is ignited in it, the spectrum consists wholly of green light.

Fixed Lines in the Solar Spectrum.

Newton, by passing a beam of light proceeding from a small circular aperture through a prism, obtained a spectrum which appeared perfectly continuous, whence he concluded that white light contained rays of all degrees of refrangibility, regularly increasing from the red to the violet. But Wollaston in 1802, by looking through a good flint glass prism at a very narrow rectangular aperture illuminated by sun-light, perceived that the spectrum was intersected by several very fine dark lines parallel to the edges of the prism, or to the boundary lines of the several colours; and fifteen years afterwards, Fraunhofer of Munich, without being acquainted with Wollaston's observations, made the same discovery by viewing a spectrum formed in the manner just described through a telescope. The lines were very fine, all dark, and some perfectly black, and Fraunhofer was able to count between 500 and 600 of them, their number increasing with the magnifying power of the telescope. These lines are distributed irregularly throughout the whole length of the spectrum, and do not, for the most part, occur at the limits of the principal colours. Eight of them, easily distinguished by their position and intensity, are denoted by the first eight letters of the alphabet, beginning from the red of the spectrum: they are shown in *fig. 667*. Some of them, when examined by a good magnifying power in a well-developed spectrum, are resolved into a number of fine lines very close together. There are two more groups of lines which are particularly conspicuous, one denoted by *a*, consisting of eight fine lines in the red between A and B, and another *b* in the green near E, consisting of three fine lines, the two stronger of which are separated by a bright space.

These dark lines show that the solar spectrum is not continuous; in other words, that there do not exist rays of all degrees of refrangibility between the red and the violet.

The aspect, order, and relative distances of the lines in the solar spectrum remain the same, for a prism of given substance, whatever may be the magnitude of its refracting angle; but if the substance of the prism be changed, the relative distances of the fixed lines and the relative widths of the several coloured spaces are likewise altered.

To obtain the lines of the spectrum well developed, it is necessary to use a prism of very uniform substance, free from striae, and having a refracting angle large enough to yield a very pure and extended spectrum. Prisms for the purpose are generally made of flint glass or rock-crystal, substances having a high dispersive power, that is to say, the power of refracting the red and violet rays in very different degrees (p. 623). A hollow prism filled with sulphide of carbon is also well adapted for the purpose, as it is sure to be uniform, if preserved from variations of temperature, and its dispersive power is very great. To form the spectrum, the sun's rays, or the diffused light of the sky, entering a darkened room through a narrow slit, or condensed by a cylindrical lens, are made to pass through the prism, and the dispersed beam of light is viewed through an achromatic telescope. The lines and intermediate spaces are thereby magnified, the number seen being greater in proportion to the magnifying power of the telescope. The most favourable position for the prism is that of minimum deviation.

Lines also exist beyond A in the red, and beyond the violet in a space occupied by very faint lavender-coloured rays. The first were observed by Brewster in a space

equal to AB (*fig. 667*), the second by Sir John Herschel. To render these lines visible, several precautions are required; amongst others it is necessary to intercept all the rays between the red and violet, and line the tube of the telescope with black velvet. By

Fig. 667.

adopting these and other precautions, and using a prism of oil of cassia, which possesses a high dispersive power, Brewster was able to distinguish altogether about 1000 lines in the spectrum, a map of which, together with a delineation of the two extremities of the solar spectrum, as observed by Gladstone when the sun was at about his greatest altitude, is given with a paper "On the Lines of the Solar Spectrum" by Brewster and Gladstone, published in the *Philosophical Transactions* for 1860, p. 149.

A still greater development of the spectrum, and an increased number of lines, are obtained by passing the rays through a series of prisms. In this manner Kirchhoff has observed about 2000 lines, and has been enabled to lay down a very elaborate map of the solar spectrum, which is published in his work, translated by Roscoe, under the title—*Researches on the Solar Spectrum, and on the Spectra of the Chemical Elements*.

Gassiot has constructed a train of nine flint glass prisms with angles of 45° , and another of eleven sulphide-of-carbon prisms with angles of 45° , with which further observations have been made. (*Proc. Roy. Soc.* xii. 536; xiii. 183.)

Solar light reflected from a white surface, also that of the clouds, and that of the moon and planets, give spectra exhibiting the same principal lines, and disposed in the same order, as in the spectrum formed by the direct rays of the sun. In the spectra of Mars, Jupiter, and Venus, the lines D, E, F may be very clearly distinguished. But the fixed stars give spectra containing different lines. That of *Sirius* contains two dark lines in the blue, and one very strong line in the green, but none in the yellow or orange; that of *Pollux* contains several faint lines, the line D occupying apparently the same place as in the solar spectrum. See further a paper by Huggins and Miller. (*Proc. Roy. Soc.* xiii. 64.)

Effect of coloured Gases on the appearance of the Lines. When a ray of light passes through a coloured gas before falling on the prism, dark lines make their appearance due to the absorption of certain rays by the gas. When the light of a lamp, which of itself gives a spectrum containing only bright lines (p. 622), is passed through the red vapour of pernitric oxide, the violet and blue portions of the spectrum are covered with black lines or rather bands, which become broader as the density of the gas is increased, and ultimately join, so as completely to obliterate the violet rays; at the same time dark lines make their appearance in the yellow, and ultimately extend into the red (Brewster, *Phil. Mag.* [3], viii. 384). Iodine- and bromine-vapours produce dark lines different from those formed by pernitric oxide, appearing first in the green and yellow, then in the orange, and at the commencement of the red, some being quite black while others formed dark bands. The mere existence of colour in a vapour does not, however, necessitate the existence of bands in its spectrum. The red vapours of chloride of tungsten, for example, give no lines whatever. Neither can the position of the lines be inferred from the colour of the gas; with green perchloride of manganese, they are most abundant in the green, while with the red vapours of pernitric oxide, they increase in depth and number as they approach the violet. The vapours of simple bodies as well as of compounds may produce lines, and two simple bodies which singly do not produce them, may produce them abundantly in their compounds; e.g., neither oxygen, nitrogen, nor chlorine, when uncombined, produces lines, but some of the oxides, both of nitrogen and chlorine, exhibit the phenomena in the most striking manner. There are, however, oxides both of nitrogen and chlorine, some of them coloured, which do not occasion the appearance of lines. Lines may also be produced by simple substances, which disappear in their compounds; thus iodine produces lines which do not appear in the spectrum of hydriodic acid. Sometimes the same lines are produced by different degrees of oxidation of the same substance, a remarkable instance of which is afforded by the oxides of chlorine. (*W. A. Miller, Elements of Chemistry*, 3rd ed. i. 164.)

When solar light is passed through a coloured vapour, the density of which is gradually increased, absorption-bands make their appearance, faint at first and easily distinguished, but gradually becoming blacker, and ultimately obliterating the ordinary lines. The two systems of lines are in fact distinct in the spectra of all coloured vapours, excepting that of pernitric oxide, in which they coincide. (Brewster.)

As the atmosphere possesses a slight colour, it is possible that some at least of the

ordinary lines of the solar spectrum may be due to the absorption of certain rays during their passage through the earth's atmosphere; and in fact the lines are more numerous, and some of them, especially those in the red, are remarkably distinct when the sun is near the horizon, and its rays have consequently to travel through a greater thickness of atmospheric air, than when he is at a greater altitude; but the greater number of the lines are probably due to another cause, to be considered hereafter. (Brewster and Gladstone, Phil. Trans. 1860, p. 149; Gladstone, Proc. Roy. Soc. xi. 305.)

Spectra of Flames and Incandescent bodies.

Incandescent solids and liquids give continuous spectra without any dark lines or spaces. Flames, *i.e.*, incandescent gases or vapours, give spectra consisting of bright bands, more or less numerous, with dark spaces between. An alcohol flame or that of a Bunsen's burner in which common salt or other volatile sodium-compound is ignited, gives a spectrum reduced to a narrow yellow band, coincident with the solar line D. Lithium ignited in a similar manner exhibits a single bright crimson line near the solar C. The potassium-spectrum, similarly produced, consists of a red band coinciding with A, and a violet band not coinciding with any of the principal solar lines, the intermediate portion of the spectrum being filled up with a diffused light. The thallium spectrum consists of an intense green line near the solar line E, which is split up by Gassiot's train of eleven sulphide-of-carbon prisms into three separate lines. The spectra of the alkaline earths are equally definite, though more complicated. (See ANALYSIS, INORGANIC; also SPECTRAL ANALYSIS.)

In some cases, new series of bands become visible as the temperature rises; thus the spectrum of chloride of lithium in the flame of a Bunsen burner, gives but a single intense crimson line; in a hotter flame, as that of hydrogen, it gives an additional orange ray; and in the oxy-hydrogen jet and in the voltaic arc, a broad brilliant blue band likewise comes out. A similar effect is perceived in the case of metallic iron, of thallium, and other metals when heated by the voltaic arc. A. Mitscherlich (Pogg. Ann. cxvi. 499) has shown that in flames of low temperature, the lines produced vary with the compound employed, the spectrum then observed being that due to the compound, and not to its elementary constituents; the spectrum of copper, for example, differs considerably from that of an alcoholic solution of chloride of copper, while that from an alcoholic solution of iodide of copper differs from both.

Spectra of the Electric Light.—The spectrum of the electric light exhibits bright lines like those of flames. This was first observed by Wollaston, afterwards by Fraunhofer, who found that the line of bluish light obtained by discharging the electricity of a machine through a very fine wire, gave a spectrum containing a very bright line in the green. Wheatstone has shown that the electric light from the voltaic battery, the ordinary electric machine, and the induction coil, yield the same spectra when the spark passes between conductors of the same kind; but the number and position of the lines varies with the nature of the metallic poles; if they are formed of an alloy, two systems of lines are obtained, one belonging to each of the metals; the same is also the case when the two poles are formed of different metals. These facts show plainly that the electric spark contains particles of metal detached from the conductors between which it passes.

Masson, in the course of his researches on electric photometry, already cited (p. 596), examined the spectra produced by various metals when employed as dischargers to a Leyden jar, and when heated by the voltaic arc, and found them to contain a much greater number of lines than those of the same metals delineated by Wheatstone. The difference was subsequently explained by Ångström (Phil. Mag. 1855, p. 329), who showed that Masson, in consequence of the intense heat of the electric discharges which he employed, obtained two spectra, one due to the metal, the other to the atmosphere itself, which became ignited. Certain lines observed by Masson as common to the spectra of all the metals, were really those atmospheric lines. By causing the spark to pass between the same metals immersed in various gases, the particular lines due to the metal remained unaltered, whilst the others due to the gaseous medium, disappeared and were replaced by new lines.

For further details, and for the methods of examining the spectra of flames and incandescent bodies, see SPECTRAL ANALYSIS.

Kirchhoff's theory of the Lines in the Solar Spectrum. The vapour of any substance absorbs rays of the same degree of refrangibility as those which are emitted by the same substance in the state of incandescence, that is to say, those which form the bright lines of its spectrum. Thus ignited sodium emits a yellow light, the spectrum of which consists of two bright bands coincident with the double line of the spectrum. If now, through a flame coloured by sodium, the light from the oxy-hydrogen flame, or that of the voltaic arc between carbon electrodes, is passed, the

mitted, the continuous spectrum produced by either of these sources is interrupted by a black line coinciding with the solar line D. In like manner the spectra of potassium, lithium, barium, strontium and copper, may be reversed. On these facts Kirchhoff founds an explanation of Fraunhofer's lines. He supposes that the luminous atmosphere, or *photosphere*, of the sun contains the vapours of various metals, and that behind this incandescent atmosphere is the still more intensely heated solid or liquid nucleus of the sun, which emits light of all degrees of refrangibility, and would produce a continuous spectrum, were it not that some of the rays, in passing through the photosphere, are absorbed by vapours which are themselves capable of emitting rays of the same degree of refrangibility, so that Fraunhofer's lines are only the reversed bright lines which would be visible if the more intensely heated nucleus were not there. A very careful comparison of the solar spectrum with those of various metals, has shown that the former contains dark lines coincident with certain bright lines in the spectra of sodium, potassium, magnesium, calcium, iron, chromium, and nickel: hence Kirchhoff infers that the solar atmosphere contains these metals, and possibly also zinc, cobalt, and manganese, but not lithium, copper, or silver. Angström is of opinion that the presence of hydrogen and aluminium may also be considered as proved, and that barium and strontium are probably also present. (See Kirchhoff's *Researches on the Solar Spectrum and on the Spectra of the Chemical Elements*, translated by Roscoe; also the article SPECTRAL ANALYSIS in this Dictionary.)

Dispersive Powers of different Media.

The separation of the extreme rays of the spectrum, and consequently the length of the spectrum produced by different media, exhibits great diversity. Suppose three prisms to be formed, one of water, the second of crown-glass, and the third of flint-glass, with such refracting angles as to produce equal deviations for any given ray of the spectrum, say the line F, about the middle: then it will be found that the crown-glass spectrum is about $1\frac{1}{2}$, and the flint-glass spectrum $3\frac{1}{2}$ times as long as the water spectrum. It appears then that flint-glass disperses the different coloured rays much more than crown-glass, and crown-glass much more than water.

It is this difference in the dispersion produced by different media for the same amount of refraction of a given ray, which renders it possible to form achromatic combinations of prisms and lenses. The object of such combinations is to reproduce white light by recombining the coloured rays which have suffered dispersion; and this is effected by passing the rays which have been dispersed by one lens or prism through a second lens or prism which refracts them the contrary way (see *fig. 665*, p. 619). But it is evident that if all refracting media dispersed the rays equally for a given amount of mean refraction, the only way of effecting this would be to give the two prisms the same refracting angle (see *fig. 665*), or the two lenses (one convex, and the other concave) equal curvatures; but in this case all the rays would be brought back to the same degree of convergence or divergence as they had before passing through the first lens or prism; indeed the combination would act just like a plate of glass with parallel faces, and would produce no alteration in the direction of the rays. But suppose two prisms, the first of crown- and the second of flint-glass, to be placed together as in *fig. 665*, and their refracting angles to be so proportioned as to produce equal deviations of the middle ray of the spectrum; then, as already observed, the flint prism will disperse the rays about twice as much as the crown; and if instead of this, the refracting angles are so adjusted as to produce equal amounts of dispersion, or spectra of the same length, then the angle of the second must be of such a magnitude as to deviate the mean ray less than the crown-glass prism does. Such a combination will recombine the coloured rays and reproduce white light, without bringing back the rays to their original direction. In like manner, if a concave lens of flint-glass be placed behind a convex lens of crown-glass, its curvature may be so adjusted as to recombine the colours without destroying the convergence of the rays produced by the crown-glass lens.

The difference between the indices of refraction of the extreme rays of the spectrum $\mu_v - \mu_r$, or more precisely of the fixed lines B and H, produced by any refracting medium is called the coefficient of dispersion, or simply the dispersion of that medium.

The following is a list of thirteen substances placed in the order of their coefficients of dispersion, as determined by Wollaston, the most dispersive being placed first; Sulphur, oil of turpentine, flint-glass, oil of turpentine, Iceland-spar, diamond, crown-glass, water, sulphuric acid, alcohol, heavy-spar, rock-crystal, fluor-spar. The most dispersive of all known substances is melted phosphorus, then a solution of phosphorus in sulphide of carbon, and finally of carbon itself (see p. 629).

The term *dispersion* is applied to the difference of the refractive indices

of any other two colours, the red and yellow, blue and green, &c., always referred to the principal fixed line belonging to each colour. The partial dispersions of any two substances are by no means proportional to their total dispersions; consequently the colours are not distributed in the same manner in the spectra formed by the two substances.

Sulphuric acid and oil of cassia, for example, produce spectra of nearly equal lengths; but in the oil of cassia spectrum, the least refrangible portion—namely, the red, orange and yellow—is much less, and the more refrangible portion, from blue to violet, is much more expanded than in that produced by sulphuric acid. In like manner, flint-glass contracts the less, and expands the more refrangible portion of the spectrum, to a greater extent than crown-glass. This irrationality of dispersion must of course be attended to in the formation of achromatic combinations.

The ratio of dispersion of two media is the ratio of the coefficients of dispersion, $\frac{\mu_y - \mu_r}{\mu_v - \mu_r}$, or of the partial coefficients belonging to the corresponding fixed lines in the two spectra. This ratio has different values according to the two lines which are considered.

The term dispersive power is applied to the ratio of the dispersion-coefficient to the index of refraction of the mean ray diminished by 1. Taking as the mean ray the line E in the yellow, and calling its index of refraction μ_y , the dispersive power is expressed by the formula, $\frac{\mu_v - \mu_r}{\mu_y - 1}$.

The following table contains the refractive indices of several media for the principal lines of the spectrum, as determined by Fraunhofer; the last column contains the coefficients of dispersion between the lines B and H:

Babinet has given a method of measuring the dispersions of bodies which can only be procured in small fragments. The substance being cut into the form of a prism, and its angle measured, a spectrum projected on a screen by a prism of known angle, is viewed through the small prism whose dispersion is to be determined, in such a manner as to recompose the colours (p. 619), the observer gradually increasing his distance from the spectrum till he sees nothing but white light. If the prisms are in the position of least deviation, and their angles are not too large, their dispersions are to one another in the inverse ratio of their distances from the screen.

Gladstone and Dale have made an extensive series of researches on the refraction, dispersion, and sensitiveness of liquids, the last term being used to signify the relation between the change of refraction and the change of volume by heat. The following are the principal results obtained:

1. *Both refraction and dispersion diminish as the temperature increases.* This law has been verified by observations on about 90 liquids (see p. 626).

The following table exhibits these results in the case of a highly dispersive liquid; it will be observed that the sensitiveness of the rays increases in the order of their refrangibility.

Refractive Indices of Sulphide of Carbon for the several Fixed Lines.

	A.	B.	D.	E.	F.	G.	H.
11°	1.6142	1.6207	1.6333	1.6465	1.6584	1.6386	1.7090
36.5	1.5945	1.6004	1.6120	1.6248	1.6362	1.6600	1.6827
Difference .	0.0197	0.0203	0.0213	0.0217	0.0222	0.0236	0.0263

On comparing the change of refraction by heat with the corresponding change of volume in sulphide of carbon, water, methylic, ethylic, and amylic alcohols, acetone, acetic acid, formic, acetic, and butyric ethers, methylic and ethylic iodides, salicylate of methyl, bromoform, benzene, xylene, cumene, nitrobenzene, hydrate of phenyl, the rectified oils of turpentine and Portugal, and eugenic acid, it was found that the refractive index minus unity ($\mu - 1$), multiplied into the volume, gives very nearly a constant product at different temperatures. The quantity $\mu - 1$ is termed by the authors, the refractive energy of a substance, and this multiplied into the volume, or divided by the density, is termed the specific refractive energy. The preceding law may then be stated as follows:—*The refractive energy of a body varies directly with its density, under the influence of change of temperature; or in other words, the specific refractive energy of a liquid is a constant not affected by temperature.* The influence of dispersion, however, renders this law not absolutely accurate in the observed numbers: for the change of dispersion does not follow the same law, the spectrum contracting in some cases much more, and in other cases much less rapidly as the volume increases; indeed no relation is as yet discoverable between change of dispersion and density.

2. The results obtained with mixed liquids, appear to show that *the specific refractive energy of a mixture is the mean of the specific refractive energies of its components.* This law was tested with sulphide of carbon and ether, substances which are almost at the opposite limits of the scale, and were found to mix without condensation; also with aniline and alcohol, on mixing which, however, some diminution of volume occurs. In both these cases, the experimental numbers were slightly below those deduced from the mean of the specific refractive energies; yet no other formula could be devised which would give a nearer approximation to the indices actually observed.

3. *Compounds belonging to the same homologous series exhibit a progressive change in refraction and dispersion as they advance in the series; but the deviation and extent of those changes depend on the other substances with which the radicle is combined. If, however, we regard, not the actual indices, but these minus unity divided by the specific gravity, we find an invariable increase as the series advances.*

The following tables exhibit this with regard to various groups of compounds containing the alcohol-radicles, C^mH^{2m+1} .

With regard to other groups of homologous bodies, it was found that benzene, benzylene, xylene, cumene and cymene, gave nearly the same numbers, and no regular progressions. Pyridine, picoline, lutidine, and collidine showed an augmentation of the specific refractive energy, but a diminution of the specific dispersion with the advancing series: chinoline and lepidine (the most refractive organic liquid known) showed an increase of each of the optical properties by addition of CH^3 . Hence it appears that the influence of the added increment on the rays of light differs in different groups, just as it does in respect to the boiling point.

4. *Isomeric bodies are sometimes widely different in their optical properties: but in many cases, especially where there is close chemical relationship, there is identity also in this respect.* Several hydrocarbons of the type $C^{10}H^{14}$, from essential oils, appear to be identical in actual refractive power, notwithstanding slight differences of density. In dispersion there are some variations, but not in sensitiveness. Other hydrocarbons, however, of the same ultimate composition, but differing considerably in physical properties differ also optically. Metameric compound ethers, such as valerate of ethyl and acetate of amyl, are optically identical. Aniline and picoline, each empirically C^8H^7N , are totally different.

5. *Effect of Chemical Substitution.*—When hydrogen is replaced by some other body, there is generally an increase of the actual refraction and dispersion; but this is due to the increased weight, hydrogen having a very low actual, but a very high specific influence on the rays of light. When two substitution-products are formed by substitution of the same element in a given compound, e.g. mono- and tri-chlorobenzene from benzene, the lower one always retains, in its optical properties, a position intermediate between the original substance and the higher product.

From these facts, it may be inferred, as approximately, if not absolutely, true, that: *Every liquid has a specific refractive energy composed of the specific refractive energies of its component elements, modified by the manner of combination, but unaffected by change of temperature; and this refractive energy accompanies it when mixed with other liquids.* The product of the specific refractive energy and the density at any given temperature, is, when added to unity, the refractive index.

The following tables exhibit the numerical results from which the preceding conclusions are deduced.

TABLE A.

Refractive indices of the lines A, D, H at different temperatures.

The sign ? attached to a liquid denotes that the purity of the specimen is doubted.

An asterisk * attached to a degree of temperature signifies that the observations at that temperature were made on a different occasion to the observations at other temperatures.

Specific gravities not determined from the specimens examined are included in brackets.

Cause of Dispersion.—As the several colours correspond to vibrations of different rapidity, and the deviation of rays of light in refraction depends on the change of velocity of light in passing from one medium into another, it follows that in order to explain dispersion, we must suppose that this change of velocity is different for rays of different colours, that is to say, that waves of different length travel through refracting media with different velocities. This consequence was for a long time regarded as a grave objection to the undulatory theory of light, being in fact in contradiction to the general formula for the velocity of undulations established by Newton, viz. $v = \frac{c}{\lambda}$. It must, however, be remembered that though the velocity of light in

free space is the same for rays of all colours (p. 594), it is by no means necessarily so in transparent media, which retain the ether imprisoned, as it were, between their particles. The waves must then turn round these molecules, and it is easily conceivable that the retardations thus produced may be greater for the shorter than for the longer undulations. That such is the case has in fact been proved by the analytical researches of Cauchy; but the demonstration is not of a character to be introduced into this work, and does not admit of representation in a more elementary form.

Heating, Chemical, and Phosphorescent Rays of the Spectrum.

All the rays of the solar spectrum are capable of giving heat as well as light. A thermometer held in any part of the spectrum indicates a rise of temperature; but the heating effect is very different in different parts, being greatest at the red end of the spectrum; but the particular position of the maximum heating effect varies with the kind of prism used. Moreover, there are invisible heat-rays situated beyond the red, and therefore of lower refrangibility than any of the luminous rays; and when a flint-glass prism is used, the maximum of heating power is situated beyond the visible red rays.

The spectra of flames exhibit similar results, provided the heat-rays which they emit are capable of passing through the substance of which the prism is formed, which is not always the case. (See RADIATION OF HEAT.)

The solar rays are also capable of producing chemical change, chiefly of the reducing order. Thus silver-salts are blackened and more or less reduced by exposure to daylight, and the leaves of plants, under the influence of sunlight, decompose the carbonic acid in the air, and assimilate its carbon. This action is exerted by all the luminous rays of the spectrum, but chiefly by the violet rays, and by non-luminous rays extending to a considerable distance beyond the violet. The yellow and red rays have but little chemical power: hence ordinary flames (hydrocarbon flames) in which these rays greatly predominate, exert but little action on chloride of silver and other bodies, which change rapidly under the influence of solar light; and in monochromatic yellow flames, such as that of alcohol containing a sodium-salt, the chemical action is altogether imperceptible. Photographers develop their pictures in rooms into which light is admitted only through yellow glass or yellow paper. Violet flames, on the other hand, like that of burning magnesium, emit rays whose chemical activity rivals that of sunlight, though their luminosity is incomparably less. The maximum of chemical action is not, however, produced upon all substances in the same part of

the spectrum. According to E. Becquerel (Ann. Ch. Phys. [3], ix. 257), chloride of silver begins to blacken in the extreme violet between the lines H and G, the coloration extending on the one side nearly to F, and on the other considerably beyond the visible violet. With the iodide and bromide of silver, the effect is similar, excepting that the action does not extend so far beyond the violet, and the maximum does not occupy the same place. Guaiac-resin, which is turned blue by exposure to sunlight, is not at all affected by any of the visible rays of the spectrum, the action beginning only in the ultra-violet, and the maximum being situated a long way beyond the end of the visible spectrum.

The chemical spectrum contains fixed lines, that is to say, portions in which no chemical action is produced, so that when a piece of paper covered with chloride of silver or other sensitive substance has been exposed to the spectrum, the blackened surface is traversed by lines of the same colour as the original substance, in the ultra-violet as well as in the visible portion of the spectrum. A diagram of these lines will be given in the next article on the CHEMICAL ACTION OF LIGHT.

The interposition of *colourless plates or films* does not modify the chemical action in the visible part of the spectrum between A and H; that of the rays between H and P is likewise unaltered by certain transparent substances, such as water, alcohol, sulphuric acid, &c., whereas other substances, both liquid and solid, weaken the chemical action of the most refrangible chemical rays situated beyond the visible spectrum, from P to a point more or less near to H. With nitric acid and oil of lemons, the absorbent action stops at N; with creosote, bitter almond-oil, and a dilute aqueous solution of sulphate of quinine, at H. (For further details respecting the chemical action of light, see the next article.)

The different rays of the spectrum also differ in their power of producing phosphorescence. When Canton's phosphorus spread on a sheet of paper is exposed in a dark room to the action of the spectrum, phosphorescence is produced by the rays between G and P (see figure in the next article); there is a less luminous portion between I and N, and two maxima, one between H and G, the other in O. The Bolognian phosphorus gives similar results, excepting that there is no minimum in I N, and only one maximum between I and M. It appears therefore that the phosphorogenic rays occupy the same portion of the spectrum as the chemical rays.

The colour of the phosphorescent light, which may vary from orange-red to violet, has no relation to that of the exciting rays, excepting in the case of three substances: *sulphide of barium*, which shines with an orange-yellow light when it has been exposed to the rays between H and P, with a more reddish light when it receives the blue and violet rays; *sulphide of calcium*, which shines with an orange-red light when it has been exposed to the rays between F and O, and exhibits a slight greenish shade when the incident rays are comprised between O and P; lastly, the substance obtained by the action of sulphide of potassium on oyster-shells calcined with lime, which emits a violet-indigo light after exposure to rays of the same tint, and becomes blue in the ultra-violet rays. In general, the emitted rays are less refrangible than the exciting rays, the last-mentioned substance, however, forming an exception to this rule.

The *electric light*, which is very bright and very rich in highly refrangible rays, produces phosphorescence more actively than the solar rays. The sudden discharge is more efficacious than the continuous light of the voltaic arc.

The phosphorogenic spectrum likewise exhibits dark lines or lines of no action; but to see them it is necessary to extend the spectrum to about ten times its usual length by means of diverging lenses. Dark lines are then seen on the phosphorescent surface, occupying the same position as those of the luminous and chemical spectra. They may be rendered more distinct by heating the phosphorescent body to between 200° and 300°; the luminous portions then become brighter, and the lines more distinct.

Transparent substances, both coloured and colourless, placed in the course of the incident rays, absorb the phosphorogenic rays in the same parts of the spectrum as the luminous and chemical rays.

Identity of the calorific, luminous, chemical, and phosphorogenic rays.—It was formerly supposed that the rays producing these several effects are distinct from each other; in fact, that luminous bodies emit four kinds of rays, which, when dispersed by a prism, form four spectra superposed over each other, but having their maxima and minima at different places. But it is much more probable that the rays or undulations are all of one kind, and capable of producing one or other of the effects above mentioned, according to the nature of the bodies or organs upon which they act. In fact, the calorific and chemical rays are reflected and refracted in the same manner as luminous rays of equal refrangibility; the calorific, luminous, and chemical spectra are interrupted by the same lines; and bodies which absorb the luminous rays likewise absorb heat-rays and chemical rays of the same degree of refrangibility. The same is true with regard to the phosphorogenic rays, so far as they extend into the luminous

part of the spectrum. Moreover, Fizeau and Foucault have shown that the chemical actions produced at the focus of a lens by the light of the voltaic arc and the lime-light, are to one another in the same ratio as the luminous intensity.

The production of the several effects above mentioned by the same rays, is quite in accordance with the wave-theory of light. The waves of the ether striking on the surface of ponderable bodies throw their particles into vibration, and the particular effects produced are determined by the rate and mode of vibration thus excited, which themselves depend upon the manner in which the particles of the body are held together, as well as upon the rate of vibration of the incident waves. Rays whose length and rapidity of vibration are such as to excite in our organs the sensations of both heat and light, may, when they impinge upon a ponderable body, set its particles into such a rate of vibration as to excite in the surrounding ether, waves whose length and rapidity of vibration correspond to the least refrangible rays of the spectrum beyond the visible red. In like manner, we shall presently see that the invisible chemical rays at the other end of the spectrum may excite vibrations of less rapidity, which render visible the body on which they impinge. The effect thus produced is called

Fluorescence.

It was observed some years ago, by Sir John Herschel, that a solution of sulphate of quinine, though perfectly colourless by transmitted light, exhibits in certain aspects a peculiar blue colour. This blue light was found to be produced only by a very thin stratum of liquid adjacent to the surface by which the light entered, and the incident beam, after having passed through the stratum from which the blue light came, was not sensibly weakened or coloured, but had lost the power of producing the usual blue colour when admitted into another solution of sulphate of quinine. Light thus modified was said by Sir J. Herschel to be *epipolised*.

Similar phenomena were observed by Sir D. Brewster in an alcoholic solution of chlorophyll, the green colouring matter of leaves, the path of a beam of sunlight admitted into the green solution being marked by a bright light of a blood-red colour. The same appearance was afterwards observed in various vegetable solutions and essential oils, and in some solids. Brewster distinguished this phenomenon by the name of *internal dispersion*, attributing it to the irregular reflection of the light from coloured particles suspended in the liquid, and was of opinion that Herschel's epipolised dispersion was only a particular case of this internal dispersion.

The true explanation of these remarkable phenomena has, however, been given by Professor Stokes, who has shown that the peculiar dispersion produced by sulphate of quinine, and the other liquids above mentioned, is due to a *change of refrangibility in the rays of light*. The following experiment renders this evident:—

A solar spectrum is formed by means of an achromatic lens, and one or more prisms of flint glass, sufficiently pure to render visible the principal fixed lines, and a tube filled with a solution of sulphate of quinine is passed along this spectrum, from the red towards the violet end. Nothing peculiar is observed while the tube is held in the less refrangible part of the spectrum, the light passing through it freely and without sensible modification; but just before it reaches the extremity of the violet, a peculiar blue diffused light makes its appearance at the surface of the fluid by which the light enters, and remains visible, even after the tube has passed beyond the violet into the invisible portion of the spectrum, acquiring, in fact, its greatest intensity at a certain distance beyond the extreme violet.

The stratum of liquid from which the diffused blue light emanates is thinner in proportion as the incident rays are more refrangible; and, from a little beyond the extreme violet to the end of the spectrum, the blue space is reduced to an excessively thin stratum adjacent to the surface by which the rays enter. It appears, therefore, that the solution, though transparent with respect to nearly the whole of the visible rays, is of an inky blackness with respect to the invisible rays more refrangible than the violet. Nevertheless, these rays, when once they have been converted into the visible blue light, pass through the liquid with facility. They must, therefore, be essentially altered in character. Now, a change in the quality of light must consist, either in a modification of its state of polarisation, or in its period of undulation. The former supposition is excluded by the fact that the light thus modified is not polarised at all. It must, therefore, have undergone a change in its rate of vibration, and consequently a change of refrangibility. The existence of this change is, moreover, distinctly proved by examining the diffused light with a prism. It is then found to be by no means homogeneous, but to be resolvable into rays of unequal refrangibility, the whole of which are, however, comprised within the limits of the visible spectrum. *The diffused blue light consists of the chemical rays rendered visible by a change in their refrangibility.*

The diffusion thus produced is entirely distinct from that which is due to reflection

from irregularities or suspended particles. The two phenomena are often produced together in the same medium; but they are easily distinguished by the fact that the light diffused by irregular reflection is more or less polarised, whereas the light diffused in the manner above described is entirely unpolarised, even if the incident rays were themselves polarised. This phenomenon, to which Professor Stokes originally gave the name of *true diffusion*, to distinguish it from the false diffusion produced by irregular reflection, is now called FLUORESCENCE.

It is exhibited by many solutions, and by many solid bodies, opaque as well as transparent, the colour of the diffused light varying with the nature of the medium. An aqueous infusion of horse-chestnut bark exhibits it very strongly, producing a blue colour similar to that of sulphate of quinine. Many compounds of sesquioxide of uranium are also highly fluorescent, and diffuse a greenish-blue light, especially the nitrate, and *canary-glass*. A decoction of madder mixed with alum gives a yellow or orange-yellow fluorescence; tincture of turmeric and alcoholic extract of thorn-apple seeds diffuse a greenish light; an alcoholic solution of chlorophyll, a red light.

When the fluorescence is strong, as with sulphate of quinine, it may be seen by merely viewing the substance by ordinary diffused daylight. For more accurate observation and for detecting fluorescence when it exists only in a slight degree, the following method is recommended by Stokes (Phil. Mag. [4], vi. 304):—

Light is admitted into a darkened room through a hole several inches in diameter in the window-shutter, and the object to be examined is placed on a small shelf, blackened at the top, and fixed just below. The hole is covered with an absorbing medium, called the *principal absorbent*, so selected as to transmit only the feebly luminous and invisible rays of high refrangibility. The body on the shelf is viewed through the second medium, the *complementary absorbent*, which is chosen so as to be as transparent as possible to those rays which are absorbed by the first, and to absorb all the rays which are transmitted by the first. If the media are well selected, they produce a very near approach to perfect darkness; and if the object appears unduly luminous, that effect most probably arises from fluorescence. To determine whether the illumination is really due to that cause, the complementary absorbent is removed from before the eyes to the front of the aperture, when the illumination, if really due to fluorescence, almost wholly disappears; whereas, if it be due merely to scattered light capable of passing through both media, it remains. In examining feebly fluorescent substances, however, it is better to keep the second medium in its place before the eye, and to use a third medium, the *transfer-medium*, placing the last alternately in the path of the incident rays, and between the object and the eye. Still greater delicacy of observation is attained by placing the substance side by side with a small white porcelain tablet, which is quite destitute of fluorescence, and examining the two as above. Or, again, the object being placed on the tablet, a slit is held close to it, in such a position as to be seen projected partly on the object, partly on the tablet, and the slit is viewed through a prism. The fluorescence of the object is evidenced by light appearing in regions of the spectrum, in which the rays coming through the principal absorbent, and scattered by the tablet, then produce nothing but darkness. These methods are delicate enough to show the fluorescence of white paper, even on a very gloomy day.

It is not merely the most refrangible rays that are capable of producing fluorescence; the rays of any part of the spectrum may undergo this change. By examining different media with the spectrum in the manner already described, it is seen that the fluorescence begins, sometimes in the blue, sometimes in the yellow. With an alcoholic solution of chlorophyll, it begins in the red. But wherever the change of refrangibility may begin, it is always in one direction, consisting in a diminution of the index of refraction, and a consequent depression of the light in the scale of colours. In other words, the *length of the wave is increased, and its velocity of undulation diminished*. The vibrations of the ether in the incident ray appear to excite disturbances within the complex molecules of the fluorescent medium, whereby new vibrations are excited in the ether, differing in period from those of the incident ray. The portion of the light which has produced this molecular disturbance is used up or *absorbed*, and thereby lost to visual perception, just as heat is converted into mechanical work. It is probable that the absorption of light always takes place in this manner. The well-known fact of the conversion of luminous rays into invisible calorific rays, is, as already observed, a striking instance of diminution of refrangibility accompanied by absorption.

As the most refrangible rays are the most active in producing fluorescence, it is natural that this effect should be most strikingly exhibited by the light of flames which are rich in those rays,—the flame of alcohol and of sulphur, for example. These flames do, in fact, produce the effect in a higher degree even than sunlight. An extremely beautiful effect is produced by exposing a number of highly fluorescent media, such as sulphate of quinine, infusion of horse-chestnut bark, and *canary-glass*, to the flame of sulphur burning in oxygen in a dark room.

The colour and composition of fluorescent light sometimes afford valuable aid in distinguishing between one substance and another, and in testing the purity of solutions. With a solution of a *pure substance*, the tint of the fluorescent light is almost perfectly constant. But this tint, it must be remembered, is that of the light *as emitted*, not as *subsequently modified* by absorption on the part of the solution, in case the solution be sensibly coloured, and some precautions are required in order to observe it correctly. The fluorescence observed in solutions from the barks of the horse-chesnut, ash, &c., was formerly attributed indiscriminately to the presence of *æsculin*, whereas a purified solution from the bark of the horse-chesnut exhibits a fluorescence very sensibly different from that of *æsculin*, which observation alone would suffice to show that the bark must contain some other fluorescent substance besides *æsculin*.

The best mode of observing the true fluorescent tint is to dilute the liquid considerably, and to pass into it a beam of sunlight, condensed by a lens fixed in a board in such a manner that as small a thickness of the liquid as possible shall intervene between the fluorescent substance and the eye. If a stratum of this thickness of the dilute solution is sensibly colourless, the tint of the fluorescent light will not be sensibly modified by subsequent absorption. But as direct sunlight is not always to be had, the following method, requiring only diffused daylight, may also be used, the solutions being pretty strong, or at least not extremely dilute.

A glass containing water and blackened internally at the bottom is placed at a window, and the solution to be examined as to its fluorescent tint is placed in a test-tube which is held vertically in the water, the top slightly inclining from the window, and the observer regarding the fluorescent light from above, looking outside the test-tube. Since by far the greater part of the fluorescent light comes from a very thin stratum of liquid next the surface by which the light enters, the fluorescent rays have mostly to traverse only a very small thickness of the coloured liquid before reaching the eye; the water permits the escape of those fluorescent rays which would otherwise be internally reflected at the external surface of the test-tube, and the intensity of the light of which the tint is to be observed is increased by foreshortening. (Stokes, Chem. Soc. J. xi. 19.)

The nature of the solvent must also be attended to. The colour of the fluorescent light is liable to change, not merely in passing from an alkaline to a neutral or acid solution, but even occasionally in passing from one neutral solvent to another.

The composition of fluorescent light, as revealed by the prism, occasionally presents peculiarities, but in such cases they are found to be connected with peculiarities in the mode of absorption, so that the two are not to be regarded as *independent* characters of a substance; and as the peculiarities in the absorption are, as a general rule, the more easily observed, it is only rarely that the analysis of the fluorescent light is of much use.

The distribution of fluorescence in the spectrum often affords valuable information, but its observation requires the use of somewhat complicated apparatus. The observation is restricted to times when the sun is shining pretty steadily (unless the observer has recourse to electric light, or at least lime-light); it is requisite to reflect the sun's light horizontally, without which the observation would be most troublesome; and unless the reflexion be made by the mirror of a heliostat, the continual change in the direction of the reflected light is most inconvenient. It is requisite to use at least one good prism, better two or three, which must be of tolerable size, in order to have light of sufficient intensity, and the prisms must be combined with a lens, which need not however be achromatic.

It has already been stated, as the result of experience, that the colour of the fluorescent light of a single substance is constant throughout the spectrum, or very nearly so. If, therefore, on examining a solution in a pure spectrum thus formed by projection, we find the fluorescence taking a fresh start *with a different colour*, we may be almost certain that we have to do with a mixture of two different fluorescent substances, the presence of which is thus revealed without any chemical process. If, however, the fluorescence of two fluorescent substances, which may be mixed together, begins at nearly the same point in the spectrum (as commonly happens when there is merely a slight difference of tint in the colour of the fluorescent light of the two substances), the coexistence of the two may escape detection when the mixed solution is merely examined in a pure spectrum; and in such cases a combination of processes of fractional separation with the observation of the tint of the fluorescent light is more searching. This is the case, for instance, with the mixture of *æsculin* and *fraxin* contained in a solution from the bark of the horse-chesnut.

As the occurrence of a decided difference of colour in the fluorescent light seen at two different parts of the spectrum implies, almost to a certainty, the presence of two different fluorescent substances, so, conversely, the exhibition of the same colour is an argument in favour of the identity of the substance producing the fluorescence at the

two parts. We cannot, indeed, say that there may not be two substances present, the fluorescence of which commences at nearly the same part of the spectrum; but two different substances, the fluorescence of which commenced at two widely different parts of the spectrum, would certainly reveal themselves by the difference of colour. For experience shows that the refrangibility of the light emitted at any part of the incident spectrum, by the solution of a pure substance, extends nearly up to that of the point of the incident spectrum at which the fluorescence commences, but not much beyond; and though, in passing from one pure substance to another, variations do occur in the relative brightness of the rays of less refrangibility which compose the fluorescent light, yet, on the whole, there is so close a connection between the colour of the fluorescent light and the refrangibility of the rays by which the fluorescence is first produced, that a great variation in the one is incompatible with constancy or a mere trifling variation in the other. (Stokes, Chem. Soc. J. xvii. 312.)

Absorption.

All bodies are transparent to a certain extent; even metals, which are the most opaque of all substances, allow a small quantity of light to pass through them, when they are reduced to extremely thin leaves; thus gold-leaf laid upon glass transmits light of a green colour. On the other hand, there is no such thing as a perfectly transparent medium; even the air stops a certain quantity of light, when the thickness traversed by the rays is very considerable; on the tops of high mountains the stars appear much brighter than when seen from near the sea-level. For all ordinary thicknesses, however, colourless gases may be regarded as perfectly transparent.

Transparent media are colourless or coloured, according as they transmit the several rays composing white light, in the same or in different proportions. Thus a red glass is one which transmits the red rays more easily than those of any other colour. On viewing a solar spectrum through a piece of glass 1 millimetre thick, coloured with red oxide of copper, all the colours excepting the red disappear, the glass being opaque to all the more refrangible rays. Other media transmit rays of one or more colours, and stop the rest, and consequently exhibit compound colours by transmitted light: thus an ammoniacal solution of copper, when of a certain strength and thickness, stops all the rays excepting the red and the violet.

If rays which have passed through a red glass be passed through another glass of the same colour, the latter will absorb but a small proportion of the rays which fall upon it, because those which are incapable of passing through red glass have already been eliminated by the first medium; but if the second glass is green, it will stop the red rays, and the two together will form a perfectly opaque screen.

There is no medium which is absolutely colourless, that is to say, capable of transmitting rays of all colours in exactly the same proportion; even air, when seen through great thicknesses, appears blue; the colour of the sky is merely that of the atmosphere seen through a thickness of several miles; in like manner distant mountains appear blue, just as if they were seen through a blue glass.

On the other hand, to enable a medium to absorb the rays of one or more colours completely, it must have a certain thickness. Even metals, as already observed, when reduced to extremely thin films, transmit certain colours, and a plate of glass which, when of a certain thickness, stops all but the red rays of the spectrum, transmits a greater and greater number of coloured rays as its thickness is diminished, and at last appears almost colourless.

It was formerly supposed that the quantity of light absorbed was proportional to the thickness of the medium through which it passed, but later researches have shown that the law is more complicated. Suppose the medium divided into infinitely thin layers perpendicular to the direction of the rays which traverse it; and let a be the fraction, supposed constant, which represents the proportion between the quantity of light arriving at any layer, and that of the light which passes through unabsorbed. The quantity of light (supposed homogeneous) which arrives at the first layer being I , that which reaches the second will be Ia ; that which arrives at the third will be Ia^2 , and so on. If therefore e represents the thickness of the medium (equivalent to n layers), the intensity of the ray after having passed through this thickness, is given by the formula $i = Ia^n$. The intensity of the emergent light decreases therefore in geometric proportion, while the thickness of the medium increases in arithmetical proportion. The quantities absorbed by the successive layers follow a similar law, being, for the first layer $I - Ia = I(1 - a)$; for the second, $Ia(1 - a)$; for the third, $Ia^2(1 - a)$, and for the n th, $Ia^{n-1}(1 - a)$.

Now let $R, O, Y, &c.$, represent the intensities of the several principal colours composing a ray of incident light, the total intensity of the beam being therefore $R + O + Y + G + B + I + V$; also let $r, o, y, &c.$, be the fractions of the several coloured

rays which traverse, without absorption, a unit of thickness of the medium; then the intensity of a beam emerging from a layer whose thickness is e , will be

$$Rr^e + Oo^e Y + y^e + Gg^e + Bb^e + Ii^e + Vv^e.$$

The terms of this expression containing the smallest of the fractions r, o, y , &c., decrease most rapidly as e increases; the colours corresponding to the other terms will therefore predominate more and more, and the emergent tint will not be white, but will exhibit a compound tint depending on the relative magnitude of the several terms, Rr^e, Oo^e , &c. If the rays of any one colour, red for example, are less absorbed than the rest, it is always possible, by increasing the thickness of the film, to a certain extent, to obtain red rays sensibly homogeneous; for by increasing e , the ratios $Rr^e : Oo^e, Rr^e : Yy^e$, &c., may be increased in any required proportion. When, on the contrary, the quantities r, o, y , &c., differ but little from unity, and the thickness of the medium is small, the sum $Rr^e + Oo^e + \&c.$, differs but little from that which represents the intensity of the incident ray; that is to say, the light is not perceptibly coloured.

The relative quantities of the several coloured rays absorbed by a coloured medium of given thickness, may be observed by viewing a line of light through a prism and the coloured medium. The spectrum will then be seen to be diminished in brightness in some parts, and perhaps cut off altogether in others. This mode of observation is often of great use in chemical analysis, as many coloured substances when thus examined afford very characteristic spectra, the peculiarities of which may often be distinguished, even though the solution of the substance under examination contains a sufficient amount of coloured impurities to change its colour very considerably. The following method of making the observation is given by Professor Stokes (Chem. Soc. J. xvii. 306):

A small prism is to be chosen of dense flint glass, ground to an angle of 60° , and just large enough to cover the eye comfortably. The top and bottom should be flat, for convenience of holding the prism between the thumb and fore-finger, and laying it down on a table, so as not to scratch or soil the faces. A fine line of light is obtained by making a vertical slit in a board 6 inches square, or a little longer in a horizontal direction, and adapting to the aperture two pieces of thin metal. One of the metal pieces is movable, to allow of altering the breadth of the slit. About the fiftieth of an inch is a suitable breadth for ordinary purposes. The board and metal pieces should be well blackened.

On holding the board at arm's length against the sky or a luminous flame, the slit being, we will suppose, in a vertical direction, and viewing the line of light thus formed through the prism held close to the eye, with its edge vertical, a pure spectrum is obtained at a proper azimuth of the prism. Turning the prism round its axis alters the focus, and the proper focus is got by trial. The whole of the spectrum is not, indeed, in perfect focus at once, so that, in scrutinising one part after another, it is requisite to turn the prism a little. When daylight is used, the spectrum is known to be pure by its showing the principal fixed lines; in other cases the focus is got by the condition of seeing distinctly the other objects, whatever they may be, which are presented in the spectrum. To observe the absorption-spectrum of a liquid, an elastic band is put round the board near the top, and a test-tube containing the liquid is slipped under the band, which holds it in its place behind the slit. The spectrum is then observed just as before, the test-tube being turned from the eye.

Fig. 668.

Fig. 669.

To observe the whole progress of the absorption, different degrees of strength must be used in succession, beginning with a strength which does not render any part of

which is coloured, shows that, with very few exceptions, all the compounds of the same base or acid have the same effect on the rays of light. This law is seen to hold good in many instances which at first sight appear exceptional. Thus it is well known that some salts of chromic oxide are green, others red or purple. Now these differently coloured chromic salts all exhibit the same general form of spectrum (*fig. 668*), in which the violet and indigo rays are very soon cut off; and as the thickness increases, the light is more and more concentrated about two points—one in the red, the other in the bluish-green, the red ray penetrating with the greatest facility. Hence it is that the chloride and other salts of chromium, which are green in moderately dilute solutions, appear purple or red when we look through a strong or very deep solution. The acetate absorbs the green rays more readily, and therefore appears green only in very weak solutions, or in thin strata, while the "red potassio-oxalate" absorbs the green so speedily that the thinnest portion of it appears bluish-red.

Salts composed of a coloured base and a coloured acid exhibit colours compounded of the rays which are not absorbed by either, the resultant colour bearing, in many instances, but little resemblance to the original colours. Thus, the acid chromate of chromic oxide, a compound of two substances which give respectively yellow and green solutions, is not bright green, but brownish-red, because the chromic acid cuts off nearly all the blue and violet rays, while the oxide of chromium absorbs the yellow and the greater part of the green.

Some salts which are but slightly coloured, nevertheless exhibit very characteristic spectra. Thus, a solution of sulphate of didymium, which has but a faint rose colour, exhibits, when examined by the hollow wedge and prism, a spectrum containing two very black lines; one in the yellow, the other in the green. These lines are visible in very weak solutions of didymium, and therefore serve as a delicate test for that metal; they, moreover, afford means of distinguishing it from cerium and lanthanum, in the spectra of which they do not occur.

Brewster's Theory of the Spectrum. Newton regarded the spectrum as composed of an infinite number of simple colours, each element of it consisting of a ray of definite refrangibility and not capable of further decomposition; and this theory has been almost universally received as affording satisfactory explanations of all the phenomena of colour, and of the decomposition and recomposition of light. Brewster, however, in studying the decomposition of light by absorption, observed certain facts which he regarded as incompatible with Newton's theory, and he accordingly proposed a new theory of the constitution of the spectrum, which is as follows:—

1. White light is composed of *three* colours only, red, yellow, and blue, mixed in certain proportions.

2. The solar spectrum is formed of three superposed spectra of these colours, each of them extending the entire length of the spectrum, but with varying intensities as shown in *fig. 670*; where the horizontal line *rv* represents the length of the spectrum, and the three curves, *R*, *Y*, and *B*, are so drawn that their ordinates are proportional to the intensities of the several colours at each point, the blue having a maximum between the fixed lines *F* and *G*, the yellow near *F*, and the red, two maxima, one near *B*, and another of lower intensity near the violet end of the spectrum.

3. All the colours of the spectrum are compound, and as all the rays united in one point have the same degree of refrangibility, they cannot be further decomposed by refraction.

Brewster was led to these conclusions by observing that when the spectrum

is viewed through certain coloured media, white light may be shown to exist in any part of it. Thus, by looking through an azure-blue glass of sufficient thickness, or better, through a solution of sulphate of copper mixed with red ink, the yellow of the spectrum is replaced by white, very slightly tinged with green or red, according to the particular tint of the medium. This white light is not decomposable by refraction, but may be decomposed by viewing it through a film of gelatin of yellow or green colour, the white band then appearing yellow or green, in consequence of the absorption of the blue or red rays. By similar means Brewster found white light in the green and the orange, whence he concluded that the three primary colours exist in the yellow, green, and orange of the spectrum. In like manner, by viewing the spectrum through certain yellow liquids, he found that the blue and indigo assumed a violet tint, whence he concluded that red light exists in these parts of the spectrum. The blue of the spectrum seen through a film of blue gelatin, exhibited a white band, and the blue and indigo viewed through a blue glass assumed a violet tint; hence the presence of yellow

Fig. 670.

in the blue was inferred. By viewing the spectrum through a layer of Peruvian balsam, pitch, sulphur-balsam or red mica, yellow was seen in the red near the line C. Brewster was not able to detect yellow in the violet, but he attributed this negative result to the feebleness of the light in this part of the spectrum, and the facility with which it is absorbed by all coloured media. Lastly, the red of the spectrum seen through balsam of Peru, pitch, sulphur-balsam, or red mica, appeared green, whence it was inferred that the red of the spectrum also contained blue.

Brewster's theory has not however met with general adoption. In the first place, it is quite inconsistent with the wave-theory of light: for just as there is an infinite number of sounds corresponding with an infinity of wave-lengths in the air, so likewise must there be an infinite number of shades of colour corresponding with an infinite number of wave-lengths in the ether, and therefore also (p. 609), an infinite number of different refrangibilities. On the other hand, to account for the dark lines of the solar spectrum it would be necessary to suppose that certain rays are wanting in the component spectra exactly at the same points, which is very improbable.

Moreover there is no reason whatever for assuming that red, yellow, and blue are the component colours of white light; indeed, Helmholtz has shown, by a method to be presently described, that the actual colours of the spectrum may be more exactly imitated by combinations of red, green, and violet, but that even then the imitation is far from satisfactory.

More careful observations by Airy, Helmholtz, and others have likewise shown that Brewster's conclusions are not borne out, even by his own method of observation, when proper precautions are taken to eliminate sources of error. Airy has pointed out that to obtain correct results with such a mode of experimenting, it is necessary in the first place to exclude all extraneous light, which, being decomposed by the coloured medium, will modify the tint observed; and, secondly, to compare the spectrum viewed through the coloured medium with a pure spectrum viewed directly, the two being formed immediately one above the other, as in no other way can an exact comparison of the tints in the corresponding parts of the two be made. When these precautions were taken, he found it impossible to distinguish the slightest difference, excepting in brightness, between the colours of the spectrum seen through a coloured medium, and those of the spectrum viewed directly. Airy also observes that the intensity of the light may make a great difference in the impression produced on the eye by any particular colour.

Helmholtz has shown that the results may be modified by the light scattered by irregular refraction at the surfaces of the coloured medium, and by the lens and prism used to form the spectrum, especially when the absorbent medium used is a film of gelatin, which is not very transparent. To eliminate this diffused light, the spectrum is received on a screen having a narrow slit through which a thin coloured pencil can pass, and this pencil is made to fall upon a second prism, followed by a lens, which forms a coloured image of the slit, and a faint spectrum proceeding from the diffused light which has passed through the second aperture. This spectrum does not perceptibly alter the purity of the focal image. On examining the different colours of this purified spectrum through various coloured media, it was found impossible to distinguish any difference of tint between the colours thus observed and those viewed directly.

From all these experiments it may be inferred that it is impossible to decompose the colours of the spectrum by absorption any more than by refraction; that the colours, as Newton supposed, are simple; and that to each colour there corresponds a definite degree of refrangibility.

Decomposition of Light by Reflection.

Newton explained the colours of bodies by supposing that they decompose the light which falls on their surfaces, absorbing some of the component rays, reflecting the rest in a diffused manner if they are opaque, or reflecting one portion and transmitting another if they are transparent, the reflected and transmitted light being always more or less coloured, because the different coloured rays are not absorbed in the same proportion. Black substances are those which absorb all the rays which fall upon them; white substances, those which reflect all the rays; bodies of these two classes act in the same manner on all kinds of luminous rays. But between these two extremes, there is an infinity of substances which reflect the several coloured rays in different proportions. A red body, for example, is one which reflects red in larger proportion than the other rays composing white light. In the case of opaque bodies the decomposition of the light takes place at an insensible depth below the surface, the result being independent of the inner layers of the substance.

If rays of light dispersed by a prism be thrown on a white surface, each point reflects the light which it receives, and appears of the same colour as that light. If the surface

is *red*, it appears very bright in the red part of the spectrum, but the other colours are faint, the red surface reflecting the red rays of the spectrum abundantly, but the other colours in small proportions only. If the body is capable of absorbing certain rays completely, black bands are seen in the corresponding parts of the spectrum, and if the body be illuminated solely by rays of that particular degree of refrangibility, it appears black.

A coloured body illuminated by different sources of light may exhibit different colours, the spectra formed by the light from these several sources not being formed of the same colours or in the same proportions. It is thus that objects which are green by daylight appear blue by lamp-light, the yellow rays being less abundant in the light of ordinary flames than in solar light. Most objects appear differently coloured by moonlight, from what they do by daylight. When a series of the seven principal colours of the spectrum is illuminated by the monochromatic yellow light of a lamp fed with spirit containing common salt, the yellow, orange and red strips appear yellow of various degrees of brightness, the rest grey or black, because they do not receive rays which they are capable of reflecting, or in other words, because their particles are not susceptible of vibrating in unison with those of the light which falls upon them. In the same light, the face and lips appear of a livid hue, because the red rays which the skin reflects in daylight are wanting in the yellow light.

When the body on which the light falls is transparent, the rays which pass through it are those which have not been reflected at its surface; hence the reflected and transmitted light may be of different colours. Such is in fact the case in many instances. Gold-leaf, which is yellow by reflected light, transmits light of a bluish-green colour. Faraday formed pulverulent deposits by sending powerful electric discharges through metallic wires in an atmosphere of hydrogen; in the finely-divided state thus produced, copper appeared green by transmitted light; tin, brown; zinc, brown or bluish-grey; palladium, brown; aluminium, brown or orange-coloured. The reflected and transmitted rays are sometimes complementary to each other; but this is the case only when no part of the light is absorbed. When a body exhibits the same colour, red for example, both by reflection and by transmission, it is because it reflects part of the red rays of the incident light, transmits the rest, and absorbs the rays of all the other colours.

In many cases, however, as pointed out by Professor Stokes (*Chem. Soc. J.* xvii. 315), the colour of a body attributed on cursory examination to reflection, is really due to transmission; in fact, the instances in which substances appear coloured by reflection are comparatively rare. "A chemist views a solution contained in a test-tube by transmission and then by reflection; and seeing perhaps some perfectly different colour in the latter case, describes it as the colour of the solution by reflection, whereas it is merely the colour by transmission due to a greater thickness, the light having been reflected at the back or bottom of the test-tube, and so having twice passed through the solution. In other cases, the colour described as due to reflection really arises from fluorescence; and though the statement may be true in the sense intended, it seems objectionable to apply the term *reflection* to a process so utterly different. It is only in the case of metals, such as gold and copper, and of certain other substances, such as murexide, platinumcyanide of magnesium, &c., that colour is really seen as the result of reflection.

"When this takes place in the case of non-metallic substances, they are found to be endowed, for the colours so reflected, with an intense opacity, comparable with that of metals; while for other parts of the spectrum, they may be comparatively transparent, and these parts they reflect with an energy comparable to that of a vitreous substance only. The variations of absorbing power in passing from one part of the spectrum to another, and consequently the variations in reflecting energy, are frequently much more considerable, and accordingly the colour by reflection is much richer than in the case of metals."

"An excellent example of the intimate connection between metallic reflection and intense absorption is afforded by the crystals of permanganate of potassium. These crystals exhibit a green metallic reflection, and when crushed yield a powder of an intense purple colour by transmitted light. The colour is too intense for spectral analysis, but the solution has a similar colour, merely less intense as corresponds with its smaller concentration, and the analysis of the light transmitted by the solution presents no difficulty. The green is quickly absorbed, but when the solution is sufficiently dilute, five eminently characteristic bands of absorption are seen in that part of the spectrum. A sixth band comes out with a greater thickness or else strength of solution, but even the fifth is somewhat less strong than the others. When the light reflected from a crystal is analysed, four bright bands are seen standing out on a generally luminous ground of inferior brightness. These bright bands correspond in position with the principal dark bands in the light transmitted by the solution, and

therefore, it may be presumed, by the crystals themselves. When the angle of incidence has a suitable value, and the reflected light is analysed by a Nicol's prism, with its principal plane in the plane of incidence, and then by a common prism, the spectrum is reduced to these four bright bands. A fifth bright band could, perhaps, be made out, in the case of a fine crystal with a fresh surface. Under the circumstances described, the Nicol's prism would extinguish the light reflected from a vitreous substance, and transmit much of that reflected from a metal. We see, therefore, that, as regards its relations to light, the crystallised body passes repeatedly from the condition of a vitreous to that of a metallic substance and back again, as the refrangibility of the rays, in relation to which it is considered, is continuously increased by a small amount.

"The same relation between intense absorption and metallic reflection exists generally, though it cannot be always studied by means of a solution. The platinocyanides, for example, yield colourless solutions, so that the intense absorption which most of them exercise for certain parts of the spectrum must be attributed to the mode in which the molecules are built up in forming the crystals; but by attending to the colour of the light transmitted by thin crystals, the law is found to be obeyed. Gold can only be obtained, in solution, as gold by means of the opaque solvent mercury; but its colour by transmission may be studied in gold-leaf, or in a chemically deposited film, and is then found to be conformable to the law mentioned, the less refrangible colours, which are those which are the more copiously reflected, being also those which are the more intensely absorbed.

"When a body endowed with the property of coloured reflection, such as permanganate of potassium, is dissolved, in consequence of the necessary dilution, the opacity of the medium ceases to be, for any part of the spectrum, of that intense kind which is necessary for quasi-metallic reflection; and accordingly the light reflected by the solution is colourless.

"In order that the colour due to reflection should appear, it is necessary that the substance should have a certain amount of coherence. Thus indigo in the form of a fine loose powder is blue, even when viewed by reflection. It would be erroneous, however, to describe the body as blue by reflection, if we were speaking of the properties of the substance, and not the mere crude results of observation made under given circumstances. For though it is true that the light by which the blue colour is seen has undergone reflection (without which it would not have reached the eye) it is not in reflection that the chromatic selection is made by virtue of which the powder appears blue, but during transmission. In fact it is only a small portion of the light that is reflected at the outer irregular surface of the mass; the greater part penetrates a little way, and is reflected at various depths, and in passing through the particles, in going and returning, suffers absorption on the part of the coloured substance. Were the substance intensely opaque for all the colours of the spectrum, the powder would be not blue but black, as we see in the case of platinum-black. By burnishing, the powder is reduced to the state of a somewhat coherent mass, and it now begins to exhibit the copper colour due to reflection. The internal reflections are at the same time greatly weakened, so that the part of the light which is reflected from beneath and undergoes absorption is much reduced. A pressed mass is not, however, an optically homogeneous medium, so that the colour by reflection obtained by burnishing cannot in general be quite pure. In the state of a fine crystalline powder, indigo exhibits a mixture of the copper colour due to reflection, and the blue colour due to transmission, though observed in the light reflected from the mass as a whole; while if the substance could be obtained in large crystals, the colour by reflection would be seen in perfection, and the colour by transmission would disappear, the crystals being sensibly opaque." (Stokes.)

The Colours of Thin Plates.

All transparent substances, when reduced to very thin films, exhibit brilliant colours—a soap bubble affords a familiar instance of this; glass blown out into thin films exhibits similar phenomena—so, likewise, does a layer of oil spread over the surface of water. These effects, however, are best studied in the case of a thin film of air formed between two plates of glass. When two glass plates (of any sort of glass) are pressed hard together, a black spot is observed at the point of closest contact, and around it a series of fringes exhibiting remarkably beautiful colours: if the light be homogeneous, as that of a soda flame, the bands are alternately light and dark. The shape of the bands depends upon the greater or lesser regularity of thickness in the film of air. If the glasses be so pressed at one point that the intervening space shall increase regularly all round, the bands will be circular—otherwise they will have an

irregular shape—but in all cases the same thickness of the film of air gives, *ceteris paribus*, the same colour. Newton, to whom this experiment is due, made use of a

Fig. 671.

plano-convex lens of small curvature, resting on a piece of flat glass: by this means he obtained a film of air whose thickness was uniform at the same distance from the point of contact, and the fringes were consequently circular. By this arrangement also, knowing the diameter of the lens, he was enabled to calculate the thickness of the film of air by which any particular band was produced. For, the radius of the ring AM (fig. 671) being found by measurement, and the diameter of the lens AB being also given, we have $AB \times AN$ (or MP) = AP^2 = AM^2 (nearly);

$$\text{therefore } MP = \frac{AM^2}{AB},$$

whence also MP varies as AM^2 .

Proceeding in this manner, Newton found that the thicknesses of the films of air by which the successive dark bands were formed varied in the ratio of the even numbers

$$0, 2, 4, 6, \dots 2n;$$

and those by which the light bands were produced in the numbers

$$1, 3, 5, 7, \dots 2n+1;$$

further, that the thickness of the film at the first bright band was 6-millionths of an inch for red light, and about $4\frac{1}{2}$ -millionths for violet light.

Now comparing these numbers with those afterwards found by Fresnel for the lengths of the waves (p. 600), it is found that the thickness of the film in question = $\frac{1}{4}$ of the length of a wave.

The explanation of this phenomenon is as follows:—The bands are formed by the interference of rays reflected from the upper and under surfaces of the transparent film. Now at the centre, where the two surfaces are in almost absolute contact, we might expect the reflected rays to be in accordance—for they reach the eye after travelling over equal paths. At the first bright band, the thickness = $\frac{1}{4}$ of an undulation; hence the ray reflected from the second surface, which has to traverse this thickness twice, is behind the other by half an undulation, and might therefore be expected to destroy the other: but instead of that, the two assist each other and produce a bright band; similarly with the other bright bands, which are produced by rays whose paths differ in length by

$$\frac{2}{2}, \frac{4}{2}, \frac{6}{2}, \dots \frac{2n+1}{2} \text{ of a wave-length.}$$

The dark bands are formed by rays which differ by

$$0, \frac{2}{2}, \frac{4}{2}, \frac{6}{2}, \dots \frac{2n}{2} \text{ of a wave-length,}$$

and which might therefore be expected to be in accordance.

The explanation of this apparent anomaly is found, as pointed out by Young, in the manner in which the direction of the vibrations of the ether-molecules is changed in passing from one medium to another.

When a wave of light travels through a medium of uniform constitution, it never returns upon its path; no reflection takes place, but each particle, when thrown into a state of vibration, communicates its vibration to the next, and is itself brought to rest: just as an ivory ball striking upon another of equal size, drives that ball forward, but is itself brought to rest. But if the vibration is communicated to a medium of different constitution—as when a ray passes from air into glass, or from glass into air—this complete destruction of the vibration of the particles does not take place; and the consequence is, that the light is at the same time transmitted through the second medium, and reflected back into the first. If the ray passes from a medium in which the ether is of greater density to one in which it is of less density, as from glass into air, the direction of vibration of the particles in the reflected ray remains unchanged, just as a large billiard ball striking a small one, drives the small one before it, and continues in its own course though with less velocity. In the contrary case, as when the ray passes from air to glass, that is to say, from ether of less density to ether of greater density, the vibration of the particles in the reflected ray is reversed—just as when a small ball strikes a large one, the large ball is driven forward but the small one driven back upon its path.

To apply this to the case of Newton's rings. The bands are formed by the interference of rays reflected from the first surface with rays reflected from the second

surface of the film of air. Now in the second reflection, according to the principle just explained, the vibration in the particles of the reflected ray is reversed, because the ray passes from air to glass, whereas at the first surface, where the ray passes from glass to air, no such reversal takes place. Consequently the two rays, when they meet, will have their vibrations in accordance, just when they would have been in discordance if the reversal of vibration at the second surface had not taken place. Hence the dark bands are produced where the thickness of the film is

$$0, 2d, 4d, 6d \dots 2nd,$$

and the bright bands where the thickness is

$$d, 3d, 5d, 7d \dots (2n+1)d$$

d being = $\frac{1}{4}$ of an undulation.

That this is the true explanation of the phenomenon is proved by the fact that when a film of a transparent substance is placed between two other media, one of greater and the other of less refracting power than itself, the positions of the light and dark bands are reversed. Thus when a film of oil of saffron is placed between a plate of crown and a plate of flint glass, the central spot is *white*; and the thicknesses of the film follow the ratio of the odd numbers for the dark, and of the even numbers for the light bands.

To return to the ordinary case of a film of air between glass plates. Fringes are produced by *transmitted*, as well as by reflected light, but the colours of any particular ring are exactly complementary of those of the same ring formed by reflected light; and if the light be homogeneous, the central spot is light, and the bands follow the reverse order of that which they do when formed by reflected light. These transmission fringes are formed by the interference of rays transmitted through the film, with other rays which pass through it after having undergone two reflections, one at the second surface, and the other at the first; and since both these reflections are made in passing from air to glass, the change of direction caused by the first reflection is again reversed by the second, and consequently the rays are in accordance or discordance, just when they would have been in case of no reflection at all.

Relation between the Indices of Refraction and the Thicknesses of the Films.—The thicknesses of thin plates of different substances, at the points where they form coloured bands of the same order, are to one another in the *inverse ratio of their indices of refraction*.

Consider, for example, the bright fringe of the m th order. If λ, λ' are the wavelengths of the homogeneous light in the two substances, and e, e' their thicknesses, we have the equations,

$$e = (2m + 1)\frac{1}{2}\lambda; \quad e' = (2m + 1)\frac{1}{2}\lambda';$$

therefore $e : e' = \lambda : \lambda' = \mu' : \mu$.

Newton discovered this law by experiment. It may be verified for air and water by introducing a drop of water between the two glass plates which produce the rings, the water then penetrating between the plates by capillarity, and expelling the air from part of the circular space around the point of contact. It will then be observed that the fourth ring in air coincides with the fifth ring in water. Now the thicknesses of the film at the several bright rings in air are, $e, 3e, 5e, 7e, 9e$, &c., and in water $e', 3e', 5e', 7e', 9e'$, &c.; the result just described gives, therefore, $7e = 9e'$; whence $\frac{e}{e'} = \frac{\mu}{\mu'} = \frac{9}{7}$, which is the index of refraction of water referred to air as unity.

This law furnishes an additional method of measuring the indices of refraction of liquids with respect to air; for in the expression $e : e' = \mu' : \mu$, the ratio of the thicknesses may be replaced by that of the squares of the diameters of the rings of the same order, whence the refractive index of the liquid may be calculated as a function of that of air. The method is not however very exact, in consequence of the difficulty of measuring the diameters of the rings.

We have hitherto supposed that the eye is placed directly over the centre of the rings, so that they are seen by perpendicular incidence. If the eye be moved from this position, so as to view the rings obliquely, these diameters increase as the incident rays become more and more oblique; that is to say, the thickness of the transparent film corresponding to a ring of given order increases with the obliquity of the rays; in other respects, the diameters of the rings follow the same laws as when the incidence is perpendicular. Newton found by experiment, that the thickness e , of a ring of given order seen by perpendicular incidence, is connected with the thickness e' , for the same ring viewed at the incidence i —supposing the thin film to be formed of the same substance as the medium which surrounds the apparatus—by the equation, $e = e' \cos i$, or $e' = e \sec i$.

The diameters of the rings, like the breadths of all other interference-fringes, are greatest in red, and least in violet light; hence in white light a series of coloured rings is produced not separated by any absolutely dark spaces.

The following table exhibits the succession of colours produced by thin films or plates, and the corresponding thicknesses of three different media :

Newton's Table of the Colours of Thin Plates in Air, Water, and Glass.

Succession of Spectra or Orders of Colours.	Colours produced at the thicknesses in the last three columns.		Thicknesses in millionths of an inch.		
	Reflected.	Transmitted.	Air.	Water.	Glass.
FIRST Spectrum or Order of Colours	Very black	White	$\frac{1}{2}$	$\frac{1}{3}$	$\frac{16}{30}$
	Black		1		$\frac{32}{30}$
	Beginning of black		2	$\frac{1}{3}$	$\frac{16}{15}$
	Blue	Yellowish-red	$2\frac{1}{2}$	$\frac{1}{2}$	$\frac{11}{10}$
	White	Black	5 $\frac{1}{2}$	$3\frac{1}{3}$	$3\frac{2}{3}$
	Yellow	Violet	7 $\frac{1}{2}$	$5\frac{1}{3}$	$4\frac{2}{3}$
	Orange		8	6	$4\frac{1}{6}$
	Red	Blue	9	$6\frac{2}{3}$	$5\frac{1}{5}$
SECOND Spectrum or Order of Colours	Violet	White	$11\frac{1}{2}$	$3\frac{2}{3}$	$7\frac{1}{2}$
	Indigo		$12\frac{1}{2}$	$9\frac{1}{3}$	$8\frac{2}{3}$
	Blue	Yellow	14	$10\frac{1}{3}$	9
	Green	Red	$15\frac{1}{2}$	$11\frac{1}{3}$	$9\frac{2}{3}$
	Yellow	Violet	$16\frac{1}{2}$	$12\frac{1}{3}$	$10\frac{2}{3}$
	Orange		$17\frac{1}{2}$	13	$11\frac{1}{3}$
	Bright red	Blue	$18\frac{1}{2}$	$13\frac{2}{3}$	$11\frac{2}{3}$
	Scarlet		$19\frac{1}{2}$	$14\frac{2}{3}$	$12\frac{2}{3}$
THIRD Spectrum or Order of Colours	Purple	Green	21	$15\frac{1}{3}$	$13\frac{1}{10}$
	Indigo		$22\frac{1}{10}$	$17\frac{1}{3}$	$14\frac{1}{10}$
	Blue	Yellow	$23\frac{1}{2}$	$17\frac{1}{6}$	$15\frac{1}{10}$
	Green	Red	$25\frac{1}{2}$	$18\frac{1}{6}$	$16\frac{1}{4}$
	Yellow	Bluish-green	$27\frac{1}{2}$	$20\frac{1}{6}$	$17\frac{1}{4}$
	Red		29	$21\frac{1}{6}$	$18\frac{1}{4}$
	Bluish-red		32	24	$20\frac{1}{4}$
FOURTH Spectrum or Order of Colours	Bluish-green		24	$25\frac{1}{3}$	22
	Green	Red	$35\frac{1}{3}$	$26\frac{2}{3}$	$22\frac{2}{3}$
	Yellowish-green		36	27	$23\frac{1}{6}$
	Red	Bluish-green	$40\frac{1}{3}$	$30\frac{1}{4}$	26
FIFTH Spectrum or Order of Colours	Greenish-blue	Red	46	$34\frac{1}{2}$	$39\frac{1}{3}$
	Red		$52\frac{1}{2}$	$39\frac{1}{6}$	34
SIXTH Spectrum or Order of Colours	Greenish-blue		$58\frac{1}{2}$	44	38
	Red		65	$48\frac{1}{4}$	42
SEVENTH Spectrum or Order of Colours	Greenish-blue		71	$53\frac{1}{2}$	$45\frac{1}{3}$
	Reddish-white		71	$57\frac{1}{2}$	$49\frac{1}{3}$

Beyond these limits, the colours become mixed to such an extent as to produce white light. If, however, the rings be viewed through a prism, so as to separate the different coloured rays, a much larger number of them will come into view.

The transmitted rings are much fainter than the reflected rings, because one of the beams of light which contribute to their formation has been twice reflected, and each reflection is attended with a considerable loss of light.

We have been particular in describing the colours of 'Newton's rings,' because they are generally used as a standard of comparison for all coloured phenomena depending upon interference.

Colours of Thick Plates.—This term is applied to certain systems of coloured rings or fringes, produced by interference at the surfaces of transparent media, too thick to exhibit the peculiar phenomena known as the colours of thin plates. Newton, having

received on a concave mirror of silvered glass a thin beam of solar light passing into a dark room through a small aperture situated at the centre of curvature of the mirror, perceived round the aperture a series of coloured rings having the violet turned inwards, as in the colours of thin plates. With homogeneous light, the rings were alternately bright and dark. Newton found by measurement—1. That the diameters of the rings were regulated by the same laws as those of the rings formed by transmission in thin plates. 2. When different kinds of homogeneous light are employed, the ratios of the diameters are the same as in thin plates. 3. The diameters of the rings formed by mirrors of equal radius and different thickness, are inversely as the square roots of the thicknesses.

The formation of these rings depends, however, on a condition which Newton did not observe, viz., that the upper surface of the mirror must not be quite bright. If this surface is well polished and carefully cleansed, the rings are scarcely visible; whereas if the surface is made dull by breathing or throwing dust upon it, or by covering it with a thin coat of varnish, or of water whitened with a little milk, which is then allowed to dry, they come out with great brightness. If, on the other hand, the silvering be removed from the back of the mirror, the rings become very faint, and with a metallic mirror none at all are produced. These experiments show that the rings are produced by the interference of rays reflected from the second surface of the mirror, with diffused light reflected from the first surface, which has been dulled. This is rendered further evident by an experiment of the Duc de Chaulnes, who, instead of a glass mirror, used a metallic mirror, before which he placed a piece of plate glass having its surface somewhat tarnished, or a plate of mica, either of which fulfilled the same purpose as the anterior surface of the glass mirror.

Pouillet, instead of a transparent plate, places in front of the mirror a screen pierced with an aperture of any form whatever, but small enough to cause both the incident rays and those reflected from the mirror to come in contact with its edges. A straight-edged screen, placed in front of the mirror, is even sufficient to produce the rings; but in that case only part of their circumference is seen.

The rings formed by diffused light may be viewed directly without being projected on a screen. Stokes places a candle in the centre of curvature of the mirror with tarnished surface, so that the image of the candle may coincide with it, and places the eye at some distance beyond the centre; beautiful rings are then seen formed in the air. Quételet places a candle near the eye, at about a yard from a plane mirror with tarnished surface, so that the candle and its image may seem to coincide; he thus obtains portions of coloured rings round the image of the candle. Herschel receives a beam of solar light on a concave spherical metallic mirror, and intercepts the reflected beam by a screen; by then forming a cloud of dust in the air in front of the mirror, he obtains coloured rings of considerable brightness.

There are several other ways in which coloured rings and fringes may be formed by diffused light, but we must refer, for the description of these and for the more detailed explanation of the phenomena, to works specially devoted to light. (See Daguin, *Traité de Physique*, iv. 463.)

Composition of Colours.

Colours are either simple or compound. The simple colours are those of a pure spectrum, formed either by refraction through a prism, or by diffraction through a grating (p. 606); and compound colours are produced by the mixture of two or more of these simple colours, as in the instance of Newton's rings, or the fringes produced by diffraction. Compound colours may be similar to the pure colours of the spectrum, but are rarely identical with them in the impression which they produce on the visual organs. The resultant tint, produced by the mixture or superposition of any number of simple colours, may be investigated by one of the following methods:

1. By mixing coloured substances in fine powder. This method, however, yields only dull and deadened colours, in consequence of the large quantity of light absorbed; moreover, the rays reflected from the surfaces of the two substances are mixed with rays which have penetrated to a certain depth, and have been there reflected, so that the tint which would be produced by the mixture of the rays directly reflected from the surface is modified by colours arising from absorption.

2. By covering with black paper certain portions of a revolving disc, tinted with the colours of the spectrum (p. 619), the colour perceived being that which is produced by the composition of the remaining spectral colours.

3. By tinting two pieces of paper with the colours whose composition is to be studied, laying them on a black table, setting up between them a plate of unsilvered glass, and placing the eye so that the image of one of them seen by reflection may coincide with that of the other seen directly through the glass (Helmholtz).

This and the second method are preferable to the first, the only source of error affecting them being the deviation of the artificial colours from the pure tints of the spectrum. The only way of attaining perfectly accurate results is to operate directly on the rays of the spectrum itself, as in the following methods:

4. By intercepting some of the coloured rays as they emerge from the prism, and bringing the rest to a focus by an achromatic lens.

5. By receiving the rays of the spectrum on a row of plane mirrors, capable of being adjusted so as to reflect any required rays to the same point on a screen.

6. *Helmholtz's method* (Ann. Ch. Phys. [3] xxxvi. 600). This method, which is the most exact of all, consists in viewing, through a vertical prism, two narrow slits, ab ,

Fig. 672.

ab , forming a right angle (fig. 672), and each inclined 45° to the edge of the prism. The prism being placed about four yards from the slits, and in the position of least deviation, two spectra rv , $r'v'$, are seen, in which, with the aid of a telescope, the principal fixed lines may be distinguished parallel to the slits. These two spectra are partly superposed, and the dimensions

of the slits must be such that each coloured band oo of one spectrum shall cross all the coloured bands of the other.

To find the effect produced by the combination of two colours, the telescope is directed so that the intersection of its cross-wires is projected on the combination to be examined, and the eye is placed behind a small hole in a screen, at 50 or 60 centimetres from the telescope, so that it may perceive only a very small space around the point of intersection. The compound tint required may thus be examined without being affected by the neighbouring colours. By then covering up the two slits successively, the simple colours which have produced the combination may be seen.

In order to vary the relative quantities of light in the component colours, the prism was inclined in such a manner as to bring it more nearly parallel with one of the slits. The spectrum of this slit was thereby brought nearer to the rectangular form, and its colours were more condensed, while the contrary effect was produced upon those of the other. By adding a third slit, the effect of combining three colours may be observed. By these means Helmholtz has obtained the following results:

1. The compound tint formed by the mixture of two simple colours is sometimes identical with a simple colour of the spectrum, but in many cases it is different from them all: for example, the greenish-yellow and greenish-blue of the spectrum form a green much darker than that of the spectrum. This last green, as well as the violet and red of the spectrum, cannot be imitated exactly by the mixture of any other colours. 2. The colour produced by the union of three simple colours is different from that which would be obtained by combining one of them with a simple colour of the spectrum, similar to that which results from the combination of the other two. For instance, the red and bluish-green of the spectrum form *yellow*; but red, with the bluish-green produced by the union of green and indigo, forms *white*. 3. There are many combinations of three colours which form white. 4. With three colours only it is not possible to obtain satisfactory imitations of all the colours of the spectrum, the number of simple colours required for the purpose being at least five, viz., *red*, *yellow*, *green*, *blue*, and *violet*. Hence, according to Helmholtz, the theory of three primary colours (p. 640) does not rest on a satisfactory foundation; and if it is possible to obtain something like an imitation of all the spectral colours by the mixture of three coloured powders, the result must be attributed partly to the want of brightness in the colours used, partly to the circumstance that the resulting compound colours have not generally been directly compared with the colours of the spectrum, from which, in most instances, they differ considerably. The three colours hitherto adopted, viz., *red*, *blue*, and *yellow*, are not even the three best adapted to the purpose; better results are obtained with red, green, and violet, but even then the imitations are far from perfect. For the contrary results obtained by Maxwell, from which it appears that all colours whatever may be produced by the combination of three primary colours, see page 650.

Complementary colours.—This name was applied by Newton to any two colours which by their mixture produce white light; such are *green* and *red*; *orange* and *blue*; *yellow* and *violet*.

Every colour, whether simple or compound, has its complementary colour; moreover, every colour has an infinity of complementary colours, inasmuch as if either of the colours be mixed with white in any proportion, the two will still form white by their union.

Helmholtz has made some remarkable experiments on complementary colours by throwing the pure spectrum, formed by a prism and achromatic lens, on a screen pierced with two narrow slits parallel to the edges of the prism, and capable of being

brought close together at pleasure. The two homogeneous coloured pencils thus obtained are received on a lens which condenses and brings them to a single focus on a white screen placed at a suitable distance. By this mode of experimenting, Helmholtz has shown that there exists an infinity of binary groups of colours, which, when united in *due proportion*, produce a perfect white. With the exception of pure green, every simple colour of the spectrum is complementary of another simple colour.

By varying the breadth of one of the slits, the relative intensities of the two coloured beams could be altered, and it was thus found that the proportions between the intensities of two coloured beams which produce white light by their combination, sometimes varies with the intensity of the incident light. This is shown by the following numbers:

Group of complementary colours.	Ratio of intensity of the second colour to the first.	
	Bright light.	Faint light.
Violet—greenish-yellow	10	5
Indigo—yellow	4	3
Blue—orange	1	1
Greenish-blue—red	0.44	0.44

The same mode of experimenting led to the unexpected conclusion that the mixture of the blue and yellow rays of the spectrum produces white, whereas the mixture of blue and yellow liquids or powders always produces green. This result is confirmed by painting two paper discs, one with chromate of lead or gamboge, the other with cobalt-blue, and making the reflected image of the one coincide with or overlap the direct image of the other, as in method 3 (p. 648). The compound image thus seen is white. With the yellows above mentioned and artificial ultramarine, the white has a slight reddish tinge; with Prussian-blue, a greenish tinge. The production of green by the mixture of blue and yellow powders or liquids, arises from partial decomposition of the light by absorption, as explained at p. 647.

Newton's construction for the calculation of composite colours.—The following geometrical construction was given by Newton for calculating approximately the result of mixing a number of simple colours. The circumference of a circle (fig. 673) is divided into seven parts corresponding with the seven principal colours of the spectrum, and proportional to the numbers $\frac{1}{2}, \frac{1}{3}, \frac{1}{4}, \frac{1}{5}, \frac{1}{6}, \frac{1}{7}, \frac{1}{8}$. A simple calculation then gives the following lengths of the arcs belonging to the several colours:

Red	60° 45' 34"	Blue	54° 41' 3"
Orange	34 10 38	Indigo	34 10 38
Yellow	54 41 1	Violet	60 45 34
Green	60 45 3		

The centres of gravity of each of these arcs r, o, y, g, b, i, v , are then marked; and to obtain the resultant of the mixture of several colours, forces proportional to the quantities of the colours to be mixed are supposed to be applied to the centres of gravity of the corresponding arcs, and the point of application of the resultant of these forces is determined. The colour sought will be that of the arc of the sector in which this point of application falls. Thus, to find the result of mixing red, blue, and yellow rays whose intensities are to one another as the numbers n_r, n_b, n_y , we must seek the point of application of the resultant of three parallel forces proportional to n_r, n_b , and n_y , applied at the points r, b, y . If this point falls at n , the mixture will be yellow, inclining to green, because the point n is nearer to the limit of the green than to that of the orange. The nearer the point n is to the centre C , the more will the resulting colour be mixed with white; if it coincides exactly with C , the mixture will be white, as, for example, when the seven colours are combined in quantities proportional to the arcs which represent them, the resultant being then applied at the centre of gravity C of the entire circumference.

It follows from Newton's rule: 1. That two simple colours following one another on the circumference produce by their mixture an intermediate tint; an exception must however be made with regard to red and violet, which do not follow one another in the spectrum. 2. Two colours separated by a third, yield that third by their mixture; thus red and yellow yield orange, orange and green yield yellow, &c. Indigo and red, which are nearly at the opposite extremities of the spectrum, yield a reddish colour different from violet.

Biot has reduced Newton's method to a general formula. For this purpose he

Fig. 673.

calculates the co-ordinates of the centres of gravity of the arcs, taking as the axis of abscissæ the straight line passing through the point of separation of the arcs corresponding to the violet and red, and through the centre, taken as the origin of co-ordinates; he then multiplies each co-ordinate by the number of rays of the corresponding colour which is to enter into the compound, divides the sum of the products by the sum of the rays which are to be compounded, and thus obtains the co-ordinates of the point of application of the resultant. Designating the number of rays of each colour by the initial letter of its name, these co-ordinates are:

$$X = \frac{0.82284(r+v) + 0.207398(o+i) - 0.513992(y+b) - 0.353796v}{r+o+y+g+b+i+v}.$$

$$Y = \frac{0.48235(r-v) + 0.963163(o-i) + 0.813736(y-b)}{r+o+y+g+b+i+v}.$$

These co-ordinates give the distance D, of the point of application of the resultant from the centre of the circle, as well as the angle α , which the line joining these points makes with the axis of x : for $\tan \alpha = Y : X$; and $Y = D \sin \alpha$, or $X = D \cos \alpha$.

The value of α shows in which particular sector the point of application falls, and the ratio $D : 1 - D$ shows the proportion of simple light and white light composing the resulting colour.

The preceding method was given by Newton as an empirical rule for representing the results which he obtained by forming compound colours containing given proportions of simple light at the focus of a lens. It cannot be regarded as more than a rough approximation, and is, indeed, less exact than Newton supposed: we have seen, for example, that the mixture of blue and yellow rays may produce white instead of green.

A more satisfactory method of calculating the composition of colours has been given by Maxwell (Phil. Mag. [4] xiv. 40; Proc. Roy. Soc. x. 404), from whose observations it appears that the colours of the spectrum, as laid down according to Newton's method from actual observation, lie, not in the circumference of a circle, but in the periphery of a triangle, showing that all the colours of the spectrum may be *chromatically* represented by three, which form the angles of the triangle. The wave-lengths and positions in the spectrum of these three primary colours are:

Wave-lengths in millionths of an inch.

Scarlet	2328—about one-third from line C to D.
Green	1914—about one-quarter from E to F.
Blue	1717—about half-way from F to G.

This form of the diagram of colour, as perceived by the human eye, is in accordance with Young's theory of *three primary sensations* of colour, which are excited in different proportions, when different kinds of light enter the eye. According to this theory, the threefold character of colour, as perceived by us, is due, not to a threefold composition of light, but to the constitution of the visual apparatus, which renders it capable of being affected in three different ways, the relative amount of each sensation being determined by the nature of the incident light. If we could exhibit three colours corresponding to the three primary sensations, each colour exciting one and one only of these sensations, then, since all other colours whatever must excite more than one primary sensation, they must find their places in Newton's diagram within the triangle of which the three primary colours form the angles.

If this theory be true, the complete diagram of all colour, as perceived by the human eye, will have the form of a triangle. The colours corresponding with the pure rays of the spectrum must all lie within this triangle, and all colours in nature being mixtures of these, must lie within the line formed by the spectrum. If, therefore, any colours correspond with the three primary sensations, they will be found at the angles of the triangle, and all the others will be within the triangle.

The other colours of the spectrum, though excited by undecomposed light, are compound colours: because the light, though simple, has the power of exciting two or more colour-sensations in different proportions—as, for instance, a blue-green ray, though not compounded of the blue rays and green rays, produces a sensation compounded of those of blue and green.

The three colours found by experiment to form the three angles of the triangle, and Newton's diagram, may correspond with the three primary sensations.

A different geometrical representation of the relations of colour may be thus described:—Take any point not in the plane of Newton's diagram; draw a line from this point as origin through the point representing a given colour in the plane, and produce it, so that the length of the line may be to the part cut off by the plane, as the intensity of any given colour is to that of the corresponding point in Newton's diagram. In this way, any colour may be represented by a line drawn from the origin, whose direction indicates the quality of the colour, and whose length depends on

its intensity. The resultant of two colours is represented by the diagonal of the parallelogram formed on the lines representing the colours.

Taking three lines from the origin through the points of the diagram corresponding with the three primaries as axes of co-ordinates, any colour may be expressed as the resultant of definite quantities of each of the three primaries, and the three elements of colour will then be represented by three dimensions of space.

The method of observation by which the preceding conclusions are established consists in selecting three colours of the spectrum, and mixing them in such proportions as to be identical in colour and brightness with a constant white light. Three standard colours being assumed, and the quantity of each required to produce the given white having been found, the quantities of two of these, combined with a fourth colour which will produce the given white, are then determined. A relation is thus obtained between the three standards and the fourth colour, whence its position in Newton's diagram, with reference to the three standards, may be laid down.

The instrument employed in the experiment consists of a dark chamber about 5 feet long, 9 inches broad, and 4 deep, joined to another 2 feet long, at an angle of about 100°. Light admitted by a narrow slit at the end of the shorter chamber, falls on a lens, and is refracted through two prisms in succession, so as to form a pure spectrum at the end of the long chamber. Here there is placed an apparatus consisting of three movable slits, which can be altered in breadth and position, the position being read off on a graduated scale, and the breadth ascertained by inserting a fine wedge into the slit till it touches both ends.

When white light is admitted at the shorter end, light of three different colours is refracted to the three slits. When white light is admitted at the three slits, light of these three kinds in combination is seen by an eye placed at the slit in the shorter arm of the instrument. The white light employed is that of a sheet of white paper placed on a board and illuminated by the sun's light in the open air, the instrument being in a room and the light moderated where the observer sits.

Another portion of the same white light goes down a separate compartment of the instrument, and is reflected at a surface of blackened glass, so as to be seen by the observer in immediate contact with the compound light which enters the slits and is refracted by the prisms.

Each experiment consists in altering the breadth of the slits till the two lights seen by the observer agree both in colour and in brightness. In this way the relative places of sixteen kinds of light were found by two observers, both of whom agreed in finding the positions of the colours to lie very close to the two sides of a triangle, the extreme colours of the spectrum forming doubtful fragments of the third side.

The chromatic relations between these sixteen colours being thus ascertained, the next step is to ascertain the positions of these colours with respect to Fraunhofer's lines. This is done by admitting light into the shorter arm of the instrument through the slit which forms the eye-hole in the former experiments. A pure spectrum is then seen at the other end, and the position of the fixed lines is read off on the divided scale. In order to determine the wave-lengths of each kind of light, the incident light was first reflected from a stratum of air too thick to exhibit the colours of Newton's rings. The spectrum then exhibited a series of dark bands at intervals increasing from the red to the violet. The wave-lengths corresponding with these form a series of submultiples of the retardation; and by counting the bands between two of the fixed lines, whose wave-lengths have been determined by Babinet (p. 607), the wave-lengths corresponding with all the bands may be calculated; and as there is a great number of bands, the wave-lengths become known at a great many different points. In this way, the wave-lengths of the colours compared may be ascertained, and the results obtained by one observer rendered comparable with those of another.

Another instrument, invented by Maxwell for comparing combinations of colour, is the "colour-top," which is a spinning-top, having its flat upper surface divided into two concentric circles, each circle being further divided into sectors, which can be covered with different coloured papers. When the top is spun, the colours in each of the circles produce mixed tints, and the proportions of those in the outer circle are varied till the mixed tint matches that produced by a given combination in the inner circle, the proportions being measured by a graduation on the circumference.

Nomenclature of Colours.—The terms employed to designate different shades of colour are for the most part very indefinite, being sometimes borrowed from natural objects or substances, sometimes from the names of inventors of preparations which exhibit the particular colour, and from various other sources more or less fanciful. The colours of minerals are usually distinguished by comparison with familiar natural objects which they more or less resemble: thus blues are specially distinguished as azure, violet, lavender, smalt, indigo- and sky-blue; greens as verdigris, celadine, mountain, leek, emerald, apple, grass, asparagus, olive, oil, and siskin green; yellows

as sulphur, straw, wax, honey, lemon, ochre, wine, cream, and orange-yellow; reds as aurora or roseate, hyacinth, brick, scarlet, blood, flesh, carmine, rose, crimson, peach-blossom, columbine, and cherry-red; browns as clove, hair, broccoli, pinchbeck, wood, and liver-brown; greys as pearl, smoke, and ash-grey.

To obtain greater accuracy in the nomenclature of colours, Chevreul has devised the following scheme (*De la loi du contraste simultané des couleurs*, p. 87): In the first place he assigns definite meanings to the terms tint (*nuance*), and shade, or tone (*ton*), denoting by tint the result of mixing pure colours in various proportions, and by shade or tone the result of mixing any tint or simple colour with black or white, so that each tint is susceptible of an infinite gradation of shades. A tint is weakened or lowered by the addition of white, strengthened or heightened by addition of black. Colours mixed with black are said by painters to be deadened (*rabattues*), they then reflect less light; in fact, if a coloured surface be less and less illuminated, it becomes continually darker and ultimately black. This effect is experienced at the close of day, all the colours then becoming darker and turning towards black.

Chevreul's Chromatic Circle.—Chevreul has formed a table of 72 tints passing gradually one into the other, and each modified by 20 shades, some produced by admixture of white in various proportions, the rest by admixture of black. Imagine a circle divided into 72 equal sectors. Three equidistant sectors are coloured respectively with red, yellow, and blue, and at equal distances from these three colours are placed those which result from their mixture two by two, viz. orange between red and yellow, green between yellow and blue, violet between red and blue; then between these six tints are placed the intermediate tints, and so on till the whole 72 are complete. Each of these 72 sectors is then divided into quadrangular segments by 20 concentric circles, and in the segments thus formed are placed the shades belonging to each colour. At the centre is a small white circle, starting from which each tint becomes gradually deeper by the continual abstraction of white, till the pure tint is reached, and beyond this the shade is continually deepened by addition of black till the circumference is reached, which is quite black. There is therefore a circular series of segments containing the pure tints with their maximum of intensity, and starting from these, the shades in each sector become weaker towards the centre, stronger towards the circumference. The series of colours contained in any one sector forms a gamut of shades of the corresponding tint. Each circle of segments contains the 72 tints corresponding with the shade of that circle. We have thus a diagram of 1440 colours forming types near enough to one another for the requirements of the arts. It would be useful also to add the gamut of white, that is to say, the series of grey shades from white to black. Such a diagram constructed with permanent colours, on painted porcelain for example, is capable of rendering important service in the arts, by affording a standard nomenclature of colours, which may be designated by the numbers of the sector and the circumference in which they occur.

Lecoq arranges the coloured segments in a different way. He divides the surface of a sphere into quadrangular spaces by means of meridians and parallels. The pure colours are placed at the equator, and each of them becomes darker along the course of its meridian towards one pole, at which there is a black spot, and lighter towards the other pole, where there is a white spot. It would be more convenient to use a cylinder, having one of its bases bordered with black, the other with white, and the pure colours arranged round a zone in the middle. The cylinder might also be developed on a plane, and the whole series of tints and shades thus presented to the eye at once. By repeating at one end of the diagram thus formed, some of the gamuts from the opposite end, each gamut will be placed next to those which differ from it the least. In this form the diagram is more easily constructed, especially if it is to be made in porcelain.

Polarisation and Double Refraction.

When a beam of light proceeding from a self-luminous source traverses a homogeneous medium without encountering any obstacle, it exhibits the same properties on all sides,—on the north, south, east, and west, for example, if we suppose it to be vertical. The light composing such a beam is called *ordinary* or *natural light*. But after the light has met with any obstacle, and has consequently undergone reflection or refraction, it exhibits, for the most part, different properties on different sides. If, for example, the beam of light be received obliquely on a glass mirror, and the mirror be turned round it, taking care not to alter the angle of incidence, the intensity of the reflected beam will vary according to the side of it which is presented to the mirror. A ray thus modified is said to be polarised. The properties of polarised rays all relate to changes of intensity or modifications of colour, and never affect the direction in which they are reflected or refracted.

Light may be polarised in either of the following ways:—

1. *By Reflection from the surface of transparent media.*—Suppose a ray of light AC (fig. 674) to fall upon a plate of glass (not silvered, but blackened at the lower surface)

Fig. 674.

at C, making an angle of $54\frac{1}{2}^\circ$ with the normal PC, or $35\frac{1}{2}^\circ$ with the reflecting surface. This ray will be reflected in the direction CD, making an angle $PCD = ACP$, and in the same plane as AC and CP. Now suppose the reflected ray to fall upon a second surface of glass at the same angle of $54\frac{1}{2}^\circ$ with the normal. If, then, the second mirror be so placed, that its plane of reflection is parallel to the plane of reflection from the first surface (see left-hand figure), then the ray will be reflected from the second surface in the direction DE, just as if it proceeded directly from a luminous source, and had not undergone previous reflection; but if the second mirror be so adjusted that its plane of reflection is perpendicular to that of the first (see right-hand figure), then the ray CD will not be reflected from it at all, or at least the intensity of the reflected beam will be comparatively small. In intermediate positions, still at the same angle of incidence, the ray CD will be partially reflected, the quantity of light in the reflected ray DE being greater as the planes of reflection of the two mirrors are more nearly parallel.

The ray, after reflection from glass at an angle of $54\frac{1}{2}^\circ$, appears then to exhibit different properties, according to the direction in which it is a second time reflected, being in fact reflexible in different degrees at different azimuths; it is therefore *polarised*.

The plane in which a polarised ray is most easily reflected is called the *plane of polarisation*; it coincides with the plane of reflection (or of incidence).

The angle $54\frac{1}{2}^\circ$ is called the *polarising angle* for glass. For every medium there is a particular polarising angle, the magnitude of which depends upon the refracting power of the medium, according to the following law, discovered by Brewster: *The polarising angle ACP (fig. 675) is that for which the refracted ray CD is perpendicular to the reflected ray CB.* Now let μ denote the index of refraction,

then $\mu = \frac{\sin ACP}{\sin QCD}$; but the angle $ACP = BCP$

$[= \theta]$; and since BC is perpendicular to CD, and QC to CN, angle $QCD = BCN = 90^\circ - \theta$; therefore,

$\mu = \frac{\sin \theta}{\cos \theta} = \tan \theta$; that is to say, the *polarising*

angle is the angle whose tangent is equal to the index of refraction.

The following table exhibits the polarising angles of a few transparent substances, chiefly according to the observations of Biot and Arago:—

Fig. 675.

Name of substance.	Polarising angle.		Name of substance.	Polarising angle.	
	Measured from normal.	Measured from surface.		Measured from normal.	Measured from surface.
Fluor spar . . .	54° 50'	36° 10'	Topaz . . .	58° 40'	31° 20'
Water . . .	52 45	37 15	Ice-land spar . . .	58 23	31 37
Glass . . .	54 35	35 25	Spinel ruby . . .	*60 16	29 44
Obsidian . . .	56 03	33 57	Zircon . . .	*63 08	26 52
Selenite . . .	56 28	33 32	Sulphur (native) . . .	*64 10	25 50
Amber . . .	56 35	33 25	Antimony-glass . . .	*64 45	25 15
Rock-crystal . . .	57 22	33 38	Chromate of lead . . .	*67 42	22 18
Sulphate of barium	58 0	32 0	Diamond . . .	*68 02	21 58

There are but few substances capable of completely polarising light by reflection, and generally speaking the polarising power is least in those media which have the largest indices of refraction. According to Brewster, it is only those media whose refractive index is less than 1.7, which are capable of polarising completely; such are those not marked with an asterisk in the preceding table. But even when the index is less than 1.7, the polarisation is never complete, if the beam of light is bright. In general, substances which reflect but little light, polarise a large proportion of it. Metals, with clean and polished surface, polarise scarcely at all. In all cases, however, Brewster's law applies to the incidence at which the reflected beam contains the largest proportion of polarised light.

As the several coloured rays have different indices of refraction, it is evident that only homogeneous light can be completely polarised by reflection. Solar light, or ordinary gas or candle light, can never be made to disappear completely in the manner above described. In fact, with media of high dispersive power, such as oil of cassia, diamond, chromate of lead, or specular iron, all the colours of the spectrum may be successively brought into view by slightly altering the inclination of the reflecting surface in the vicinity of the polarising angle. With glass and water, in which the angles of polarisation for the extreme rays of the spectrum do not differ by more than 15° or 20°, the colours are less perceptible; nevertheless the light never disappears entirely, and always exhibits a slight coloration after the second reflection.

Light is more or less polarised by reflection at all angles of incidence, excepting perpendicular incidence, the proportion of polarised light in the reflected beam being greater as the angle of incidence differs less from the polarising angle determined by Brewster's law.

If a ray, partially polarised by reflection at any angle differing from the polarising angle, be again reflected from the same medium at the same angle, the proportion of polarised light in it will be increased; and by a number of successive reflections, the ray may be brought indefinitely near to the state of complete polarisation, the number of reflections required for the purpose being less as the angle of reflection differs less from the polarising angle.

2. *By ordinary Refraction.*—When light passes from one medium to another, the refracted ray is polarised as well as the reflected ray, its plane of polarisation being perpendicular to the plane of refraction, or of incidence, and, therefore, also to the plane of polarisation of the reflected ray. The refracted ray will therefore be reflected from a surface of glass at an angle of $54\frac{1}{2}^\circ$, just under the circumstances in which the ray polarised by reflection would not. Light, however, is never completely polarised by one refraction; but the proportion of polarised light in the refracted beam is greater as the angle of incidence is nearer to the polarising angle; and by successive refractions through a number of surfaces of glass, or other medium, it may be brought within any assigned limit of complete polarisation. A bundle of thin plates of glass or mica, bound together in a frame, forms a very convenient apparatus for polarising light, whether by refraction or by reflection.

3. *By Double Refraction.*—All crystalline bodies not belonging to the regular system, possess the power of double refraction; that is to say, a ray of light entering such a medium is split up into two rays of equal intensity, which traverse the crystal in different directions. In all such media, however, there are either one or two directions in which double refraction does not take place, and these lines are called the optic axes of the crystal. Transparent calcspar, or Iceland spar, which crystallises in rhombohedrons, and exhibits double refraction more distinctly than any other substance, is a crystal with one optic axis, the direction of that axis being parallel to the line joining the obtuse summits of the rhomb. A ray traversing the crystal in a direction parallel to this axis is not divided into two; but in all other directions the ray is doubly refracted; and the two rays into which it is thus divided are both completely polarised, the plane of polarisation of the one being parallel to the *principal section* of the crystal, that is to say, a plane passing through the optic axis and the direction in which the ray traverses the crystal; the other in a plane at right angles to that section. The ray which is polarised in the principal section follows the ordinary laws of refraction, remaining always in the plane of incidence, and having for all incidences a constant index of refraction; but the ray polarised perpendicularly to the principal section follows different laws of refraction, its direction not being confined within the plane of incidence, unless that plane coincides with or is perpendicular to the principal section, and its index of refraction, excepting in the last-mentioned case, varying continually with the angle of incidence. The former of these rays is called the *ordinary*, the latter the *extraordinary* ray. The mode of refraction of the latter will be more fully explained hereafter.

When these two oppositely polarised rays, which have traversed a rhomb of Iceland spar, fall on a plate of glass at the angle of $54\frac{1}{2}^\circ$, so placed that the plane of reflection

is parallel to the principal section of the crystal, the ordinary ray is reflected, and the extraordinary ray is not, the contrary effect taking place when these planes are at right angles to each other. When the plane of reflection is inclined to the principal section at any angle between 0° and 90° , both rays are reflected, but with different intensities.

The two polarised beams, on emerging from the crystal, will overlap each other, or will be completely separated, according to their breadth and the thickness of the crystal. When, however, it is desired to examine only one of them, it is most convenient to throw the other completely out of the field of view. This may be effected in one of the following ways:

a. By Reflection.—The apparatus for this purpose, called a *Nichol's prism*, consists of two similar prisms of calcspar (*fig. 676*), ABCD, CDEF, cemented together with Canada balsam at the faces CD. The faces AB, EF are cut so as to make an angle of 68° with the obtuse edges AE, BF of the natural crystal (the natural faces make an angle of 71° with the obtuse edges), and the faces CD are perpendicular to AB and EF. With this arrangement, it is found that of the two rays, *no*, *ne*, into which an incident ray, *mn*, is divided, the ordinary ray, *no*, on reaching the surface of Canada balsam (whose index of refraction is less than that of the ordinary, and greater than that of the extraordinary, ray), suffers total reflection in the direction *op*, while the extraordinary ray passes on in the direction *cf*, and emerges in *fg*, parallel to *mn*. An eye placed at *f*, therefore, sees but one image, viz. that formed by the extraordinary ray. Hence, a beam of ordinary light passing through it will be polarised in a plane perpendicular to the principal section—that is to say, to the shorter diagonal of the rhomb, *ab* (*fig. 677*); and a ray, already polarised, will be stopped by the prism if its plane of polarisation is parallel to *ab*, but will pass freely through it when the plane of polarisation is perpendicular to *ab*, or parallel to the longer diagonal *cd*. Hence, also, two Nichol's prisms, placed one behind the other, appear perfectly opaque when their principal sections are at right angles to each other, perfectly transparent when the principal sections are parallel, and transmit light with diminished intensity in intermediate positions.

Fig. 676.

Fig. 677.

B. By Absorption.—Certain double-refracting crystals, especially the tourmaline, have the power of transmitting light only when polarised in a particular direction with regard to their optic axes. The tourmaline forms crystals belonging to the hexagonal system, having one optic axis parallel to the axis of figure, and transmitting light only when polarised in a plane perpendicular to the optic axis. Hence, when a ray of light polarised by reflection from glass at the angle of $54\frac{1}{2}^\circ$, is viewed through a plate of tourmaline cut with its faces parallel to the optic axis, then if the crystal be held with its optic axis perpendicular to the plane of reflection, the ray will pass through it as freely as its colour will permit; but if the tourmaline be held with its axis parallel to the plane of reflection, the reflected rays will be completely absorbed, and no light will pass. If the tourmaline be gradually turned round from the first position to the second, the quantity of light which passes through it will continually decrease, because the polarised ray is then divided by the tourmaline into two, one polarised at right angles to the axis, the other parallel thereto, the intensity of the former continually decreasing, and that of the latter increasing as the tourmaline is turned round. When a ray of ordinary light is transmitted through a tourmaline plate of a certain thickness, cut as above described, it is divided into two, as by other double-refracting crystals; but the ordinary ray is completely absorbed, and only the extraordinary ray passes through, so that the emergent beam is completely polarised in a plane perpendicular to the axis of the tourmaline. Hence if two such plates of tourmaline be superposed, and the light of the sky be viewed through them, then if the two be placed with their optic axes parallel, the light will pass through them as freely as their colour and imperfect transparency will permit; but if one of the tourmalines be then turned round, the quantity of light transmitted will decrease as the axes deviate more and more from parallelism, and at last, when the two axes cross one another at right angles, the light will be completely intercepted.

Two such tourmalines mounted with their faces parallel to each other, and so as to permit one of them to revolve in the plane of the axis, form a very convenient and portable apparatus for experiments on polarised light. A single tourmaline is also very convenient for examining light polarised by reflection or refraction. The only objection to the tourmaline is its colour, the best polarising tourmalines having always a brown colour, which greatly modifies the colour of the transmitted light, especially as, in order that the tourmaline may polarise completely, it must have a thickness of at least the tenth of an inch.

There are a few other double refracting crystals possessing similar properties; in particular the so-called "sulphate of iodo-quinine," discovered by Dr. Herapath. This substance crystallises in thin six- or eight-sided plates, which are transparent and nearly colourless by transmitted light when viewed separately; but when two of them are superposed, with their longer dimensions crossing one another at right angles, the part where they cross appears quite black, even if the thickness of the crystals does not exceed $\frac{1}{20}$ of a millimetre. The crystals of this compound may therefore be used in the same manner as tourmalines, and are even better adapted for optical use, by their greater transparency and freedom from colour; but their fragility renders it somewhat difficult to manipulate with them.

The best substitute for a tourmaline is the Nicol's prism, above described. The calc spar crystals being perfectly colourless and very transparent, transmit much more light than two superposed tourmalines.

All arrangements for examining the properties of polarised light necessarily consist of two parts; viz., the polariser, by which the light is brought into the polarised state, and the analyser, by which its state of polarisation and its properties are examined; thus, when a ray is reflected from a plate of glass at an angle of $54\frac{1}{2}^\circ$, and the reflected beam examined by a tourmaline held before the eye, the plate of glass is the polariser, and the tourmaline the analyser. It is clear that any one of the apparatus above described, namely a reflector, a refractor, a double-refracting crystal, a tourmaline, or a Nicol's prism, may be used either as polariser or analyser.

Nature of Polarised Light.—The existence of rays having different properties on different sides was regarded by Newton as a decisive objection against the wave-theory of light, on the ground that pressures or movements excited by a luminous body in an elastic medium ought to be equal in all directions; and Huyghens was obliged to admit his inability to account for the existence of polarised rays on the undulatory theory as then understood. The reason of this apparent inability of the wave-theory to explain the phenomena of polarisation, was that, at the time of which we are speaking, the vibratory movements of the ether were supposed to take place wholly in the direction of propagation of the waves, and on that hypothesis it is impossible to conceive of rays of light, any more than rays of sound, possessing different properties on different sides. But later experimental researches, and the investigation of the subject on the principles of analytical mechanics, have shown that the vibrations of the luminiferous ether take place in planes tangential to the wave-surface, or transversely to the direction of the ray. From this point of view, the difference between ordinary and polarised light is easily explained. An ordinary or natural ray is one in which the vibrations take place in all directions successively in the plane of the wave; and a polarised ray is one in which the vibrations, still tangential to the wave-surface, are confined to one plane. Suppose, for example, the direction of the ray to be vertical, or that of the wave-surface horizontal; then, if the ray be polarised, the direction of vibration of all the particles will be either north and south, or east and west, or in some one intermediate azimuth; and if it be unpolarised, the vibrations will take place in all these directions successively.

This view of the nature of polarised light is established by the experiments of Fresnel and Arago on the interference of polarised rays, the general result of which is, *that two rays whose planes of polarisation (p. 653) are parallel to one another interfere just like unpolarised rays: but two rays whose planes of polarisation are perpendicular to one another do not exhibit any phenomena of interference, whatever may be their difference of phase.* These results are easily conceivable if the vibrations are transverse to the direction of the ray; for if the vibrations of the two rays take place in directions parallel to each other, the resultant will be equal to the sum or difference of their individual movements, as explained at page 598, and will be reduced to zero, that is to say, the rays will destroy each other, when their phases are exactly opposite; but if their vibrations are performed in planes inclined to one another at any angle, there will be, at every point, a finite resultant, determined in magnitude and position by the rule of the parallelogram of velocities, and never becoming equal to nothing. Hence, two rays whose planes of polarisation are not parallel, can never interfere so as to produce complete darkness; and if their planes are at right angles to one another, they cannot interfere at all. If, on the other hand, the vibrations of the ether take

place in the direction of the ray, it is impossible to conceive any conditions which would prevent them from interfering with one another, and producing darkness when they meet one another under a certain difference of phase.

The experiments which show that the interference of polarised rays does depend, as above described, on their state of polarisation, are the following:

1. The light passing through two narrow parallel slits very close together, as in Young's experiment (pp. 599, 604), is polarised by covering the slits with two pieces of the same plate of tourmaline, cut parallel to the axis, which polarises the light in a plane perpendicular to that axis. If the two tourmaline plates have their axes parallel to one another, the two beams of light interfere and produce fringes, just as if the tourmalines were not there; but if they are placed with their axes at right angles to one another, all the fringes disappear. In intermediate positions of the tourmalines fringes are produced, but fainter as the angle between the axes approaches more nearly to a right angle. Instead of tourmalines, two small bundles of mica-plates may be placed before the slits, in a position inclined to the direction of the rays, which are then, after transmission, almost wholly polarised in a plane perpendicular to the plane of incidence. The fringes then disappear when the bundles of plates are so placed that the two planes of incidence are at right angles to each other.

2. The two slits are covered with two fragments of the same plate of calcspar or rock-crystal, cut parallel to the optic axis. Each plate then gives an ordinary and an extraordinary ray, whose planes of polarisation are at right angles to one another. If the axes of the two fragments are parallel, the two ordinary rays which emerge from them produce fringes, just as if they were unpolarised; so likewise do the two extraordinary rays, and these two systems of fringes are superposed. If now one of the crystalline plates be gradually turned round in the plane parallel to its axis, the fringes become fainter, and when the axes of the two plates are at right angles to one another, the fringes disappear altogether, and give place to uniform light. At the same time, however, other systems of fringes make their appearance on the sides, being produced by the interference of the ordinary rays proceeding from one of the slits with the extraordinary rays from the other; they are shifted to the sides on account of the difference of velocity of the ordinary and extraordinary rays within the crystal. So long as the axes of the two plates remain parallel, the ordinary ray of the one and the extraordinary ray of the other are polarised in planes at right angles to one another, and the lateral fringes are not produced; but on inclining the axes to one another, these lateral fringes appear, becoming more and more brilliant as the angle between the axes increases, and attaining their greatest brightness when the two axes form an angle of 90° .

3. When a narrow screen, such as a hair, is placed in the path of the two rays issuing from a rhomb of Iceland spar, placed before the focus of a lens, no fringes are produced within the shadow, as they would be by ordinary light, because the two rays are polarised in planes at right angles to one another.

In Fresnel's mirror experiment (p. 599), the rays are polarised by reflection in the same plane; and in that of Young (p. 602), the rays originating from the same source have their transverse vibrations at each instant parallel to one another, so that they are in the right condition for interference.

The preceding experiments show then that the vibrations of the ether are parallel to the wave-surface, and that in a polarised ray they take place, for the most part, in one plane passing through the ray. Moreover, *the vibratory movements are perpendicular to the plane of polarisation*. For when a beam of light passes through a crystal with one optic axis, like Iceland spar, the ordinary ray is polarised in a plane parallel to the principal section of the crystal; that is to say, it is most easily reflected in a plane parallel to that section (p. 653). Now as this ray follows the ordinary law of refraction, and consequently has a constant velocity whatever direction it may take through the crystal, the vibrations of the ether which form it must have a constant direction with regard to the axis of the crystal; and as they are perpendicular to the ray whatever angle it may make with the axis, they could not form a constant angle with the axis, unless they were also perpendicular to that axis. The vibratory movements constituting the ordinary ray are therefore perpendicular, both to the ray and to the optic axis, and therefore to the principal section, which is the plane passing through the ray and the axis, and in this case is identical with the plane of polarisation of the ray. Hence, as all polarised rays possess the same properties, whatever may be their origin, it follows that the vibrations of the ether are always at right angles to the plane of polarisation.

The same result may be deduced from the properties of the tourmaline, which, as already observed (p. 655), intercepts the ordinary ray. Now it is found that a plate of tourmaline, cut *perpendicular to the optic axis*, intercepts all the light which falls upon it at perpendicular incidence, which shows that all vibrations perpendicular to

the axis are arrested by it. But when the ray passes through a plate of tourmaline cut parallel to the axis, only the ordinary ray is intercepted, the extraordinary ray passing through. The vibrations of the ordinary ray must therefore be perpendicular to the axis, and consequently to the principal section of the crystal, parallel to which the ray is polarised.

From this direction of the vibratory movements, it follows that a polarised ray is most easily reflected when its vibrations are parallel to the reflecting surface, and on the contrary, that it is most easily transmitted through a pile of plates when the vibrations take place in the plane of incidence or at right angles to the surface; also that the ray passes most completely through a tourmaline cut parallel to its axis, when the vibrations are parallel to this axis. The tourmaline acts therefore like a grating, which gives free passage to a surface, such as a knife-blade, parallel to the bars, but stops it when presented transversely.

The form of the curve which the ether-molecules describe in the plane perpendicular to the direction of the ray—for example, in the row $a a'$ (fig. 677)—determines the

Fig. 677.

state of polarisation of the ray. If the oscillation consists in a mere motion of the particles backwards and forwards in a straight line, the ray is said to be rectilinearly polarised, or plane-polarised; and the plane passing through the ray at right angles to the direction in which the particles vibrate, is the plane of polarisation of the ray. The particles originally situated in

the straight line which is the direction of the ray, appear at a certain moment, arranged in the wave-line acb . If each of the vibrating particles describes a circle, the direction of its velocity will change from 0° to 180° while the vibration is extending through the space of half an undulation, and to 360° in the space of a whole undulation: hence, a series of particles in all phases of velocity, extending from one extremity of the wave to the other, will be situated on a screw-line having the direction of the ray for its axis. The ray is then circularly polarised, and right or left, according as the direction of revolution of the ether-molecules, regarded from the centre of the circle, or the axis of the screw, is like that of the hands of a watch or the contrary. The result is the same as if the ray were polarised in one plane, and this plane revolved, making a complete revolution during the time of one vibration.

If each of the vibrating particles describes an ellipse, the successive particles may be conceived as arranged on an elliptical screw-line. In this case, to determine the state of polarisation of the ray, it is necessary to specify, not only the length of the major and minor axes of the ellipse, but likewise the position of these axes in space, as determined, for example, by a system of rectangular co-ordinates, one axis coinciding with the ray, while the other two are drawn at right angles to each other in the plane of vibration of the ether-molecules. The direction of the rotation must also be stated as in the case of circular polarisation.

A circularly polarised ray examined by an analyser exhibits the same intensity in all azimuths, just like natural light, but is distinguished therefrom by appearing coloured when viewed through the analyser, after passing through a thin plate of a double refracting crystal (p. 671). An elliptically polarised ray exhibits a maximum and minimum of intensity in two positions of the analyser at right angles to each other, but is never completely extinguished like a plane-polarised ray, and is likewise coloured by transmission through a double-refracting film. The colours thus imparted both to circularly and to elliptically polarised light, differ from those exhibited under similar circumstances by plane-polarised light.

To understand the manner in which these different states of polarisation arise, it is necessary to take account of the movement impressed upon the molecules of the ether when they transmit several systems of waves at once, the velocities being then compounded according to the principle of the parallelogram of forces. When this composition is effected by construction or by calculation, it is found that when the lengths of the component waves are equal (the only case that will be here considered) the waves of the resulting system always have the same length, so that the changes produced can affect only the amplitude of vibration and the state of polarisation.

1. When the two rays are polarised in the same plane.—In this case, the amplitude of the resultant wave is equal to the sum or difference of the component waves, according as the two rays are in corresponding or in opposite phases; and if they are in exactly opposite phases, and of equal amplitude, they destroy each other's motion

completely, and produce darkness. The case is, in fact, that already considered under INTERFERENCE (p. 598).

2. *When the two rays are polarised at right angles to each other.*—In this case, the vibrations of the two wave-systems take place in planes at right angles to one another, and therefore the resulting system cannot be rectilinearly polarised, unless the difference of phase of the two component wave-systems is either nothing or an exact multiple of a half wave-length. If we imagine two rays travelling at right angles to the surface of the paper, and passing through the point A (fig. 678), the vibrations of the first (positive) half-wave of the one system being directed parallel to An , and those of the other parallel to Am ; then if both the waves affect the particle A simultaneously and with equal force, the resulting vibrations will make an angle of 45° with those of the component wave. The azimuth of the vibration is then 45° , reckoning from An . If, on the other hand, the second system is half a wave-length before or behind the other, it will affect the particle A with its negative vibration Am' , at the same time that the positive vibration An of the other system begins to act. The azimuth of vibration is then -45° , always reckoning from An .

But if the difference of phase of the two wave-systems is equal to a quarter of a wave-length, the velocity Am then affects the particle A, just as the vibration imparted to it by the other system has brought it to n , and it is about to return towards A: it therefore acquires a rotatory movement round the point A. The ray is therefore circularly polarised, and right or left, according as the system Am is before or behind the system An by a quarter of an undulation. If the amplitudes of the two systems are unequal, a difference of phase amounting to a quarter of a wave-length will produce elliptical polarisation. This kind of polarisation is likewise produced with any other difference of phase (excepting 0 or $m \cdot \frac{\lambda}{2}$), whether the amplitudes are equal or unequal.

If the two systems are polarised in planes making an oblique angle with one another, a difference of phase equal to 0 or $m \cdot \frac{\lambda}{2}$ produces rectilinear or plane polarisation, while every other difference produces elliptical polarisation.

It follows, from the preceding considerations, that elliptical polarisation is the usual state of polarised light, circular and rectilinear polarisation being merely particular cases of it.

Suppose now a plane-polarised ray to fall on the separating surface of two transparent media, its plane of vibration being inclined to the plane of incidence at an angle of 45° . Each vibration may then be regarded as resolved into a component (P) vibrating in the plane of incidence, and another (R) vibrating at right angles to that plane; and these two components will be weakened by reflection in unequal degrees. At the incidences 90° and 0° (measured from the normal), the two components of the reflected ray are of equal intensity; but from 90° to 0° the intensity of R continually diminishes, whereas that of P , though it likewise diminishes for a certain distance from 90° towards 0° , attains a minimum value at a certain angle of incidence, whose magnitude depends on the refractive index, and increases again from that point up to perpendicular incidence.

In reflection from metals, and also from non-metallic substances of high refractive power, the quotient $\frac{P}{R}$ has always a considerable value; but in the case of media of comparatively low refractive power, such as water and glass, it very nearly vanishes at the limiting angle above mentioned. Moreover, as the variously directed vibrations of an ordinary (unpolarised) ray may be resolved into the two principal components above mentioned, it follows that, at the limiting angle, the vibrations of the ray (if monochromatic) will all, or nearly all, be reduced to one plane—namely, a plane perpendicular to the plane of incidence; in other words, the ray, after reflection, will be completely polarised, or nearly so, in the plane of incidence. The limiting angle above referred to is therefore the polarising angle (p. 653). It is clear also that if the ray thus polarised falls upon a second mirror at the same angle, and this mirror is so placed that the vibrations of the polarised ray are parallel to its plane of incidence, little or no light will be reflected from it; but that, if the second reflector be turned round from this azimuth, always remaining at the same angle to the ray, the quantity

Fig. 678.

of light reflected will gradually increase till the plane of incidence upon the second mirror coincides with that upon the first, at which the quantity of light reflected from the second mirror will be a maximum. (See page 653.)

When light falls at the polarising angle on a substance of comparatively small refracting power, as glass, water, &c., the intensity of the refracted ray is much greater than that of the reflected ray, inasmuch as a small portion of the light polarised at right angles to the plane of incidence, and nearly the whole of that which is polarised parallel to the plane of incidence, pass into the refracted ray. The former component unites with an equal portion of the latter, reproducing unpolarised light, so that the refracted ray consists of natural light mixed with light polarised in the plane of incidence.

The two components P and R not only differ in intensity after reflection, but likewise exhibit a difference of phase, P being always more or less behind R , excepting, according to Jamin, in reflection from one or two varieties of silica.

At the incidence of 90° , since a ray polarised in the azimuth of 45° retains its azimuth unaltered, the difference of phase of the two components P and R is either nothing or equal to an entire wave-length (p. 659). At perpendicular incidence, the azimuth changes from 45° to -45° ; consequently the difference of phase is $\frac{\lambda}{2}$. In both cases, therefore, a plane-polarised ray remains plane-polarised after reflection. But at all other incidences, the difference of phase is between λ and $\frac{\lambda}{2}$, and consequently the plane or rectilinear polarisation is converted into elliptical polarisation. The angle of incidence for which the difference of phase $= \frac{3\lambda}{4}$ is called the principal incidence. It is very little smaller than the polarising angle (p. 653), calculated from Brewster's formula, $\tan i = \mu$; hence, at the principal incidence, the quotient $\frac{P}{R}$ differs but little from its smallest value. In substances of small refracting power, the passage from the difference of phase $\frac{\lambda}{2}$ to λ takes place quickly, so that the elliptical polarisation is perceptible only between very narrow

Fig. 679.

limits; but in bodies of greater refracting power, such as diamond, it is more easily observed. Fig. 679, in which the angles of incidence are laid down as abscissae, and the differences of phase diminished by $\frac{\lambda}{2}$ as ordinates, exhibits the difference of behaviour of glass, sulphide of arsenic, and zinc. The points p, p', p'' correspond to the principal incidences, or to a difference of phase $= \frac{3\lambda}{4}$.

The more refrangible rays acquire a greater difference of phase in their two components under a given incidence than the less refrangible rays. In many metals, as silver, copper, brass, and nickel-silver, the ratio of the intensities $P : R$ is smaller, while in others, as zinc and steel, it is larger for the more refrangible rays. In consequence of this inequality, the former metals, especially when illuminated by light vibrating in the plane of reflection, exhibit a yellow or red, the latter a bluish colour, the tints often coming out with continually greater distinctness after repeated reflection. At the incidence of 90° , that is to say, when the incident ray just grazes the surface, all well-polished metals appear white.

Theory of Double Refraction.

The phenomena of reflection, refraction, and coloration undergo considerable alterations when light falls upon media through which it travels with different velocities in different directions. This is the case in all crystals not belonging to the regular or monometric system; likewise in all media whose molecular condition is altered in particular directions by pressure, or by heating and sudden cooling, such as unannealed glass.

Crystals with one Optic Axis.—Consider, in the first place, crystals belonging to the dimetric and hexagonal systems, which resemble one another greatly in their optical as well as in their other physical properties, such as expansion by heat (iii. 72),

and capacity of conducting heat and electricity (ii. 122). In these crystals, the elasticity of the ether is either greatest (negative crystals), or least (positive crystals), in the direction of the principal crystallographic axis, but equal in all directions at right angles to that axis. If, now, from any point within the crystal, straight lines be drawn in all directions, and proportional in length to the square roots of the elasticities of the ether in these several directions, the terminal points of these lines will be situated on a surface of revolution called the surface of elasticity. To find the velocities with which rays are transmitted in these several directions, imagine a number of plane waves to pass in all directions through the centre. Every such wave cuts the surface of elasticity in a closed curve, like *fig.* 680. If the crystal is negative—calc spar, for example—the longest diameter of this curve lies in a meridional plane (called, in optical language, the principal section), the shortest diameter in the equatorial plane of the surface of elasticity. If the light-wave is polarised, and its vibrations take place in the direction *ca*, it will, after penetrating through an extremely thin layer of the crystal, divide itself into two polarised waves, which vibrate in the directions of greatest and least elasticity, *cp* and *cr*, with the amplitudes *ca* and *cb*, and will therefore travel with unequal velocities in the direction perpendicular to *mnpr*. It is as if the molecules of the ether were compressed in the direction of the principal axis, so that a vibratory movement cannot easily be propagated in a direction oblique to that axis, but is resolved into two in the manner above mentioned.

Fig. 680.

The same result will ensue if the incident wave consists, not of polarised but of natural light, excepting that the two polarised components will then have equal intensities, since they are made up, not only of the components of vibrations in the direction *cs*, but likewise of those of vibrations in all other directions within the plane *mnp*. If the incident wave coincides with the equatorial plane of the surface of elasticity, the two semidiameters *cp*, *cr* are equal. In this case, the light is not polarised in two directions at right angles to one another, but the wave travels onwards without dividing itself, in the direction of the principal crystallographic axis, which, on account of this property, is denominated the optic axis. Crystals of the dimetric and hexagonal systems are optically uniaxial.—If the plane wave passing through *o* coincides with a meridional plane, the difference of the two velocities of transmission is a maximum, since one of the components calls into action the maximum amount of elasticity in the direction of the axis itself. The velocity of transmission of the other component remains, as above mentioned, the same in all directions, inasmuch as it is always proportional to the radius, *cr*, of the surface of elasticity. If, now, we imagine the infinite number of plane wave-surfaces passing in all directions through the point *c* set in motion at the same time, according to the laws above detailed, they will, after a short time, enclose two different curved surfaces called the wave-surfaces of mon-axial crystals. One of these surfaces, corresponding to the light which vibrates in the equatorial plane, or at right angles to the principal section (i.e. polarised in the principal section, p. 657), is a sphere; the second, corresponding to that which vibrates in the principal section (or is polarised at right angles to that section), is shown by calculation to be an ellipsoid of revolution, which touches the sphere at two points situated on the optic axis. Fig. 681 is a meridional section of the two wave-surfaces. In any direction through such a crystal, two rays, polarised at right angles to each other, travel with the velocities *mg* and *mf*. The vibrations of the first ray are perpendicular to its direction, but those of the second are not; they take place in a plane touching the ellipsoid at the point *f*, so that, to find the velocity of transmission of the plane wave corresponding to the ray *mf*, it is necessary to draw a perpendicular from *m* to the plane which touches the ellipsoid *mf*.

Fig. 681.

From this theory, first developed by Fresnel, all the phenomena of double refraction may be deduced in a very simple manner. Suppose a beam of parallel rays corresponding to the plane wave bq (fig. 682) to fall upon the surface of a monocrystal—calc spar, for example—whose optic axis is in the direction bt . Round b as a centre describe the two wave-surfaces, so that, taking gf as unity, the radius of the spherical surface may be $\frac{1}{3.654}$ and that of the ellipsoid $\frac{1}{1.483}$. Imagine also a line drawn

through f at right angles to the plane of the figure, and through this line suppose planes to pass touching the sphere in h , the ellipsoid in n ; then, as explained with

Fig. 682.

reference to *fig. 655* (p. 609), bh and bn will be the directions of the two refracted rays. The vibrations of the ray bh are perpendicular to the plane of incidence, which in this case is also the principal section; those of the ray bn are parallel to the plane of incidence. The ratio of the velocities of the ray bh , without and within the crystal, is independent of the angle of incidence, as in uncrystallised media and crystals belonging to the regular system (isophanous media), since the corresponding wave-surface is a sphere. This ray is therefore called the ordinary ray (O). But the index of refraction of the second ray, bn , varies with the angle of incidence: hence this ray is called the extraordinary ray

(E). In calc spar, and all other negative crystals, it is less than that of the ordinary ray.

If the plane of incidence neither coincides with a principal section, as in the preceding example, nor is perpendicular thereto, the plane drawn through f tangential to the ellipse will touch it in a point not contained in the plane of incidence; the extraordinary ray then deviates from the plane of incidence, which is never the case in ordinary refraction. As in negative crystals, the extraordinary ray is always less refracted than the ordinary ray, and, in comparison with this, appears to be repelled from the optic axis, these crystals are sometimes called repulsive: positive crystals, on the other hand, in which the extraordinary ray is more refracted than the ordinary ray, are called attractive crystals.

Fig. 683.

shown in section in *fig. 683*. The ray E in these crystals—rock-crystal, for example—is more strongly refracted than O .

The following is a list of the most important uniaxial crystals:

Positive or Attractive Crystals.

Zircon.
Quartz.
Tungstate of zinc.
Stannite.
Boracite.

Apophyllite.
Sulphate of potassium and iron.
Acid acetate of copper and calcium.

Hydrate of magnesium.
Ice.
Hyposulphate of calcium.
Diopase.
Red silver.

Negative or Repulsive Crystals.

Iceland spar.
Carbonate of calcium and magnesium.
Carbonate of calcium and iron.
Tourmaline.
Rubellite.
Corundum.
Sapphire.
Ruby.
Beryl.
Apatite.

Idocrase.
Wernerite.
Mica.
Phosphate of lead.
Arsenio-phosphate of lead.
Hydrate of strontium.
Arsenate of potassium.
Chloride of calcium.
Chloride of strontium.
Basic phosphate of potassium.

Sulphate of nickel and copper.
Cinnabar.
Mellite.
Molybdate of lead.
Octahedrite.
Phosphate of calcium.
Arsenate of lead.
Arsenate of copper.
Nepheline.

From the explanation just given of double refraction in uniaxial crystals, it follows that, for the complete optical characterisation of such a body, it is sufficient to know the greatest and least velocities of light therein, or—which comes to the same thing—the indices of refraction for the two oppositely polarised rays which traverse the crystal in a plane perpendicular to the axis. To find these indices of refraction, the crystal must be cut in the form of a prism, with its refracting angle parallel to the optic (or principal crystallographic) axis, and the least deviations of the several coloured rays in the ordinary and extraordinary image measured by the methods already described. The values thus found are, of course, true only for the particular temperatures at which they are measured. Change of temperature likewise affects the refractive indices of double-refracting crystals in a peculiar manner, because the rate of expansion by heat of these crystals, in the direction of the optic axis, is not the same as in directions perpendicular to that axis. Calc spar, for example, expands in the direction of its optic axis joining two obtuse summits of the rhombohedron, more strongly than in any other direction, the rhombohedron at the same time approaching in form to the cube, while the double refraction perceptibly diminishes, or, in other words, the refractive indices of the rays *E* and *O* approach more nearly to equality. Very exact measurements of indices of refraction of Fraunhofer's seven lines (*B—H*), in the ordinary and extraordinary images of calc spar and rock-crystal, together with the alterations produced in them by change of temperature, have been made by Rudberg (Pogg. Ann. xiv. 45; xxvi. 291). Double refraction is frequently also different in degree for the different coloured rays. In apophyllite, indeed, this inequality is so great that the crystal is positively double-refracting for the blue, negatively for the red rays, and single-refracting for an intermediate ray.

2. *Crystals with two Optic axes.*—In all crystals belonging to the remaining systems, viz., the trimetric, monoclinic, diclinic, and triclinic, there are two directions or axes in which an ordinary ray of light may pass without being split into two. Hence these crystals are called bi- or di-axial. The somewhat more complex phenomena which they exhibit are also completely explained by Fresnel's theory.

The elasticity of the ether in these crystals is of unequal magnitude in three directions at right angles to each other (the three axes of elasticity). If we call the modulus of greatest elasticity a^2 , of the middle b^2 , and of the least c^2 , and imagine lines drawn from the centre of the crystal in all directions, proportional to the square roots of the elasticities called into activity in these several directions, the ends of these lines will be situated on a surface, called the surface of elasticity, having three unequal axes, $2a$, $2b$, $2c$, at right angles to one another; and if plane waves be supposed to pass through the centre of this surface in all possible directions, as in the case of uniaxial crystals, each of these will cut the surface of elasticity in a closed curve. All vibrations in such a plane wave-surface are very quickly resolved in the direction of the greatest and least diameters of the plane section, which are perpendicular to one another; and the wave is divided into two which travel onwards parallel to each other, but with unequal velocities, proportional to the square roots of the elasticities which are set in action in the direction of those diameters. If all these plane waves are supposed to be set in motion at once, they will, after a given time, enclose the wave-surface of biaxial media.

Fig. 684 exhibits three sections of the wave-surface cutting one another at right angles. Of the two perpendicular to the plane of the figure, the vertical section contains an ellipse enveloped by a circle; the horizontal section, a circle enveloped by an ellipse; the section in the plane of the paper consists of an ellipse and a circle intersecting one another: they are represented separately in fig. 685. The circle in each section belongs to rays whose vibrations are perpendicular to the plane of that section, and therefore in the direction of an axis of elasticity: such rays suffer ordinary refraction. The ellipse, on the other hand, gives the velocity of transmission of the extraordinary rays, whose vibrations are parallel to the plane of the section. To obtain the three characteristic refractive indices of μ , μ' , μ'' of a biaxial crystal, three prisms must be cut, having their refracting angles respectively parallel to the three axes of elasticity, and the minimum deviation of the seven principal rays determined in each of them, for that one of the two coloured images, whose plane of polarisation is perpendicular to the refracting angle. This measurement has been very carefully performed by Rudberg for arragonite and topaz. Both the refractive indices, and the ratios between them, vary with the temperature in biaxial as well as in uniaxial crystals.

The ratios $\frac{\mu''}{\mu}$, $\frac{\mu'}{\mu}$, which express the strength of the double refraction, appear to increase in all crystals from the less to the more refrangible rays. In crystals of the trimetric system, the axes of elasticity have the same direction for all the coloured rays. The crystals of the mono-, di-, and tri-clinic systems appear to exhibit a different

behaviour in this respect. Their peculiarities will be considered in connection with the colours which they exhibit in polarised light (p. 669).

Fig. 684.

Fig. 685.

In two directions, ab and $a'b'$ (fig. 686) making equal angles with the axis of greatest,

and also with that of least elasticity, the surface of elasticity is cut in circles. At right angles to the planes of these circles, and therefore in the directions Cr , Cr' , a plane wave is propagated without being resolved into others, or altered as to its state of polarisation. These directions were designated by Fresnel, as the true optic axes of the crystal. But, as shown by fig. 685, there are likewise two directions in which the ordinary and extraordinary rays, which, therefore, belong to different waves, are transmitted with the same velocity. These directions, which unite the points of intersection P of the

ellipse and circle with the centre M , have received the name of apparent optic axes.

As may be seen from the figure, it depends upon the ratio of the mean velocity of transmission Mq to the greatest Mn and least Mo' , whether the apparent optic axes form a smaller angle with the axis of greatest elasticity and least velocity of transmission, or with that of least elasticity and greatest velocity of transmission. In the former case, the crystal approximates in its optical character to calc spar, and is therefore called optically negative (*e.g.* arragonite); in the latter, to rock-crystal, and is therefore called optically positive (*e.g.* topaz). The line which bisects the acute angle of the optic axes is the median line; that which bisects their obtuse angle, the supplemental line; and the line perpendicular to both of these is the normal. The last is always the axis of mean elasticity; the median line coincides with the axis of greatest elasticity in negative, and with that of least elasticity in positive crystals.

To find the rays belonging to a given plane wave-surface, planes must be drawn parallel to this plane and tangential to the wave-surface, and the points of contact joined with the centre. This construction always yields two tangent-planes, and therefore two rays. It is only when the wave-plane is perpendicular to one of the true optic axes, that the two tangent planes coincide in one, which, however, then touches the wave-surface in a circle. At the point P (fig. 685), the wave-surface forms funnel-shaped depressions or re-entering cones, the plane wave RS , which is perpendicular to the true optic axis MT , closing the funnel and touching the curved wave-surface in a circle having the diameter QT . To this wave-plane, therefore, correspond all rays proceeding from the centre M to the several points of the circumference of that circle. If, therefore, a ray of common light falls upon a plate of arragonite cut and polished at right angles to the median line, in such a direction that it would emerge in the direction of the true optic axis, it divides itself into a conical beam of rays, which, as they belong to the same wave-plane, proceed, after emerging, parallel to one another in a cylindrical beam. This phenomenon, the so-called cylindrical or inner

conical refraction, becomes perceptible only when the arragonite plate has a thickness of at least a centimetre.

Every line drawn from the centre to the surface of the wave, *e.g.* MT or MQ, cuts this surface in two points corresponding to the two rays which travel in this direction. The wave-planes belonging to these rays are found by drawing tangent-planes to the points of intersection with the upper wave-surface. It is only the ray MP, which travels in the direction of the apparent optic axis, that cuts the wave-surface in a single point only: at this point, however, the wave-surface has an infinite number of tangent planes; and, consequently, since the velocity of the wave-plane within the crystal determines the strength of the refraction, the ray MP yields an infinite number of refracted rays diverging from one another in a cone. This remarkable phenomenon, called external conical refraction, may be observed by covering the two parallel faces of a plate of arragonite cut perpendicular to the median line, with screens, each having a fine aperture so situated that the line joining the two apertures coincides with an apparent optic axis of the crystal. If a converging pencil of rays from a near source of light be directed on one face of the arragonite plate, a conically divergent pencil emerges from the other.

The polarisation phenomena of the two rays proceeding in any given direction are easily determined. If planes be made to pass through the ray and the two apparent optic axes, the direction of vibration of the one ray bisects the acute, and that of the other ray the obtuse angle of the two planes. The directions of vibration (and therefore also the planes of polarisation) of the two rays are therefore always perpendicular to one another.

If the three characteristic refractive indices, μ , μ' , μ'' , of a crystal are known, and $\mu'' > \mu' > \mu$, then, as Fresnel has shown, the angle 2β of the true optic axes may be calculated by the formulæ:

$$\begin{array}{ll} \text{For negative crystals.} & \text{For positive crystals.} \\ \sin^2 \beta = \frac{\mu^2}{\mu'^2} \cdot \frac{\mu''^2 - \mu^2}{\mu'^2 - \mu^2}; & \sin^2 \beta = \frac{\mu'^2}{\mu''^2} \cdot \frac{\mu^2 - \mu'^2}{\mu''^2 - \mu'^2}; \end{array}$$

and the angle 2α of the apparent optic axes by the formulæ:

$$\sin^2 \alpha = \frac{\mu''^2 - \mu'^2}{\mu'^2 - \mu^2}; \quad \sin^2 \alpha = \frac{\mu'^2 - \mu^2}{\mu''^2 - \mu^2}.$$

It will be seen that, in negative crystals, the apparent optic axes form a somewhat larger angle than the true optic axes, whereas in positive crystals the contrary is the case.

TABLE OF BIAXIAL CRYSTALS.

	Angle of axes.		Angle of axes.
Sulphate of nickel (certain specimens)	30° 0'	Sugar	50° 0'
Nitrate of potassium	5 20	Sulphate of strontium	50 0
Carbonate of strontium	6 56	Sulphohydrochlorate of magnesium and iron	51 16
Carbonate of barium	6 56	Sulphate of magnesium and ammonium	51 22
Talc	7 24	Phosphate of sodium	55 20
Sulphocarbonate of lead	10 35	Comptonite	56 6
Mother of pearl	11 28	Sulphate of calcium	60 0
Hydrate of barium	13 18	Nitrate of silver	62 16
Arragonite	18 18	Iolite	62 60
Cyanide of potassium	19 24	Felspar	63 0
Cymophane	27 51	Sulphate of potassium	67 0
Anhydrite	28 7	Carbonate of sodium	70 1
Borax	28 42	Acetate of lead	70 25
Apophyllite	35 8	Citric acid	70 29
Sulphate of magnesium	37 24	Tartrate of potassium	71 20
Sulphate of barium	37 42	Tartaric acid	79 0
Spermaceti (about)	37 40	Tartrate of potassium and sodium	80 0
Borax (native)	38 48	Carbonate of potassium	80 30
Nitrate of zinc	40 48	Cyanite	81 48
Stilbite	41 42	Chlorate of potassium	82 0
Sulphate of nickel	42 4	Epidote	84 19
Anhydrite (Biot)	44 41	Chloride of copper	84 30
Lepidolite	45 41	Peridote	87 56
Benzoate of ammonium	45 8	Succinic acid (about)	90 0
Sulphate of sodium and magnesium	46 49	Sulphate of iron (about)	90 0
Sulphate of ammonium	46 8	Mica	0° to 76 0
Topas	49° to 65 0		

It will be observed that topaz, and more especially mica, exhibit very different angles in different specimens. Sénarmont explains this anomaly by regarding these bodies as mixtures of two isomorphous substances, in which the planes of the axes are perpendicular to each other. He has shown, in fact, that a crystal formed by a mixture of two substances has its axes more or less inclined to one another, or situated in planes whose position varies by 90° from one specimen to another, according to the proportions of the mixture. In the case of mica, which, as Sénarmont has shown, crystallises in right prisms with rhombic base (trimetric), the plane of the axes is parallel, sometimes to the longer, sometimes to the shorter diagonal of the base. (Daguin, *Traité de Physique*, iv. 489.)

Reflection of Light from Double-refracting Media.—The reflection of light from the surface of double-refracting crystals follows, so far as regards the difference of phase of the two principal components polarised parallel and perpendicular to the plane of incidence, the same laws as those which are observed in reflection from isophanous media.

On the other hand, the alterations in the azimuth of polarisation depend, not only on the angle of incidence, but likewise on the inclination of the reflecting surface, and the plane of incidence to the axes of the crystal. Even when a polarised ray falls perpendicularly on a double-refracting surface, the azimuth of polarisation does not remain unaltered. In particular cases, however, no alteration takes place: for example, in uniaxial crystals, when the reflecting surface is perpendicular to the optic axis, or when the plane of incidence coincides with the principal section. For each relative position of the reflecting surface and the plane of incidence, there is always an angle of incidence at which the azimuth remains unaltered. It must also be observed, that when light is reflected within a double-refracting medium, each incident ray gives two reflected rays; that in uniaxial crystals, only one of the reflected rays remains constantly in the plane of incidence, whereas the other may deviate therefrom; and that in biaxial crystals, for the most part, neither of the two reflected rays remains in the plane of incidence.

Colours of Polarised Light.

Double-refracting substances viewed in polarised light often exhibit brilliant colours, the exact observation of which affords, in most cases, an easier method of determining the position of the axes of the crystal, than the mere separation of a ray of light into two, which is distinctly perceptible only when the double refraction is strong, and the crystal has a considerable thickness. Hence, the observation of these coloured phenomena is of great service in the study of crystalline structure.

Since the two rays into which an incident ray of common light is divided on entering a double-refracting medium travel through that medium with unequal velocities (p. 661), they will, on emerging from the medium, exhibit a certain difference of phase. As, however, the vibrations of the two rays always take place in planes at right angles to one another, they cannot interfere so as to produce any coloration or variation of intensity. Hence, the two images seen through a double-refracting crystal in ordinary light are colourless.

But the case is different when the crystalline plate is viewed in a polarising apparatus, say, between two tourmalines, or two Nicol's prisms, one serving as polariser, the other as analyser (p. 655). The rays which fall on this plate are then polarised by the action of the first prism or tourmaline, that is to say, their vibrations are reduced to one plane. If this plane is parallel to one of the directions of vibration in the double-refracting plate, they pass through it without further decomposition, so that only one ray—ordinary or extraordinary, as the case may be—passes through the plate. But if the direction of vibration CP (*Fig. 687*) of the polariser is inclined at 45° to the

Fig. 687.

two directions of vibration Co, Ce, of the double-refracting plate, two components, Co, Ce, of equal intensity are obtained. Suppose now that the difference of path of the two corresponding rays, after passing through the plate, is equal to an even number of half wave-lengths; the vibrations will then proceed simultaneously from C towards o and e; and if the direction of vibration, pq, of the analyser is at right angles to that of the polariser, Ps, the vibrations Co, Ce, will then yield two equal and opposite components, Cp, Cq, which will destroy one another. Consequently, if the incident light is monochromatic, the field of view, in this position of the analyser, will be dark. If, on the other hand, the polariser and analyser are placed with their axes parallel, so that pq coincides with CP, the components of Co and Ce will both lie in the direction Cr, and will strengthen one another, so that the field will be light.

If the difference of path of the ordinary and extraordinary rays is equal to an uneven number of half wave-lengths, the vibrations will proceed from C simultaneously in the

directions Co and Ce' ; consequently, the phenomena just described will be exactly reversed, the field being dark when the axes of the two tourmalines or Nicol's prisms are parallel, and light when they are crossed.

When the incident light is white, it is only particular coloured rays that destroy each other completely, or strengthen one another's effect in the greatest degree; consequently, the field is never dark, but the double-refracting plate appears coloured, the colours varying according to the thickness of the plate; and for any particular thickness, being complementary to one another in the two relative positions of the polariser and analyser. When a double-refracting prism (p. 655) is used as analyser, two images are seen, the colours of which are complementary to one another; and if they are large enough to intersect, the overlapping portion is white.

When a thin wedge-shaped plate of a double-refracting crystal—gypsum, for example—is placed between the crossed Nicol's prisms or tourmalines, a series of coloured stripes is observed following exactly the order of colours of Newton's rings (p. 646). In the thinnest part, the wedge is colourless, because there the difference of path of o and e is only a small fraction of the wave-lengths of all the coloured rays. At a somewhat greater thickness, the violet and blue rays disappear first, and the colour passes through yellowish white and orange into red of the first order. Beyond this point the yellow and red rays disappear, and a blue stripe is produced, and so on. When the thickness is so great that the difference in length of path of o and e amounts to a multiple of the wave-lengths of a great number of rays diffused through the entire spectrum, the remaining rays together produce white light: hence plates of double-refracting substances, above a certain thickness, no longer appear coloured in polarised light. If, however, the white light which has passed through such a plate be decomposed by a prism, the resulting spectrum is seen to be traversed by a great number of black lines.

When the tourmalines or Nicol's prisms are placed with their axes parallel, the colours produced are complementary to those above described; hence it is clear that unpolarised light can never produce any colours in double-refracting plates, inasmuch as it consists of vibrations in all possible azimuths, so that the colour produced by any particular set of vibrations is exactly compensated by the complementary colour of another set at right angles to the first, the two together reproducing white light.

A thin film of gypsum in which a circular cavity of very long radius is made, exhibits in polarised light a series of coloured rings exactly similar to Newton's rings.

The order of the colour of any crystalline plate in polarised light may be determined by laying it over the above-described wedge, in such a manner that the o of the plate may coincide in its direction of vibration with the e of the wedge. At the place where the plate and wedge give equal differences of path, their actions compensate one another, so that a black stripe is seen with the tourmalines crossed, and a white stripe if they are parallel. The order of the colour may then be read off on the wedge.

We have hitherto supposed the plate to be placed at right angles to the rays. On gradually inclining it, the colours change—first, because the rays have then to pass through a greater thickness of the plate; secondly, because the angle which the rays form with the axis or axes of the crystal also varies, and this circumstance likewise affects the difference of path corresponding to a given thickness of the crystal.

Coloured Rings.—A plate of a double-refracting crystal cut perpendicularly to the axis does not exhibit the colours above described when viewed by parallel rays, because, in the direction of the axis, the two rays o and e have equal velocities, or, in other words, are reduced to one ray. But, when diverging light, proceeding from a luminous point at a short distance, is made to pass through the crystalline plate placed between two tourmalines, or when the analysing tourmaline is placed so close to the eye that the visual rays converge strongly towards the optic centre of the eye, brilliantly-coloured rings are produced, the form of which differs according as the crystalline plate is uniaxial or biaxial. Fig. 688.

A simple apparatus for viewing these phenomena consists of two plates of tourmaline capable of rotating in their own planes in two rings, or sockets, a, b (fig. 688), fixed to the end of a spring, c , so that the crystalline plate, attached to a piece of cork, may be firmly held between them, but still be capable of turning round in its own plane.

A plate of a uniaxial crystal, such as calc spar, cut with parallel faces perpendicular to the optic axis, exhibits, when viewed between the crossed tourmalines, a series of circular coloured rings, intersected by a black cross (fig. 689). If, on the other hand, the tourmalines are placed with their axes parallel, the cross is white, as in fig. 690, and the colours are complementary to the former. To understand their formation, it is merely necessary to remember that, in the direction of the axis be (fig. 690), the rays o and e have equal velocities, but that their difference of

path becomes greater and greater in proportion as they are more inclined to the axis because, in the first place, the difference of velocity of the two rays then becomes con-

Fig. 689.

Fig. 690.

usually greater; and, secondly, because the thickness of the plate which has to be traversed by the rays increases at the same time. The colours which, in the wedge above described (p. 667), are arranged parallel to the edge are, in this case, grouped in concentric circles round the axis, the order of the tints being again that of Newton's rings.

The vibrations parallel and perpendicular to the axis of the second tourmaline not being resolved into two components, there can be no interference along lines passing through the centre of the field in those directions. Hence the appearance of the black cross when the tourmalines are crossed, and of the white one when their axes are parallel.

The rings are closer together in proportion as the double refraction is stronger, and the thickness of the plate greater.

The colours of the rings change, to a certain extent, according to the relative amount of double refraction for the different coloured rays. A very peculiar character, in this respect, is exhibited by apophyllite, which, as already observed, is positive for the blue, and negative for the red rays.

A plate of a biaxial crystal, cut at right angles to the median line, and placed between two tourmalines, in such a manner that the plane of the optic axes is parallel to the axis of one of the tourmalines, exhibits, when the tourmalines are crossed, the system of rings delineated in *fig. 691*. The mode of formation of the black cross is the same as that above explained with regard to uniaxial crystals. But, as the difference of path of the rays o and e increases with their inclination to both the optic axes, the rings of colour embrace both these axes. The form of these rings is nearly that of the lemniscate, a curve distinguished by the property that the product of any two radii vectores, drawn from the two poles to any point of the curve, is a constant quantity. On turning the double-refracting plate round in its own plane, the whole system of rings turns round in the same direction, and the black cross separates into two branches, presenting

Fig. 691.

Fig. 692.

Fig. 693.

the appearance shown in *fig. 692*; and when the plane of the axes makes an angle of 45° with the axes of the two tourmalines, the two black bands form branches of hyperbolae, as in *fig. 693*. The general direction of the branches of the black bands is always parallel or perpendicular to the plane of primitive polarisation. On continuing the rotation of the plate from 45° to 90° , the same appearances are presented in the reverse order, and the whole series of changes is repeated in each of the four quadrants.

When the polariser and analyser are placed with their axes parallel, the form of the curves and of the cross are exactly the same as above, but the colours are complementary and the cross is white.

The preceding figures represent the appearance in crystals, such as nitre, which have their optic axes inclined at a small angle not exceeding 5° or 6° ; when the axes are more inclined, only half the figure can be seen at once.

Fig. 694 shows the appearance of the rings formed by a biaxial crystal cut perpendicularly to one of its optic axes.

The distribution of the colours in the neighbourhood of the axes shows plainly whether the angle of inclination of the axes increases or diminishes from the violet to the red rays. The former is the case in tartrate of potassium, the latter in nitrate of potassium. In crystals of the monoclinic, as also of the di- and tri-clinic systems, even the direction of the axes of elasticity is different for the different coloured rays: thus in gypsum, diopside, and cupric formate, the position of the median line varies according to the colour. In borax, adularia, tartaric acid, and acetate of sodium, the different colours have the same median line, but differently directed ordinates, so that the planes of their axes vary with the refrangibility of the light.

The optical phenomena exhibited by many biaxial crystals are altered in a very remarkable manner by change of temperature. Glauberite, for example, is uniaxial at ordinary temperatures for violet light, but biaxial for all other colours. At lower temperatures, the violet axis also splits into two, and the angles between the axes of the other rays increase. When, on the other hand, the temperature is raised, the violet axis becomes divided in a plane at right angles to the former; the axial angles of the other colours diminish, become nothing, and then likewise pass into the perpendicular plane, in which they are all situated together, even before the temperature rises as high as the boiling point of water.

Determination of the Axes.—The form of the curves, and of the dark bands which cross them, afford the best means of determining the position of the axes in biaxial crystals. To find the position of the plane of the optic axes, the crystal, cut in the form of a plate with parallel faces, is placed between a polariser and analyser with their planes of polarisation crossed, so as to produce darkness, and the plate is turned round in its own plane till its presence does not restore the light. Two positions are thus found, for which the traces of the primitive plane of polarisation are to be marked on the crystalline plate. These two traces form a right angle, and one of them is situated in the plane of the axes. The plate is then turned round in its own plane, till each of the traces makes an angle of 45° with the primitive plane of polarisation; then, by inclining it successively round those traces, a position is sought in which the rings can be seen surrounding the axes. The plane of the axes is perpendicular to the line round which the plane has been turned to discover the rings.

Measurement of the Angle between the Axes.—The most convenient apparatus for this purpose, and for all exact measurements of the coloured rings, is that of Soleil, represented in fig. 695.

A beam of light, polarised by reflection from the mirror V, which may be placed at any required inclination by means of the joint o , passes through a lens l , and is brought to a focus on the crystalline plate c , where the rays cross each other and issue in diverging cones. They then pass through an eyepiece, l' , l'' , forming at ff , the focus of the lens l , an image of the curves produced by the plate c , and this image is viewed through the lens l' and the analyser a . At ff is placed a micrometer, m , represented separately at M. It has three wires, two parallel to one another, perpendicular to the third, and capable of being brought together or separated by a screw, one part of which is right-handed, and the other left-handed. The plate c is held by a socket capable of turning on a horizontal axis, its rotation being measured by a divided screw-head, n , and a vernier which is read off by the magnifier v . The support of the socket is also capable of turning on o , so that the crystalline plate c may be placed in any required position.

Fig. 694.

Fig. 695.

To measure the angle between the axes, it is best to use homogeneous light. The crystalline plate *c*, cut nearly at right angles to the median line, is fixed in the socket in such a position that the plane of its axes may be vertical, and the socket is turned round in its own plane, so as to bring each of the poles successively to coincide with the intersection of the wires of the micrometer. The arc through which the screw is turned between the two positions gives the observed angle $2\alpha'$ between the apparent optic axes (p. 664). From this the real angle between these axes is calculated by the equation $\sin \alpha' = \mu' \sin \alpha$, in which μ' is the middle of the three characteristic refractive indices for the coloured ray observed.

Soleil's apparatus serves also to measure the diameters of the rings; the micrometer being capable of turning round on itself, the diameters can easily be measured in any required direction.

Double-refracting structure produced by Molecular Tension.—Glass, gelatin, and other amorphous bodies, also crystals belonging to the regular system, acquire the double-refracting structure, when pressed, stretched, or heated unequally in different parts, and exhibit, when examined by polarised light, coloured bands similar to those produced by double-refracting crystals. A rectangular plate of glass laid edge-ways on a very hot iron plate, exhibits, when examined in a polarising apparatus, a series of coloured bands parallel to its edges, these bands altering their arrangements as the heat is gradually conducted across the plate, and disappearing altogether when it becomes uniformly heated all over. A similar effect is produced by placing the glass in the same manner on a plate of metal cooled by a freezing mixture, or by subjecting it to lateral compression.

These effects are, however, most strikingly exhibited by unannealed glass—that is to say, glass which has been heated and quickly cooled. Glass thus treated has an irregular structure, the parts near the surface having been more quickly cooled than the interior parts, and torn away from them, as it were, by the sudden contraction in cooling. In consequence of this irregularity of structure, the glass produces double refraction on all rays which traverse it, but in different degrees in its different parts, whence there results a variable coloration when the glass is viewed by polarised light. The figures produced exhibit a symmetry depending on that of the contour of the plate. A circular plate of unannealed glass, the structure of which is symmetrical round the axis, acts like a uniaxial crystal, exhibiting concentric rings, intersected by a black or white cross, according to the relative positions of the polariser and analyser. If the structure is not quite symmetrical round the axis, the rings and cross are distorted. A square plate exhibits a cross with coloured fringes in the angles. An elliptical plate exhibits a figure resembling those of biaxial crystals.

Absorption of Light by Double-refracting Crystals. Dichroïsm.

Certain coloured double-refracting crystals, when traversed by ordinary white light, exhibit different colours according to the direction of the rays with regard to their axes; thus dichroïte or iolite (ii. 320) appears of a yellowish white colour inclining to brown, or of a fine azure blue, according as the rays traverse it parallel or perpendicular to the axis; in like manner, chloride of palladium and potassium exhibits either a dark-brown, or a fine green colour; some varieties of sapphire are blue or yellowish green. Some green tourmalines appear dark brown-red when viewed along the axis.

This effect is due to the property possessed by double-refracting media, of absorbing polarised rays in different proportions according to the inclination of those rays with regard to their axes. The tourmaline absorbs completely all rays polarised in a plane parallel to its axis, and transmits them in greater and greater proportion as this axis is inclined to the plane of polarisation; moreover it absorbs all the simple rays composing white light in the same proportion, consequently the transmitted light remains always of the same colour, excepting in the case of the green tourmalines above mentioned. But when the absorption-coefficients of the several simple rays vary in different proportions with the change of direction of the rays in the crystal, the tint formed by the mixture of the unabsorbed rays likewise varies with their inclination to the axis.

Some biaxial crystals exhibit trichroïsm; thus certain Brazilian topazes of a yellowish rose tint in the direction of the median line, are violet when viewed along the complementary line, and yellowish white perpendicular to the plane of the axes.

Babinet has observed that, of the two rays into which an incident ray is divided on entering a uniaxial crystal, that which travels most slowly and is therefore most refracted, is also absorbed in the largest proportion; in positive crystals therefore, such as tourmaline, it is the ordinary, and in negative crystals, like smoky quartz, it is the extraordinary ray which is most absorbed. This law, true in the greater number of cases, nevertheless admits of numerous exceptions. Thus, Haidinger observed that

the order of absorption is different in the blue and yellow varieties of beryl, although both are negative. Beer observed that acid chromate of potassium, cyanite, and certain varieties of topaz also form exceptions to the rule; and that idocrase and cupric acetate, which follow the law as regards the blue rays, deviate from it as regards the yellow, orange, and red.

Hagen has demonstrated the following laws regarding the absorption of light by double-refracting crystals.

1. The general law of the decrease of intensity in geometric progression as the thicknesses increase in arithmetic progression (p. 636), holds good for double-refracting, as well as for isophanous media, so that the ratio $o : e$ likewise varies according to the same law.

2. The ratio $o : e$ is a continuous function of λ , exhibiting, in all the crystals observed, a maximum and a minimum.

3. The variations of $o : e$ are equal on either side of the maximum or the minimum; so that if the maximum or minimum occurs at a particular wave-length λ' , the values of $o : e$ for $\lambda' + n$ and $\lambda' - n$ are equal.

4. The absolute value and the position of the maximum and minimum depend upon the direction of the plate with regard to the axes of the crystal.

5. From the mode of variation of the function $o : e$, it is probable that in crystals, which form exceptions to Babinet's law, the exception applies only to certain rays of the spectrum.

Circular Polarisation.

It has already been pointed out (p. 658), that when two rays of light travelling along the same path are polarised in planes at right angles to each other, and differ in phase by a quarter of a wave-length, then if the amplitudes of vibration of the two are equal, the molecules of the resultant wave vibrate in circles transversely to the direction of the ray. In this state the ray is said to be circularly polarised, and the phenomena which it exhibits are the same as if the ray were polarised in one plane, and that plane were made to rotate round the direction of the ray as an axis.

Circular polarisation is exhibited in a remarkable manner by quartz, in which it was first discovered. A plate of this substance (which is uniaxial) cut at right angles to the optic axis, exhibits when viewed between two tourmalines or Nicol's prisms with their axes crossed, a system of coloured rings similar to those produced by calcispar (p. 668); but the centre of the field of view, instead of exhibiting a black cross, is illuminated with brilliant colours, red, yellow, green, blue, &c., according to the thickness of the plate. On turning the analyser on its axis, the colours in the centre go through the regular prismatic series from red to violet, or the contrary, according to the direction of rotation, but no alteration of colour is produced by rotating the plate of quartz while the analyser remains stationary.

To understand these phenomena, we must examine what takes place when homogeneous light is used. Suppose, then, a plate of dark red glass coloured with red oxide of copper to be interposed between the two tourmalines or Nicol's prisms, crossed as before, so that no light is transmitted by the analyser. If the plate of quartz be now interposed, a red light immediately makes its appearance, and to render the field again dark, it is necessary to turn the analyser through a certain angle, either to the right or to the left. Hence it follows that the ray which has traversed the quartz must have had its plane of vibration deflected through an angle equal to that through which the analyser has been moved.

Precisely similar effects are produced with yellow, green, violet, or any other kind of homogeneous light; but the angle of rotation varies according to the nature of the ray, being least for red and greatest for violet light.

Colours.	Angle of rotation.	
	Plate 1 mm. thick.	Plate 375 mm. thick.
Medium red	15°	56½°
" orange	19	71½
" yellow	24	90
" green	27	101½
" blue	32	120
" indigo	38	142½
" violet	44	165

Some crystals of quartz rotate the plane of polarisation of a ray to the right, others to the left; the former are called right-handed, the latter left-handed quartz. But in whichever direction the rotation takes place, a plate of quartz of given thickness always produces the same amount of angular deviation for a ray of given refrangibility; and for plates of different thickness the deviation for any particular ray increases in direct proportion to the thickness. The preceding table gives the angles of deviation for the principal rays of the spectrum produced by plates of quartz of the thickness of 1 millimetre and 3.75 millimetres.

Biot found by observation that the angles of rotation for the different simple colours are nearly proportional to the squares of the indices of refraction, or inversely as the squares of the wave-lengths. This law is approximately true also for most substances which exhibit circular polarisation, while some, on the other hand, exhibit remarkable deviations from it: thus an aqueous solution of tartaric acid deflects the green rays more than the violet; and an alcoholic solution of camphor, though it deflects the several coloured rays in the order of their refrangibility, produces a much greater difference of deviation between the less and the more refrangible rays than that which is indicated by Biot's law.

We can now explain the succession of colours produced when ordinary daylight is used. Suppose a beam of white light, polarised by a Nicol's prism, whose principal action is parallel to AA' (fig. 696), to pass through a plate of right-handed quartz.

Fig. 696.

3.75 mm. thick. The vibrations of the several coloured rays composing the beam of polarised light are all at first parallel to AA' ; but by passing through the quartz, their planes of vibration are deflected through the several angles given in the above table, the red ray then vibrating in the line rr' , the yellow in yy' , the violet in vv' , &c. Now, let the ray be viewed through another Nicol's prism, placed with its principal section also parallel to AA' ; then on resolving each of these vibrations into two others, one parallel and the other perpendicular to AA' , it will be seen that the red and violet rays will be transmitted with but slightly diminished intensity, the orange and blue with less, the yellow still less, and the green not at all. The result will, therefore, be a purple tint. Now let the eye-piece be turned from left to right. As the principal section passes successively over the lines rr' , oo' , &c., the red, orange, yellow, &c., will, in succession, be more fully transmitted than the other rays, so that a series of tints will be produced, agreeing nearly

with the colours of the spectrum and following in the same order, from red through yellow to violet. If the analyser be turned the contrary way, the order of the tints will be reversed. If the quartz were left-handed, the phenomena would be precisely similar, excepting that the colours would change from red through yellow to violet when the analyser was turned from right to left.

Similar changes of colour are produced with a plate of quartz of any other thickness; but the tint produced at any given inclination of the polariser and eye-piece is, of course, different.

The tint produced with a quartz-plate 3.75 mm. thick, when the principal sections of the polariser and analyser are parallel to one another, deserves particular notice. As already observed, it is a purple, and, moreover, it changes very quickly to red or to violet, when the analyser is turned one way or the other, the change of colour thus produced being, in fact, very much more rapid and decided than in any other part of the circuit. This peculiar tint is accordingly distinguished by the term sensitive tint, or transition tint (*couleur sensible, teinte de passage*). On account of the facility and certainty with which it may be recognised, it is frequently adopted as the standard tint in measuring the angles of rotation produced by different substances; it is, in fact, much easier to determine when this particular colour makes its appearance, than to seize the exact moment when a ray of red, yellow, or other homogeneous light completely disappears.

The rotatory power of quartz is essentially related to its crystalline form, as will be more fully explained hereafter. It is not exhibited by opal, or any other amorphous variety of silica, or by silica dissolved in potash, or fused by the oxyhydrogen blowpipe. The same is true with regard to a few metallic salts possessing the rotatory power, viz. chlorate of sodium, bromate of sodium, and sodio-uranic acetate, these salts exhibiting that power only when crystallised, not in solution.

Circular polarisation in organic bodies.—The power of rotating the plane of vibra-

tion of a polarised ray is much more widely diffused among organic than among inorganic bodies; moreover, organic substances possess it in the liquid, as well as in the crystalline state. Among organic compounds which rotate the plane of polarisation to the right, may be mentioned: Cane-sugar, glucose, diabetic sugar, milk-sugar, dextrin, camphor, asparagin, cinchonine, quinine, narcotine, tartaric acid, camphoric acid, aspartic acid, oil of lemons, castor-oil, croton-oil. The following rotate to the left: Sugar of fruits, starch, albumin, amygdalin, quinine, nicotine, strychnine, brucine, morphine, codeine, malic acid, antitartaric acid, oil of turpentine, oil of valerian.

By passing a polarised ray through tubes of different lengths, filled with the same solution of cane-sugar, or other rotatory substance, it is found that the angle of deviation is proportional to the length of the column of liquid; and, by filling the same tube with solutions containing different quantities of sugar, &c., it is found that the angle of deviation is proportional to the quantity of the substance contained in a column of given length. Generally, then, the angle of deviation is proportionate to the number of active particles which the light has to pass.

If, then, ϵ be the quantity of active substance contained in a unit of weight of the solution, l the length of the column, and α the observed angle of rotation for a particular tint—the transition-tint, for example,—the angle of rotation for the unit of length, supposing the entire column to be filled with the optically active substance, will be $\frac{\alpha}{\epsilon l}$. But as the solution of a substance is often attended with condensation

of volume, it is best, in order to obtain a measure of the rotatory power, independent of such irregularities, to refer the observed angle of deviation to a hypothetical unit of density, that is to say, to divide the quantity $\frac{\alpha}{\epsilon l}$ by the density, δ , of the solution.

The fraction thus obtained, viz. $[\alpha] = \frac{\alpha}{\epsilon l \delta}$, is called the specific rotatory power, and expresses the angle of rotation which the pure substance, in a column of the unit of length and density = 1, would impart to the ray corresponding to the transition-tint. For example, a solution containing 155 milligrammes of cane-sugar in a gramme of liquid, has a specific gravity = 1.06, and deflects the transition-tint by 24° , in a column 20 centimetres long; its specific rotatory power is therefore

$$[\alpha] = \frac{24}{0.155 \cdot 20 \cdot 1.06} = 7.3^\circ.$$

The apparatus used for measuring the rotatory power of liquids consists of a glass tube, surrounded with a case of wood or brass, and closed at both ends with plate-glass discs ground to fit water-tight, and pressed against the tube by means of screw-caps. The tube, being completely filled with the liquid, is placed on the supports, between two Nicol's prisms, one of which serves as polariser, the other as analyser. The latter carries a vernier moving round a graduated circle. The simplest way of using this apparatus is to interpose between the tube and the polariser a glass coloured with red oxide of copper, the tint of which corresponds with the red of the fixed line C of the spectrum, and, having set the analyser with its principal section at right angles to that of the polariser (which makes the field of view dark so long as the tube is not interposed), adjust the tube in its place, and turn the eye-piece round till the red light completely disappears. The angle through which the eye-piece is turned measures the deviation produced by the liquid.

The direct measurement of the rotation of the red ray is not, however, always the best mode of observation, because, as already observed (p. 672), it is difficult to tell with precision when the light completely disappears. For this purpose, there is introduced behind the polarising prism, instead of the red glass, a plate of quartz 3.75 millimetres thick, which, when the polariser and analyser are set with their principal sections parallel, exhibits the transition-tint. The interposition of the circularly polarising liquid causes this tint to change, and the rotation is measured by the number of degrees through which the prism must be turned to show the transition-tint.

Greater exactness is obtained by using a double plate of quartz 3.75 millimetres thick, one-half being composed of right-handed, the other of left-handed quartz. Such a plate exhibits the transition-tint with perfect uniformity on both halves, when the polariser and analyser are set with their principal sections parallel; but on turning the analyser to the right, one-half of the plate inclines to red, and the other to blue. The same change will, of course, take place on introducing the tube containing the circularly polarising liquid; and to restore the uniformity of tint, the analyser must be turned a certain number of degrees the contrary way. If the liquid has but a slight rotatory power, this method is quite satisfactory; but if the rotatory power is considerable, an

error may arise from the different angles of rotation imparted to the different-coloured rays.

To obviate this source of inaccuracy, a contrivance called the compensator has been invented by Soleil, which, together with the other parts of his apparatus—called a saccharimeter, being especially adapted to the estimation of the strength of saccharine solutions—is represented in *fig. 697*. The tube *T*, containing the saccharine

solution, or other liquid to be examined, is placed between two perforated diaphragms, one of which, *D*, is fixed, while the other, *D'*, can be removed at pleasure to a greater distance from *D*, towards which it is again pressed by a spring, shown in section at *p*: this arrangement keeps the tube in position, and facilitates its adjustment. The incident light is polarised by the achromatised calc-spar prism *n*, one image of which is intercepted by a screen. At *p* is a double plate of quartz, 3.75 millimetres thick, a front view of which is shown at *g d*—one-half, *d*, being dextro-, and the other half, *g*, laevo-rotatory. The light having traversed this double quartz-plate and then

the tube *T*, arrives at a quartz-plate, *q*, cut perpendicularly to its axis, then passes through the compensator, *r*, is analysed by the double-refracting prism, *a*, and is finally viewed through the small telescope, *L L*.

RR' is a horizontal section of the compensator, consisting of two quartz prisms perpendicular to the axis, and of contrary rotation to the plate *g*. These prisms can slide one over the other horizontally, and in contrary directions, so as to vary the thickness which the modified light has to traverse. They are set in motion by a toothed pinion fixed to the button *b*, and acting on two racks adapted to the lower part of the mounting of the prisms. One of these mountings carries an ivory scale, *c*, represented separately at *E*; the other, a vernier, which slides along the scale, and serves to measure the opposite displacements of the two prisms. When the zeros of the scale and vernier coincide, the two prisms are opposite to one another, and their thicknesses are together equal to that of the plate *g*, the rotatory power of which is therefore neutralised by them. The analyser may then be turned by means of the endless screw, *v*, into such a position, that the two halves of the double quartz-plate, *g d*, may exhibit the sensitive tint. If the tube *T*, containing the liquid, be then put in its place, the two halves, *g d*, will then exhibit very different colours; and to restore them to equality the compensator, *r*, must be so adjusted as to produce, together with the plate *g*, an inversion opposite to that of the liquid, either by increasing the thickness of the double prism, *r*, or diminishing it, so as to allow the action of the plate *g* to predominate. The direction in which the vernier is moved along the rule, which is marked with two series of divisions on opposite sides of the zero point, indicates the direction of the rotation exerted by the liquid, and the displacement of the vernier gives the angle of deviation when the thickness of quartz corresponding to one division of the scale is known. These divisions are usually made to correspond with the tenth of a millimetre; the vernier indicates the tenth of these, so that the estimation may be made to the hundredth of a millimetre. The half of this quantity suffices to produce an appreciable difference of tint in the two halves of the double quartz-plate.

When either the light, or the liquid in the tube, is coloured, this colour, added to that produced by the polarisation, modifies the sensitive tint, and diminishes the accuracy of the observation. To neutralise this colour, Soleil places at the extremity, *K*, of the instrument, a double-refracting prism, *n*, and a quartz-plate, *i*, fixed in a socket, which can be turned round in its own plane by means of a toothed wheel or pinion, *t*, and the button *B*. This plate is interposed between the two prisms *n* and *c*, the second of which acts as analyser, and yields a colour which may be varied by turning the prism *n*, so that a position of this prism may be found which gives a tint capable of sensibly neutralising that of the liquid, or of the light employed.

As the apparatus above described requires the observation of the transition-tint, its

results are exact only when applied to liquids which disperse polarised light according to the same law. Now Biot has shown that this is the case with saccharine solutions, to which, indeed, Soleil's apparatus is especially adapted; but with other liquids, such as aqueous tartaric acid, whose rotatory power for the different coloured rays does not follow Biot's law (p. 672), the observation of the transition-tint does not give good results. With such liquids it is best to resort to the simpler mode of observation previously described (p. 673), using homogeneous light.

Relation between Optical Rotatory power and Crystalline form.—Circular polarisation appears to depend on a certain want of symmetry in the molecules of the medium through which the rays pass: in fact, all crystals which exhibit circular polarisation are hemihedral or tetartohedral. This is remarkably the case with quartz, which is a combination of the opposite rhombohedrons + R and - R with the hexagonal prism ∞R , some varieties of it exhibiting hemihedral and tetartohedral combinations (CRYSTALLOGRAPHY, ii. 143, fig. 258). Moreover the six faces y ($6P_2^y$), which are unequally inclined to those of the prism, are not always placed alike, occurring in some crystals on the right of a prismatic face above, and on the left below, and the contrary in others, as shown in figs. 698, 699. The two forms of crystal thus produced, though their faces are alike in number and in form, are not superposable, but one may be regarded as the reflected image of the other. The crystals of the one kind exhibit dextro-rotatory, those of the other lævo-rotatory power. The same kind of opposite tetartohedry, accompanied by a corresponding opposition of optical rotatory power, is found also in other bodies which exhibit circular polarisation.

Fig. 698.

Fig. 699.

Tartaric acid and its salts turn the plane of polarisation to the right; racemic acid, which is identical in chemical composition with tartaric acid, and agrees with it in nearly all its chemical relations, has no action whatever on polarised light, either in the free state, or when combined with bases. Now, the crystals of tartaric acid and the tartrates are hemihedral; those of racemic acid and the racemates, with one exception, are holohedral. The exception alluded to is the racemate of sodium and ammonium. A solution of racemate of sodium and racemate of ammonium, in equivalent proportions, yields by evaporation, crystals of a double salt, the form of which is represented in figs. 700, 701.

It is a right rectangular prism, P, M, T, having its lateral edges replaced by the faces h , and the intersection of these latter faces, with the face T, replaced by a face b . If the crystal were holohedral, there would be eight of these faces, four above, and four below; but, as the figures show, there are but four of them, placed alternately: moreover, these hemihedral faces occupy in different crystals, not similar, but opposite positions; so that, as in the case of quartz, the one kind of crystal is, as it were, the reflected image of the other.

Fig. 700.

Fig. 701.

But further; by carefully picking out the two kinds of crystals, and dissolving them separately in water, solutions are obtained which, at the same degree of concentration, exert equal and opposite actions upon polarised light, the one deflecting the plane of polarisation to the right, the other, by an equal amount, to the left. Moreover, the solutions of the right and left-handed crystals, yield by evaporation, crystals, each of its own kind only; and by mixing the solutions of these crystals with chloride of calcium, calcium-salts are obtained, which, when decomposed by sulphuric acid, yield acids, agreeing with each other in composition, and in every other respect, except that their crystalline forms exhibit opposite hemihedral modifications, and their solutions, when reduced to the same degree of concentration, exhibit equal and opposite effects on polarised light.

Of the two acids thus obtained, the one which turns the plane of polarisation to the right is identical in every respect with ordinary tartaric acid; the other is called anti-tartaric acid. The two acids are also distinguished as dextro- and lævo-racemic, dextro- and lævo-tartaric acid. When equal weights of these two acids are dissolved in water, and the solutions mixed, a liquid is obtained, which has no action whatever on polarised light, and yields by evaporation, holohedral crystals of racemic acid. A similar result is obtained by mixing equal quantities of any of the salts of the two acids, excepting the double salt of sodium and ammonium.

Hence it appears that racemic acid, a body which has no action upon polarised light, and crystallises in holohedral forms, is a compound of two acids (tartaric and antitartaric), which have equal and opposite effects on polarised light, and crystallise in similar but opposite hemihedral forms. These acids differ also in their pyro-electric relations. The crystals of both become electric when heated, but the corresponding extremities of the two exhibit opposite electrical states. Racemic acid is not pyro-electric.

Tartaric acid may be converted into racemic acid by the action of heat, provided only it be associated with some substance which will enable it to bear a somewhat high temperature without decomposing. There are many substances whose effect on polarised light is altered by heat. This is remarkably the case with the alkaloids of cinchona bark. When cinchonine, or any of its salts (which rotate to the right), is heated in such a manner as not to produce decomposition, it is transformed into an isomeric alkaloid, cinchonidine, which turns the plane of polarisation to the left. Similarly, quinine, which rotates the plane of polarisation to the left, is converted by heat into quinidine, which turns it to the right. Now, when tartrate of cinchonine is heated, it is first converted into tartrate of cinchonidine, and if the heat be then continued, the change extends to the tartaric acid, half of which is converted into anti-tartaric acid. If the process be stopped at a certain point, and the fused mass treated with water, a solution is obtained which yields, first, crystals of antitartrate, and afterwards, of tartrate of cinchonidine. But if the heat be longer continued, the two acids unite, and form racemate of cinchonidine, from which racemic acid may be prepared, identical in every respect with ordinary racemic acid, and separable by the same means into the two opposite tartaric acids.

But, what is very remarkable, there is formed at the same time a modification of tartaric acid, which has no action whatever on polarised light, and yet is not separable into the two opposite acids. In fact, when the fused mass obtained by heating tartrate of cinchonine is treated with water, and chloride of calcium added, a precipitate is formed, consisting of racemate of calcium, and the filtrate, if left at rest, deposits crystals of the calcium-salt of inactive tartaric acid.

There are other organic compounds, which are also optically active in their ordinary forms, but exhibit inactive and inseparable modifications. Malic acid, as it exists in fruits, turns the plane of polarisation to the right; so likewise does aspartic acid, obtained by the action of acids and alkalis on asparagin. Now, both these acids may be formed from fumaric acid, an optically inactive substance. Acid fumarate of ammonium is $\text{C}^{\text{H}}(\text{NH}^+\text{O}^-) = \text{C}^{\text{H}}\text{NO}^+$, which is also the formula of aspartic acid, and this acid is actually formed by heating the acid fumarate of ammonium. But the aspartic acid thus produced is, like fumaric acid, optically inactive. Again, aspartic acid is converted into malic acid by the action of nitrous acid:

Both active and inactive aspartic acids undergo this transformation; but active aspartic acid yields active malic acid, and inactive aspartic acid yields inactive malic acid. Neither inactive aspartic nor inactive malic acid can be separated into two acids oppositely active.

Common oil of turpentine possesses considerable dextro-rotatory power; but the isomeric substance obtained by heating the artificial solid camphor of turpentine with quicklime is optically inactive.

Fusel oil has been shown by Pasteur to be a mixture of two kinds of amylic alcohol, which differ slightly in boiling point. One of these acids is optically active, the other inactive.

Circular Polarisation induced by Magnetic action.—Faraday, in 1845, made the important discovery, that bodies which, in their ordinary state, exert no particular action on polarised light, acquire the power of circular polarisation, when subjected to the influence of powerful electric or magnetic forces. A polarised ray passing along the axis of a prism or cylinder of a transparent substance, such as water or glass, has its plane of polarisation deflected to the right or left, as soon as the medium is subjected to the action of an electric current passing round it at right angles to the ray, or to that of two opposite magnetic poles (permanent or electro-magnetic), so placed

that their line of junction coincides with the direction of the ray. The rotation ceases as soon as the electric or magnetic force ceases to act; its amount varies directly as the strength of the current, and its direction changes with that of the current or of the magnetic force. If the medium has a rotatory power of its own, the total effect is equal to the sum or difference of the natural and induced rotations, according as the electric or magnetic force acts with or against the natural rotatory power of the medium. (Faraday, Phil. Trans. 1846, p. 1.)

These remarkable phenomena, which led to the discovery of the universality of magnetic action, have since been followed out in greater detail by Pouillet, E. Becquerel, Wiedemann, Matthiessen, Verdet, and others.

Verdet (Ann. Ch. Phys. [3] xli. 370; xliii. 37) has confirmed Faraday's result relating to the proportionality of the rotation to the magnetic force; and has also shown that when the magnetic force acts obliquely to the ray, *the rotation of the plane of polarisation is proportional to the cosine of the angle contained between the direction of the ray and that of the magnetic action*; in other words, *the rotation is proportional to the component of the magnetic force which is parallel to the ray*. In accordance with this law, the action is greatest when the direction of the magnetic force coincides with that of the ray, and is reduced to nothing when it acts at right angles to the ray.

Direction of the rotation.—Faraday found that the direction of the induced rotation is the same as that of the acting electric current, or of an electric current which would induce the acting magnetic polarity. This law is true with regard to all diamagnetic substances; but Verdet has shown that in certain magnetic bodies the direction of the induced rotation is opposite to that of the current. This inverse or *negative* rotation is exhibited by the salts of iron, titanium, cerium, and lanthanum; whereas those of nickel, cobalt, and molybdenum exhibit *positive* rotation, that is, in the same direction as the current; while of manganese salts, some exhibit positive, others negative rotation. When a salt, such as ferric chloride, which exhibits negative rotatory power, is dissolved in water, which is positive, the negative rotation actually produced increases with the strength of the solution; the same salt dissolved in alcohol, ether, or wood-spirit, which produce much less positive solution than water, exhibits a still greater negative rotation.

Magnetic rotatory powers of different substances.—All the liquids and transparent non-crystalline solids on which Faraday experimented, exhibited more or less magnetic rotatory power. According to Matthiessen (Pogg. Ann. lxxiii. 66, 71; Compt. rend. xxiv. 969; xxv. 200), this power is not exhibited by fused phosphoric acid, flint, agate, or fluoride of calcium. Crystallised bodies in general do not exhibit it; rock-salt, however, is susceptible of it in a very high degree. Mercuric chloride, carbonate of lead, and chromate of lead are quite unsusceptible of magnetic rotatory power, when crystallised, but exhibit it strongly in the amorphous state.

Faraday's heavy glass (boro-silicate of lead) was formerly regarded as the substance most highly susceptible of magnetic rotatory power; but Matthiessen has shown that several other kinds of glass exhibit it in a still higher degree. The greatest rotatory power is exhibited by the silicates, and perhaps by the chlorides. Among bases, oxide of lead is the one which, when introduced into glass, produces the greatest increase of magnetic rotatory power; then follow the oxides of bismuth, antimony, zinc, mercury, silver. Magnesia, strontia, and baryta do not appear to exert any influence; lime, potash, and soda diminish the effect.

Bertin (Ann. Ch. Phys. [3] xxiii. 6) has obtained the following values of the magnetic rotatory powers of several substances, as compared with that of Faraday's heavy glass:

Heavy glass	100	Trichloride of phosphorus	61
Guinand's flint-glass	87	Solution of chloride of zinc	66
Matthiessen's flint-glass	89	Solution of chloride of calcium	46
Common flint-glass	63	Water	26
Stannic chloride	77	Alcohol at 36°	18
Sulphide of carbon	74	Ether	16

The dispersion of the different coloured rays by magnetic rotation in flint-glass (Bertin) and in oil of turpentine (Wiedemann), follows the same laws as in circular polarisation, produced by quartz (p. 672).

Cause of the Magnetic Rotatory action.—Faraday at first attributed the observed effects to the direct action of the magnet on the rays of light; but further research convinced him that the rotation of the plane of polarisation is due to a temporary modification in the molecular structure of the transparent medium, induced by the action of the current or magnet. In accordance with this view, it is found that any cause which interferes with molecular displacement, likewise impedes the development

of the rotatory power by magnetic action: hence it is that this power is but rarely developed in crystals. The development of this power is likewise hindered by pressure, but favoured by heat, which increases the spaces between the molecules, and thereby facilitates their displacement by magnetic action.

H. W.

LIGHT, CHEMICAL ACTION OF. A large number of substances suffer chemical change on exposure either to sunlight or to certain artificial sources of light; the action thus effected is said to be chemical action induced by light. The undulatory or mechanical theory of light and heat easily explains this peculiar action of light, inasmuch as this theory supposes, in accordance with the principle of the conservation of energy, that the rapid vibrations of the luminiferous ether, giving rise to what we term light, are transferred to the smallest particles of the material substance, thus producing the chemical change. Amongst the most striking effects of the chemical changes effected by the action of light may in the first place be mentioned the action by light upon the salts of silver, giving rise to all the marvellous results of photography; and secondly, the conversion of the carbonic acid gas contained in the air into its constituent elements, by plants in sunlight, a chemical decomposition upon which the whole living world depends.

The peculiar blackening which exposure to light effects upon chloride of silver was observed as early as the middle of the sixteenth century, but the explanation of the phenomenon was first given by Scheele in the year 1777 (*Von der Luft und dem Feuer*, Leipsic, 1784, p. 64). He clearly proved that when chloride of silver is exposed to light a black substance, insoluble in ammonia, but soluble in acids, is formed, whilst at the same time hydrochloric acid is set free; and hence Scheele concluded "that the blackness which the *luna cornua* acquires from the sun's light is silver by reduction." Scheele likewise proved that the variously coloured solar rays do not affect silver-salts in the same degree, and that the chloride of silver is blackened sooner in the violet than in any other of the rays. The theory of the decomposition of silver-salts by light has made but slight progress since these first experiments of Scheele, in spite of the enormous development which practical photography has attained; and even at the present day, as regards the chemistry of the photographic processes, we are unable to advance far beyond Scheele's three fundamental discoveries, (1) the production of a black powder insoluble in nitric acid, (2) the formation of free hydrochloric acid, (3) the specific activity of the violet rays.

The first definite experiments made on the chemical action of light upon vegetation were those of Priestley. This acute reasoner and active experimenter showed (*Experiments and Observations on Different Kinds of Air*, Birmingham, 1790, p. 293), that it is only in presence of light that plants are able to decompose the carbonic acid of the air, assimilating the carbon, and liberating the oxygen, and thus purifying a closed atmosphere rendered impure by the respiration of animals or by the burning of a candle. These results were soon afterwards confirmed and enlarged by the labours of many chemists and botanists, amongst others by Ingenhousz, Decandolle, Saussure, and Ritter, and thus by degrees the grand relations of the atmospheric equilibrium of animal and vegetable life became apparent. It is, however, only within the last few years that the immediate dependence of all terrestrial life upon the solar radiations has been universally admitted. We now know that the animal, through the vegetable, derives its power from the sun; that it is the rapidly vibrating solar rays which are absorbed by plants and stored up in them, to be given out again in the various forms of energy, either animal or mechanical, upon the destruction of the vegetable organism by oxidation. Only the most rapidly vibrating of the solar rays are able, as a rule, to effect chemical change, and hence these violet or most refrangible rays have received the special name of the "chemical rays;" there is, however, no difference in kind between these and the other solar radiations, they all differ only in wave-lengths and in intensity of vibration.

Measurement of the Chemical action of Light.

The measurement of the chemical action of light and the investigation of the laws which regulate these important actions are subjects which have naturally attracted considerable attention. The first person who succeeded in measuring, although but roughly, the chemical action of light was Dr. Draper of New York. He employed for this purpose a reaction originally observed by Gay-Lussac and Thénard, that chlorine and hydrogen when mixed in equal volumes, do not combine in the dark, but when exposed to diffused light, gradually unite, and even combine so rapidly as to produce an explosion when placed in direct sunlight. Draper constructed an instrument by which the quantity of hydrochloric acid formed by the action of light during a given time could be approximately determined, and although the method which he employed was very incomplete, his experiments led him to the first great law of photo-chemical

actions, viz., that the chemical action of light varies in direct proportion to the intensity of the light, and to the time of the exposure. The subject of the measurement of the chemical action of light has been placed upon an exact scientific basis by the researches of Bunsen and Roscoe. For the detailed description of the methods employed, and for many of the results which these chemists obtained, we must refer to their original memoirs (Phil. Trans. 1857, pp. 355, 381, 601; 1859, p. 879; 1862, p. 139), as we can here only give a short summary of the principles upon which their modes of measuring the chemical action of light are founded, and a statement of some of the more important results to which they have been led.

Description of the Chlorine and Hydrogen Chemical Photometer of Bunsen and Roscoe.—This instrument is founded on the same principle as the photometer of Draper, that of the combination of a mixture of chlorine and hydrogen when exposed to light, but differs from Draper's instrument in being capable of giving accurate and trustworthy measurements, inasmuch as certain necessary conditions for giving exactness to the indications are fulfilled. These consist mainly in the perfect uniformity of the gaseous mixture, constancy of pressure on the gas and liquids throughout the apparatus, and elimination of the disturbing action of radiant heat. This most delicate chemical photometer is represented in fig. 702. It consists essentially of three

Fig. 702.

parts; namely, first the apparatus in which the sensitive gas is generated by the electrolysis of hydrochloric acid; secondly, the apparatus in which the gas is exposed to light, and thirdly, the apparatus in which the volume of hydrochloric acid produced in a given time is read off. The mixed gas, consisting of hydrogen and chlorine in equal volumes, is evolved from hydrochloric acid in the glass vessel *a* containing two carbon poles, by means of the four cells of the Bunsen battery *C*. By help of the gyrotrope *D*, the current of electricity can be greatly weakened at pleasure, and the evolution of gas in the vessel *a* reduced to a small amount. The mixed gases pass from the vessel *a* through the water contained in the washing-bulbs *w*, and thence through a horizontal tube provided with a glass stopcock *s*, into the insolation vessel *i*, in which the gases are exposed to the action of light. From the insolation vessel, the gas passes through the horizontal measuring tube *k* provided with a millimetre scale, then through the water in the vessel *l*, and finally into a cylinder filled with slaked lime and charcoal to absorb the chlorine. When the gas is allowed to pass through the apparatus, the liquids in *a*, *w*, *i* and *l* gradually become saturated with the gas; but as the saturation goes on the composition of the gas varies, and it is only after the gas has continued to pass through for three or four days that the liquids become perfectly saturated, and the mixture consists of exactly equal volumes of hydrogen and chlorine. During the process of saturation, the photochemical sensitiveness of the gas increases continually, until, when the absorptometric equilibrium is attained, the sensitiveness reaches its maximum degree and the apparatus is ready for use. It retains this same sensitiveness for weeks, and only requires a short saturation each day previous to the actual observation. The observations are made by closing the stop-cock *s*, and allowing the light to act on the gas in the upper part of the vessel *i*. Combination then occurs, accompanied by a diminution of volume, owing to the absorption by the water of the hydrochloric acid formed, so that the atmospheric pressure forces the water in through the tube *k* towards *i*. The rate of movement of the column of water per minute gives the diminution of volume, and therefore the chemical action effected. The pressure on the gas in the jar in the insolation-vessel and measuring-tube, during the observations, is necessarily uniform, from the construction of the apparatus; but it is also necessary that uniformity of pressure be insured in all other parts of the apparatus in the intervals

between the observations; otherwise the composition of the gaseous mixture will be altered, and the results will be no longer exact. This uniformity of pressure is insured, by making the gas pass, after the stop-cock *s* is closed, through the bent tube *m v*, containing water, and thence through the tube *h*, which dips under the water in the vessel *E*, the pressure being regulated by raising or depressing the tube through the caoutchouc mouthpiece *z*. When the stop-cock is open the gas will pass either through the insolation vessel or through the pressure-regulator *F*, according to the depth to which the tube *h* is immersed in the water.

To prevent any disturbance from the effects of radiant heat (for the instrument acts as a delicate air-thermometer) the light from a coal-gas flame, or other source, having been condensed by the convex lens *M*, is made to pass through the cylinder *N*, closed with plate-glass ends, and filled with water. A screen is also placed in front of the insolation vessel to prevent radiation of heat from the body of the observer; and this, together with the screen *L*, serves to prevent radiation from external objects. It was found by experiment that the heat evolved by the combination of the mixed gases did not exert any sensible influence upon the results. The whole of the apparatus between *a* and *l* is connected by ground-glass joints, or by fusion, no caoutchouc or other organic substance, which could be acted upon by chlorine, being introduced, except where the waste gas is carried off. The instrument, when thus arranged, is extremely delicate; the light emitted from a small straight flame of coal-gas, 42 mm. in height, placed at a distance of 216 mm. from the insolation vessel, producing an action represented by the motion of the column of water over nearly 14 divisions of the scale in one minute. The several indications obtained agree closely with each other, and show that the instrument gives both accurate and trustworthy results. Thus the action effected by a coal-gas flame of constant dimensions on different days was as follows:

Date.	Action in 1 minute.	Difference from mean.
June 11 . . .	14.00 . . .	+ 0.01
" 12 . . .	14.26 . . .	+ 0.35
" 13 . . .	13.80 . . .	- 0.11
" 19 . . .	13.83 . . .	- 0.08
" 21 . . .	13.88 . . .	- 0.03
" 26 . . .	13.72 . . .	- 0.19
	13.91	

Observations made with the constant flame placed at different known distances from the insolation vessel, proved that the amount of the chemical action varied inversely as the square of the distance; and experiments made in September with a flame of the same dimensions as used in June, gave results agreeing most exactly with those obtained three months previously.

Photochemical Induction.—When the gas is exposed to light, the quantity of hydrochloric acid does not at once attain the maximum. A certain time always elapses before any alteration of volume is observed; a slight alteration is, however, soon noticed, and this gradually increases until the permanent maximum is attained. This remarkable fact was first observed by Draper, who explained it by supposing that the chlorine, on exposure to light, underwent a permanent allotropic modification, in which it possessed more than usually active properties. Bunsen and Roscoe have, however, shown that neither chlorine nor hydrogen, when separately insulated, undergoes any such modification, no difference indeed being perceptible between the action of light on the gases which have been separately insulated before mixing, and on a mixture of the same gases evolved, and previously kept in the dark. The light appears, therefore, to act by increasing the attraction between the chemically active molecules, or by overcoming certain resistances which oppose their combination. This peculiar action is termed photochemical induction. The authors have fully investigated the laws of photochemical induction, and have determined the relation existing between the intensity of the light, the mass of the gas, and the duration of the inductive action; for the results thereby obtained we must, however, refer the reader to the original papers.

The resistance to combination which prevents the union of the chlorine and hydrogen gases until the action is assisted by light, is increased to a remarkable extent by the presence of even the minutest trace of foreign gases. Thus, an excess of $\frac{1}{1000}$ of hydrogen above that contained in the normal mixture reduces the action from 100 to 38. The following table shows the effect of the presence of small quantities of foreign gases upon the sensitiveness of the mixture. In each case the rate of combination of the pure gases is supposed to be 100.

Nature of foreign gas.	Volume of chlorine + hydrogen.	Volume of foreign gas.	Ratio of combination of mixture.
None	1000	0	100·00
Hydrochloric acid . . .	1000	1·3	100·0
Chlorine	1000	10·	60·2
		75·	60·3
		180·	41·3
Hydrogen	1000	3·	37·8
Oxygen	1000	5·	9·7
		13·	2·7
Non-insolated gas . . .	1000	6·	55·6

The increase in the rate at which combination goes on up to a certain point, under the influence of light, appears to arise, not from any peculiarity in light, but rather from the mode of action of the chemical attractions themselves. Chemical induction is in fact observed, when there is nothing but pure chemical action to produce the change. Thus, if a dilute solution of aqueous bromine be mixed with tartaric acid and left in the dark, hydrobromic acid is formed, and the rate at which this hydrobromic acid is produced is not uniform, but increases up to a certain point, according to a law similar to that which is observed in photochemical induction. These phenomena seem to lead to the conclusion, that the chemical attraction between any two bodies is in itself a force of constant amount, but that its action is liable to be modified by opposing forces, similar to those which affect the conduction of heat or electricity, or the distribution of magnetism in steel. We overcome those resistances when we accelerate the formation of a precipitate by agitation, or a decomposition by insolation.

One of the many interesting applications of the law of photochemical induction relates to the phenomena of photography. As an instance of this application, Bunsen and Roscoe quote the remarkable observations of Becquerel, from which he assumed the existence of certain rays which can continue but not commence chemical action. In order to explain the phenomenon observed by the French physicist, it is not necessary to suppose the existence of a new property of light, as the facts are easily explained by the laws of photochemical induction (*Phil. Trans.* 1857, p. 400). It is probable, indeed, according to Bunsen and Roscoe, that the relations thus proved in the case of chlorine and hydrogen occur in a slightly modified form in other photochemical processes.

Comparative and Absolute Measurement of the Chemical Rays.—The first essential for the exact measurement of photochemical actions is the possession of a constant source of light. This Bunsen and Roscoe secured by employing a flame of pure carbonic oxide gas, burning from a platinum jet of 7 mm. in diameter, and issuing at a given rate and under a pressure very slightly differing from that of the atmosphere. The action which such a standard flame produces in a given time on the sensitive mixture of the chlorine and hydrogen, placed at a given distance, is taken as the arbitrary unit of photochemical illumination. This action is, however, not that which is directly observed on the scale of the instrument. The true action is obtained only by taking account of the absorption and extinction which the light undergoes in passing through the various glass-, water-, and mica-screens placed between the flame and the sensitive gas. These reductions can be made by help of the determinations detailed in the memoirs above referred to. When these sources of error are eliminated, it is possible, by means of this standard flame, to reduce the indications of different instruments to the same unit of luminous intensity, and thus to render them comparable. For this purpose, the authors define the photometric unit for the chemically active rays, as *the amount of action produced in one minute by a standard flame placed at a distance of one metre from the normal mixture of chlorine and hydrogen*; and they determine experimentally for each instrument the number of such units which correspond to one division on the scale of the instrument. By multiplying the observed number of divisions by the number of photometric units equal to one division, the observations are reduced to a comparable standard. It is proposed to call this unit a chemical unit of light, and ten thousand of them, one chemical degree of light. According to this standard of measurement, the chemical illumination of a surface, that is, the amount of chemically active light which falls perpendicularly on the plane surface, can be obtained. It has thus been found that the distance to which two flames of coal-gas and carbonic oxide, each fed with gas at the rate of 4·105 c. c. per second, must be removed from a plane surface, in order to effect upon it an amount of chemical action represented by one degree of light, was, in the case of the coal-gas flame, 0·929 metre, in that of carbonic

oxide, 0.561 metre. The chemical illuminating power, or chemical intensity, of various sources of light, measured by the chemical action effected by these sources at equal distances and in equal times, can also be expressed in terms of this unit of light; and these chemical intensities may be compared with the visible light-giving intensities. In like manner, the authors define *chemical brightness*, as the amount of light measured photochemically, which falls perpendicularly from a luminous surface upon a physical point, divided by the apparent magnitude of the surface; and this chemical brightness of circles of zenith-sky of different sizes has been determined. Experiment shows that the chemical brightness of various sized portions of zenith-sky, not exceeding 0.00009 of the total heavens, is the same; or, that the chemical action effected is directly proportional to the apparent magnitude of the illuminating surface of zenith-sky. It is, however, possible to express photochemical actions, not only according to an arbitrary standard, but in absolute units of time and space. This has been done by determining the absolute volume of hydrochloric acid formed by the action of a fixed source of light during a given space of time; and in this way the chemical illumination of any surface may be expressed by the height of the column of hydrochloric acid which the light falling upon that surface would produce, if it passed through an unlimited atmosphere of chlorine and hydrogen. This height, measured in metres, Bunsen and Roscoe call a *light-metre*. The chemical action of the solar rays can be expressed in light-metres, and the mean daily or annual light thus obtained regulates the chemical climate of a place, and points the way to relations for the chemical actions of the solar rays, which in the thermic actions are already represented by isothermals, isotherals, &c.

Chemical Action of Diffuse Daylight.—In order to determine the chemical action exerted by the whole diffuse daylight upon a given point on the earth's surface, the authors were obliged to have recourse to an indirect method of experimenting, owing to the impossibility of measuring the whole action directly, by means of the sensitive mixture of chlorine and hydrogen. For the purpose of obtaining the wished-for result, the chemical action proceeding from a portion of sky at the zenith, of known magnitude, was determined in absolute measure; and then, by means of a photometer, whose peculiar construction can only be understood by a long description, the relation between the *visible* illuminating power of the same portion of zenith-sky and that of the total heavens was determined. As, in the case of lights from the same source, but of different degrees of intensity, the *chemical* actions are proportioned to the *visible* illuminating effects, it was only necessary, in order to obtain the chemical action produced by the total diffuse light, to multiply the chemical action of the zenith-portion of sky by the number representing the relation between the visible illumination of the total sky and that of the same zenith-portion. The laws according to which the chemical rays are dispersed by the atmosphere can only be ascertained from experiments made when the sky is perfectly cloudless. In the determinations made with this specially arranged photometer, care was therefore taken that the slightest trace of cloud or mist was absent, and the relations between the visible illuminating effect of a portion of sky at the zenith and that of the whole visible heavens, was determined for every half hour from sunrise to sunset, the observations being made on the summit of a hill near Heidelberg, from which the horizon was perfectly free.

The amount of chemical illumination which a point on the earth's surface receives from the whole heavens, depends on the height of the sun above the horizon, and on the transparency of the atmosphere. If the atmospheric transparency undergoes much change when the sky is cloudless, a long series of experiments would be needed before the true relations of atmospheric extinction for the chemical rays could be arrived at; the authors, however, believe that the alterations in the transparency of the air with a cloudless sky are very slight, and they think themselves justified in considering the chemical illumination of the earth's surface on cloudless days to be represented simply as a function of the sun's zenith-distance. This supposition is confirmed by experiments made on different occasions with varying zenith-distance of the sun, inasmuch as these all agree closely amongst themselves. From a series of observations made on June 6, 1858, the relation between the amount of light *optically* measured, falling from the whole sky, and the amount (taken as unity) which at the same time falls from a portion of zenith-sky equal to $\frac{1}{1000}$ th part of the whole visible heavens, has been calculated for every degree of the sun's zenith-distance from 20° to 90°. These numbers multiplied by the *chemical* light proceeding from the same portion of zenith-sky for the same zenith-distance, give the chemical action effected by the whole diffuse light. The amount of chemical light which falls from the zenith-portion of sky is, however, the chemical brightness of that portion of sky. This chemical brightness was determined by the chlorine and hydrogen photometer on various days and at various hours when the sky was perfectly cloudless; thence the authors obtained the chemical action, expressed in degrees of light, which is effected on the earth's surface by a portion of

zenith-sky equal in area to $\frac{1}{1800}$ th part of the whole heavens, under corresponding sun's zenith-distances from 20° to 90° . The numbers thus obtained have only to be multiplied by those of the former series of observations, in order to give the chemical action effected by the total diffuse light of day for zenith-distances varying from 20° to 90° . Knowing the relation existing between the sun's altitude and the chemical action, the chemical illumination effected during each minute at any given locality at a given time may be calculated. For the following places, the amount of chemical illumination expressed in degrees of light which falls from sunrise to sunset at the vernal equinox is:

Melville Island	10,590	Heidelberg	18,220
Reikiavik	15,020	Naples	20,550
St. Petersburg	16,410	Cairo	21,670
Manchester	18,220		

Chemical Action of Direct Sunlight.—The chemical action of the direct sunlight was determined by allowing a small but known portion of direct sunlight to fall into the dark room in which the instrument was placed, so that the insolation vessel was bathed in the pencil of rays thus admitted. By help of Silbermann's heliostat, the sun's image was reflected during the whole day upon one spot, a small opening of known size, in the window-shutter of a dark room. The fraction of the total sun's rays thus admitted and allowed to fall upon the chemical photometer was calculated, and the action thus effected was observed: hence the amount of action can be found which the sun would have produced if directly shining upon the instrument,—a condition impossible of course to fulfil, as the action would become too rapid and the whole apparatus would be shattered by explosion.

The day chosen for observation of the sun's action must obviously be cloudless, if we wish to obtain an idea of the relation existing between the chemical action and the height of the sun. Beginning the observations as near sunrise as possible, we find, for instance, on September 15, 1858, one of the days on which such a series of experiments was made, that at $7^h 9^m$ a.m., when the sun's zenith-distance was $76^\circ 30'$, the observed action amounted to 1.52: that is, in one minute the column of water moved through 1.52 division; or the quantity of hydrochloric acid formed, when the sun stood at the height mentioned, was represented by 1.52 division on the scale. Gradually, as the day wore on, the observed action for each minute became larger; until at $9^h 14^m$ a.m., the latest observation possible on the day in question, owing to the formation of clouds, the action reached 18.6 divisions, or was thirteen times as large as at $7^h 9^m$. In the last column of the accompanying table is found the action, expressed in degrees of light, which would have been observed at the foregoing times, if the whole sunlight had been allowed to fall on the instrument:

Hour.	Sun's zenith-distance.	Observed action. 1 minute.	Total sun's action in degrees of light.
$7^h 9^m$	$76^\circ 30'$	1.52	5.54
7 26	73 49	4.22	15.50
7 40	71 37	6.09	22.43
8 0	68 34	7.56	27.85
8 7	67 30	8.38	38.87
8 26	64 42	12.48	45.85
8 54	60 48	17.09	62.59
9 14	58 11	18.61	67.61

This great increase in the chemical action with the rise of the sun in the heavens results simply from the fact that the solar rays, in passing through the air, are extinguished or absorbed, lost in fact as light; and that as the sun rises higher above the horizon, the column of air through which the rays pass is constantly being lessened: consequently, more of the direct rays reach the earth.

Now, the law according to which the direct rays of the sun are thus absorbed in the air can be obtained from the experiments, of which the foregoing is only an example: hence, if the action which the sun produces, when at a given height, is known, it is possible to calculate the action which it would produce at any other height.

The law regulating the chemical action of direct sunlight may be thus expressed: The amount of chemical action effected at a point upon the earth's surface on any cloudless day, by the direct solar rays, depends alone upon the sun's zenith-distance, or upon the height of the column of air through which the rays have to pass.

That these calculated results agree very closely with the experimental data—with

the observed action—is seen by comparing the numbers in Table II., expressing the observed and calculated action:

TABLE II.

Sun's zenith-distance at time of observation.	Chemical illumination of sun's direct rays at the earth's surface expressed in degrees of light.	
	Observed.	Calculated.
46° 8'	93·0	96·4
50 51	89·2	85·8
57 35	63·1	67·9
58 11	67·6	66·2
60 48	62·6	58·3
64 42	45·9	47·9
67 30	38·9	36·6
68 34	27·9	33·1
71 37	22·4	24·5
73 49	15·5	16·3
76 30	5·5	9·2
Probable error = $\pm 2\cdot7$ degrees of light.		

Knowing the law which regulates the absorption of the chemical rays, we can calculate what the action would be if there were no atmosphere to diminish the power of the rays. It is thus found that if the sun's rays were not thus weakened, by passage through the atmosphere, they would produce an illumination represented by 318 *degrees of light*; or they would effect a combination in one minute, upon an unlimited atmosphere of chlorine and hydrogen on which they fell perpendicularly, of a column of hydrochloric acid, 35·3 *metres in height*. The sun's rays having passed perpendicularly through our atmosphere to the sea's level, effect an action of only 14·4 *light-metres*; or three-fifths of their chemical activity has been lost by extinction and dispersion in the atmosphere.

A large number of most interesting conclusions may be drawn from the facts already noticed. Thus, for instance, we may determine the chemical action which the solar rays will produce on the various planets; for we know that the intensity of the chemical illumination varies inversely as the square of the distance of the planet from the sun. The numbers in Table III. express this chemical action in degrees of light, and in heights of columns of hydrochloric acid called *light-metres*. Hence, we see how much the sun's chemical action varies on the different planets, the superior planets receiving so small a portion as to render it impossible that the kind of animal and vegetable life which we here enjoy can there exist.

TABLE III.—Chemical Action produced by Direct Sunlight on each Planet.

	Mean distances.	Chemical action in	
		Light-degrees.	Light-metres.
Mercury	0·387	2125·0	235·4
Venus	0·723	608·9	67·5
Earth	1·000	318·3	35·3
Mars	1·524	137·1	15·2
Jupiter	5·203	11·8	1·2
Saturn	9·539	3·5	0·4
Uranus	19·133	1·0	0·1
Neptune	30·040	0·4	0·04

Interesting conclusions can be drawn from these facts, concerning the distribution of the chemical rays on the surface of our earth in different latitudes, and at different elevations above the sea's level. The farther removed a situation is from the level of the sea, the higher up in the atmosphere it is placed, the greater is the amount of chemical action which it receives. Thus, in the highlands of Thibet, where corn and grain flourish at a height of from 12,000 to 14,000 feet, the chemical action of the direct sunlight is $1\frac{1}{2}$ times as great as in the neighbouring lowland plains of Hindostan. In the same way we can calculate, for any point of the earth's surface whose latitude is known, the amount of chemical action which the direct sunlight effects at any given time of day or year. In Table IV. the numbers represent the chemical action effected by direct sunlight in one minute at the places and hours named, on the 21st of March. Curves

accompany the original memoirs, showing the rise of the action with the progress of the sun through the heavens. By comparing the numbers in the table, it is seen how greatly this chemical action differs at various points on the earth's surface; and we can understand how it is, that at the latitude of Cairo, where the chemical action of the direct sunlight is twice as great as it is in that of Manchester, the whole flora and fauna assume a more tropical and luxuriant character.

Measurement of the Chemical Action of the Constituent parts of the Solar Spectrum.—For the purpose of measuring the chemical activity of the various portions of the solar spectrum (as regards the mixture of chlorine and hydrogen), Bunsen and Roscoe reflected the sun's rays through a narrow slit, and then decomposed them by passing them through two quartz prisms. The spectrum thus produced was allowed to fall upon a white screen covered with a solution of quinine, and any desired portion of the light measured by a finely-divided scale allowed to fall upon the insolation vessel of the photometer. For the purpose of identifying the fixed lines in the lavender rays, use was made of a map of those lines made by Professor Stokes. As the various components of white light are irregularly absorbed by the atmosphere, it was necessary to make all the observations quickly one after the other, so that no appreciable difference in the column of air through which the rays passed should occur. Fig. 703 exhibits the chemical action effected by various portions of the spectrum on

Fig. 703.

the sensitive mixture for one particular zenith-distance of the sun. Several maxima of chemical intensity in the spectrum are here noticed.

Between the lines G in the indigo, and H in the violet, the greatest amount of action was observed, whilst another maximum was found to lie near I in the ultra-violet rays. In the direction of the red end of the spectrum, the action became imperceptible about D in the orange (the maximum of visible illumination); but towards the other end of the spectrum, the action was found to extend as far as Stokes's line U, or to a distance from the line H greater than the total length of the ordinary visible spectrum.

We must, however, remember that the curve which represents the amount of decomposition effected by the chemically active rays, varies according to the nature of the substance acted upon; thus Sir John Herschel showed (*Phil. Trans.* 1840, Part I.) that iodide of silver washed with nitrate was decomposed by ultra-violet rays which exerted no action whatever upon the chloride of silver; and whereas, in the case of the iodide, the action extends but a little beyond the line E, the action in the case of the bromide is visible to the very extremity of the visible red rays, and the maximum action on the bromide lies in the indigo rays, that of the iodide lying in the lavender rays between the lines I and M. (See also Becquerel's results, p. 632; and Daguin, *Traité de Physique*, iv. 226.)

Chemical Photometer adapted to the purposes of Meteorological Registration.—Having thus ascertained the chief laws regulating the chemical action of light, and the distribution of direct and diffuse sunlight upon the earth's surface when the sky is unclouded, Professors Bunsen and Roscoe proceeded to found a method of measuring applicable to the direct determination of the total effect produced by the varying cloud and sunshine of our changing climate. The object of this new investigation (*Phil. Trans.* 1863, p. 139) has been to invent a trustworthy mode of measuring the daily variation in the sun's chemical intensity, which shall be so easy and simple of practice as to be applicable to regular meteorological registration.

Although many fruitless attempts have been made to construct photometers by a comparison of the blackness produced by sunlight upon photographic paper, Bunsen and Roscoe found that the desired end could be obtained in this way by attention to certain essential conditions.

For this purpose it was necessary to construct an apparatus in which photographic sensitive paper could be exposed to sunlight for definite times measured by small fractions of a second. This instrument, called a pendulum photometer, is represented in *fig. 704*.

Fig. 704.

of the slit is exposed for a different period. If we wish to use this instrument for the purpose of exposing a photographic surface to the action of the light for different times, the paper is gummed upon the white surface of the metallic slide (G, *fig. 704*); this is then covered by a metallic lid, which does not touch the paper, and the whole arrangement pushed into the dark groove *h*, placed directly under the slit, and protected from the entrance of light by a lappet of cloth, which hangs in front. The metallic lid is then withdrawn, the screw *k* turned, and thus the paper is slightly pressed against the slit, so that no light can enter sideways between the paper and the thin metallic edges of the slit. By raising the lever *nm* at *l*, the pendulum is released from the catch at *m*, and, after completing a vibration, it is held fast by a lower catch at *n*. If it be required to double or to multiply the time of insolation, it is only necessary to repeat the vibration, once or several times, care being taken before each vibration to raise the rod of the pendulum so as to allow the end to fall into the upper catch. In order thus to set the pendulum in motion, and to stop it with certainty and ease, the lever is once for all balanced by a small weight at *l*, so that the arm *nm* is but slightly heavier than the arm *l*.

Before this instrument can be used for measuring the chemical action of light, it is necessary—

1. To know the relation existing between the several tints and the intensity of the light necessary to produce such tints.

2. To construct sensitive paper which shall always possess the same degree of sensitiveness, and can easily be prepared when required.

It was found, by a long series of experiments, that it was possible, by adhering strictly to a certain method of manipulation, to prepare standard papers which, when made, possess a constant degree of sensitiveness; so that if the same light falls upon them, the papers are always coloured to the same tint.

Experiment likewise showed that the tint attained by such a paper was constant when the *quantity* of light falling upon it also remained constant; so that light of the intensity 50 falling upon the paper for the time 1, produced the same blackening effect as light of the intensity 1 falling upon it for the time 50.

Knowing this law, which regulates the degree of shade of the paper, and having a surface of a perfectly constant degree of sensitiveness, it is easy to obtain absolute measurements of the chemical action of light. For this purpose, an arbitrary unit of measurement is chosen, by making a standard tint or paint which can be easily and exactly reproduced at any time.

The quantity of light which shall, in a second, or the unit of time, produce a blackening effect on the standard photographic paper equal to that of the standard tint, is said to have the chemical intensity 1. If the time needed to produce this same tint is found by experiment with the pendulum-photometer to be 2 seconds, then the chemical intensity is one half, and so on.

All that is needed, in order to obtain accurate measurements of the chemical action of diffuse daylight or sunlight, is to be able to find the time necessary to effect a blackening of the normal paper equal in shade to the standard tint. This is done by means of the graduated strip made in the pendulum-photometer.

For the purpose of accurately comparing these tints, the ordinary daylight, or even lamplight, cannot be used, as a change would thereby be produced on the sensitive paper. A light which does not act chemically must be used; such a light is the monochromatic soda-flame. The light from this flame possesses another advantage, namely, that the unavoidable differences of colour are not seen; variation in *shade* alone being perceptible. The arrangement for thus reading off the point having a shade equal to that of the standard tint is seen in *fig. 705*. A millimetre scale, similar to the one upon the slit, is fastened upon a wooden board, *a* (*fig. 705*), covered with paper, and moveable in a groove across a fixed wooden stand. The strip of photographically

Figs. 705 and 706.

tinted paper is then cut off from the slide *G* and gummed upon the board *a*, so that it has the same position relative to the scale on the board as it had to the scale on the slit. *A*, *fig. 706*, represents a small square wooden block having a circular hole in the middle 5 to 6 mm. in diameter, the lower half being covered by the paper of which the degree of shade has to be determined. This block is pressed by means of a spring, as is seen in *fig. 705* in a fixed position against the strip of paper. On throwing the image

of the soda-flame C, by help of the convex lens D, upon the circular opening in the block, it is easy, by drawing the slide backwards and forwards, to determine the exact point at which the upper and lower halves of the circular hole appear equally dark. It is then only necessary to read off on the scale the number representing the time which the paper at that point has been insolated, in order to determine the degree of shade which the paper in that time has attained. To ensure accuracy in the observations, it is necessary that the eye should always be placed in one and the same position; most advantageously in a direction nearly perpendicular to the surface of the strip of paper.

By help of this soda-flame, the coincidence of shade of the graduated strip with the standard tint can be read off with the greatest precision. This fact, as well as the possibility of preparing a constant sensitive paper, is seen by reference to the following tables, extracted from the detailed paper printed in the Philosophical Transactions for 1863, to which we must refer for positive proof of the delicacy and trustworthiness of the method.

Papers variously prepared were exposed for the same time to the same light.

Each reading is the mean of several observations; identity in the numbers shows identity in the shade, and, therefore, the constant sensitiveness of the papers.

The standard paper is prepared by soaking photographic paper in a solution of common salt of given strength (3 to 100), and then allowing it to lie upon the surface of a silver solution (12 nitrate of silver to 100 of water). When the strength of the salt solution varies, the sensitiveness of the paper alters very rapidly. Variation in the strength of the silver-bath produces, on the contrary, but little change in the sensitiveness of the paper.

Different qualities of paper and alterations of atmospheric moisture and temperature do not affect the sensitiveness of the paper.

1. *Effect of altering the Strength of the Silver-bath. Paper salted in a Solution containing 3 pts. Chloride of sodium to 100 of Water.*

Nitrate of silver to 100 of water.	Observer A.	Readings.	Observer B.
12	128.6	129.7
10	128.7	127.0
8	128.7	128.0
6	129.7	130.0

2. *Effect of altering the Strength of the Salt Solution.*

NaCl to 100 of water.	Observer A.	Readings.	Observer B.
1	2.6	60.4
2	95.7	94.6
3	132.6	129.6
4	167.0	168.0

3. *Experiment showing the constant Sensitiveness of the Standard Paper.*

Paper.	NaCl to 100 of water.	Intensity No. 1.		Intensity No. 2.	
		Observer A.	Observer B.	Observer A.	Observer B.
Upper part of sheet 2	2.950	70.2	70.0	101.3	101.5
Lower part of sheet 2	3.026	70.6	69.3	101.5	101.7
Middle of sheet 1 .	3.026	70.0	69.5	100.9	100.9
Middle of sheet 3 .	3.000	70.0	70.4	101.0	100.0

All these papers were silvered in a solution containing 12 pts. of nitrate of silver to 100 of water.

In order to measure the chemical intensity of the daylight at any time, all that is needed is to expose a strip of standard paper in the pendulum-photometer for a given number of vibrations, and then to find upon the strip thus exposed the point at which a shade equal to the standard tint has been produced. Reference to a table gives the time of exposure necessary to produce this tint, and the reciprocal of this time represents the intensity of the acting light. If the time necessary were 3 seconds, the chemical intensity would be $\frac{1}{3}$; if the time were $\frac{1}{2}$ second, the intensity would be 2. In this way curves of daily chemical intensity are made, which show the variation caused by clouds, or by the changing altitude of the sun. These curves show maxima and minima exactly corresponding to the appearance and disappearance of the sun

behind a cloud. The difference between the sun's chemical intensity in summer and winter is clearly seen by reference to the curves on *fig. 707*.

Fig. 707.

Based upon the principles of the pendulum-photometer, a much simpler method of making these measurements has been arranged, as follows. A graduated strip made in the pendulum-photometer is fixed in hyposulphite of sodium, and pasted upon a board furnished with a scale. The shades of certain points on this fixed strip are compared with the shades on given points upon a graduated strip prepared in the usual way, and not fixed in hyposulphite. The fixed strip is thus calibrated in terms of the unit of measurement, and it may then be used as a means of measuring the chemical action of light. Small pieces of the standard paper are then exposed for a given time to the light which it is desired to measure, until the shade approaches that of a part of the fixed strip. The point of exact coincidence is then read off by the soda flame as usual. In this way a piece of standard paper of 1 square inch of area will serve for 40 separate determinations, and the whole arrangement for exposure may be carried in the pocket. The curve of the chemical intensity of day- and sun-light in Manchester, made with this small instrument on more than 40 separate days of the year 1864, fully bears out the accuracy and ease with which these measurements can be made, and the results of his experiments induces the writer of this article to express a hope that before long these instruments may be introduced into meteorological observatories.

Chemical Brightness of various Points on the Sun's Surface.—The determination of the chemical brightness of the various portions of the sun's disc is an interesting application of this new method of photometric measurements.

By help of a camera placed on a 3-inch refractor, the writer allowed the image of the sun—of about 4 inches in diameter—to fall upon the standard paper. The sun-picture thus obtained presents interesting features: in the first place, the chemical intensity of the central portions are 3-5 times as great as that of the portions on the limb. A difference of this kind, in the case of the luminous and calorific rays, has already been observed by astronomers, and it is doubtless caused by the absorption effected by the solar atmosphere.

The following results were obtained by measuring the chemical brightness at various points on the sun's disc, on May 9, 1863; from these numbers it will be seen that the luminous intensity varies very irregularly.

CHEMICAL BRIGHTNESS OF SUN'S DISC.

1. At centre of sun's disc.	2. 15° from edge of sun's disc.			3. At the edge of sun's disc.		
	N. Pole.	Equator.	S. Pole.	N. Pole.	Equator.	S. Pole.
No. 1. . . 100·0	38·8	48·4	58·1	18·7	30·2	28·2
No. 2. . . 100·0	52·8	—	56·6	30·5	—	41·0

Bright patches of considerable area were seen on the picture; these patches, which were not caused by irregularity in the paper or in the lenses, are probably owing to the presence of clouds in the luminous atmosphere of the sun, and they may probably have some intimate connection with the well-known phenomena of the red prominences seen during the solar eclipse.

Optical and Chemical Extinction of the Chemical Rays.—In order to determine whether the act of photochemical combination (in the case of chlorine and hydrogen) necessitates the production of a certain amount of mechanical effect, for which an equivalent quantity of light is expended, or whether this phenomenon is dependent upon a restoration of equilibrium effected without any corresponding equivalent loss of light, Bunsen and Roscoe have studied the phenomena occurring at the bounding surfaces, and in the interior of a medium exposed to the chemical rays.

When light passes through any medium, part of it is lost by reflection at the surface, another portion by absorption within the medium, so that the quantity of emergent light is only a fraction of the incident light. This is true with the chemical as with the luminous rays, and Bunsen and Roscoe have determined the coefficients of absorption and reflection of the chemical rays for glass, water, and mica. By passing light from a constant source, through cylinders with plate-glass ends filled with dry chlorine, they found that, with a given length of cylinder, the quantity of chemical rays transmitted, when no chemical action takes place, is to the quantity in the incident light in a constant ratio; or in other words, the absorption of the chemical rays is proportional to the intensity of the light. They also found that the quantity of the chemical rays transmitted varies proportionally to the density of the absorbing medium. If, however, the light passes through a medium in which it is not only absorbed, but also excites chemical action, it is found that, in addition to the optical extinction already spoken of, a quantity of light is lost proportional to the amount of chemical action produced. Thus the depth of pure chlorine gas at 0° C. and 0.76 m. pressure, through which the light of a coal-gas flame must pass in order to be reduced to $\frac{1}{10}$, is found to be 173.3 mm.: hence, since the quantity of light absorbed varies as the density, the depth of chlorine diluted with an equal volume of air or other non-absorbing and chemically inactive gas required to produce an extinction of $\frac{1}{10}$ would be 346.6 mm. But when the sensitive mixture of equal volumes of chlorine and hydrogen is used, the depth of the mixture to which the light must penetrate in order to be reduced to $\frac{1}{10}$ is found only to be 234 mm. Hence Bunsen and Roscoe conclude that *light is in this case absorbed in doing chemical work.*

Light from other sources gives results similar in character, although different in amount. Diffuse light of morning reflected from the zenith of a cloudless sky is reduced to $\frac{1}{10}$ by passing through 45.6 mm. of chlorine, and through 73.5 mm. of the sensitive mixture; diffuse light is reduced to $\frac{1}{10}$ by passing through 19.7 mm. of chlorine, and through 57.4 mm. of the sensitive mixture. Hence it appears that the chemical rays of diffuse morning light are absorbed by chlorine much more quickly than those of lamp-light; and those of evening light with still greater facility. From this we may conclude that the chemical rays reflected at different times and hours, possess, not only quantitative, but also qualitative differences, similar to the various coloured rays of the visible spectrum. Photographers are well aware of this qualitative difference in the light, as they know that the amount of light photometrically estimated gives no measure of its photochemical activity; they prefer a less intense morning light to a bright evening light for taking pictures.

Photographic Transparency, or Diactinic Power of different Media.—It has already been mentioned (p. 632), that the chemical rays of the spectrum are absorbed in various degrees by different media. On this subject, some important experiments have lately been made by Professor W. A. Miller (Phil. Trans. 1863, p. 1; Chem. Soc. J. xvii. 69). The mode of observation consisted in refracting the rays which had traversed a transparent medium, through a prism and lens of quartz, and receiving them on a surface of collodion coated with iodide of silver (p. 693), whereby a permanent image of the chemical spectrum was obtained. The light employed was the electric light (obtained from an induction-coil between two metallic wires, generally of fine silver), which is peculiarly rich in chemical rays, yielding a chemical spectrum equal to four or five times the length of the visible spectrum. The following are among the most important results obtained:

1. Colourless solids which are equally transparent to the visible rays, vary greatly in permeability to the chemical rays.
2. Bodies which are photographically transparent in the solid form, preserve their transparency in the liquid and gaseous states.
3. Colourless transparent solids which absorb the chemical rays, preserve their absorptive action in the liquid and gaseous states.
4. Pure water is photographically

transparent, so that many compounds which cannot be obtained in the solid form sufficiently transparent for such experiments, may be subjected to trial in aqueous solution.

The following tables exhibit the photographic transparency of a few of the various solids, liquids, gases, and vapours subjected to experiment:—

PHOTOGRAPHIC TRANSPARENCY OR DIACTINIC POWER OF

Solids.		Liquids, 0·75 in.		Gases and Vapours.	
Rock-crystal	74	Water	74	Oxygen	74
Ice	74	Alcohol	63	Nitrogen	74

Topaz	65	Chloroform	26	Carbonic anhydride	74
Rock-salt	63	Benzene	21	Ethylene	66
Iceland spar	63	Methylic alcohol	20	Marsh-gas	63
Sulphate of magnesium	62	Amylic alcohol	20	Hydrochloric acid	65
Borax	62	Oxalic ether	19	Coal-gas	37
Diamond	62	Glycerin	18	Benzene vapour	36
Bromide of potassium	48	Ether	16	Hydrobromic acid	23
Thin glass (0·009 in.)	20	Acetic acid	16	Hydriodic acid	16
Iodide of potassium	18	Oil of turpentine	8	Sulphurous anhydride	14
Mica (0·007 in.)	16	Sulphide of carbon	6	Sulphydic acid	14
Nitrate of potassium	16	Trichloride of arsenic	6	Air, 0·1 in. pressure	74

The photographic image obtained upon the collodion plate commenced in each case at the same point of the spectrum, corresponding with a spot a little more refrangible than the line G. Calling the line H 100, and numbering backwards for the less refrangible rays, the line B being at 84, the commencement of the photograph in each case is at 96·5, and the extreme limit of the most refrangible rays at 170·5.

When absorption occurs, it is almost always exerted upon the most refrangible rays; but in the case of the coloured gases and vapours, chlorine, bromine, and iodine, the absorption differs from the general rule, and is by no means proportional to the depth of colour. A column of chlorine, with its yellowish-green colour, cuts off the rays of the less refrangible extremity through fully two-thirds of the spectrum; the red vapour of bromine cuts off about one-sixth of the length of the spectrum, the absorbent action being limited to the less refrangible extremity, whilst the deep violet vapours of iodine allow the less refrangible rays to pass freely for the first fourth of the spectrum; then a considerable absorption occurs, and afterwards a feeble renewal of the photographic action is exhibited towards the more refrangible end.

Among the various compounds submitted to examination, the fluorides were found to be chemically the most transparent; then follow the chlorides of the alkali-metals and alkaline earth-metals; the bromides are less diactinic, and the iodides show a striking diminution in this respect. The group most remarkable for its absorptive power is that of the nitrates. Nitric acid, whether simply dissolved in water or combined with bases, has a specific power in arresting the chemical rays; the less refrangible portion it transmits freely, but intercepts the spectrum abruptly at the same points, whatever salt be employed, provided the base be diactinic. The chlorates are remarkably diactinic.

Glass, even in very thin layers, absorbs the whole of the more refrangible chemical rays. Hence it might appear that lenses of quartz, or of water enclosed in quartz, would be far superior to those of glass for the use of the photographer. This, however, is not the case; for glass is very transparent to the less refrangible portion of the chemical rays, extending beyond the violet end of the visible spectrum to a distance as much beyond the line H as the red end of the spectrum is below it; and these rays are precisely the most abundant and powerful chemical rays in the solar spectrum, which contains but few rays of refrangibility much beyond this point; whereas in the electric arc, these highly refrangible rays predominate.

Diactinic bases, united with diactinic acids, usually furnish diactinic salts; but such a result is not uniform: none of the silicates are as diactinic as silica itself in the form of rock-crystal. Again, hydrogen is eminently diactinic; and iodine-vapour, notwithstanding its deep violet colour, is also largely diactinic, but hydriodic acid gas is greatly inferior to either of them.

Compounds, as such, do not appear to act more energetically as absorbents than simple bodies.

Stokes (Phil. Trans. 1862, p. 606), by receiving the invisible rays upon a fluorescent screen, finds that the vegetable alkaloids and the glucosides are, almost without

exception, intensely opaque for a portion of the invisible rays, absorbing them with an energy comparable, for the most part, to that with which colouring matters, such as indigo or madder, absorb the visible rays. The mode of absorption is also generally highly characteristic of each compound, and frequently very different in the same body, according as it is examined in an acid or an alkaline solution.

The quality of the rays reflected from polished surfaces varies in a manner which cannot be predicted from the degree of luminosity of the surface. Gold and lead, though not the most brilliant of the metals, reflect the chemical rays more uniformly than the brilliant white surfaces of silver and speculum-metal. (Miller's *Elements of Chemistry*, 3rd ed. vol. ii. p. 899.)

Influence of Light upon Plants.

The important effects produced by sun-light on living plants has already been noticed. Many experiments have been made for the purpose of determining the action which the different portions of solar light effect upon plants during various stages of their growth. The subject is an extremely complicated one, and the results of various experimenters differ widely. Thus, for instance, whilst Payer concludes that the violet rays are those which especially determine the growth of the plant, Daubeny and Draper state, as the result of their experiments, that the yellow, or most luminous rays, are those which act most powerfully in decomposing the carbonic acid of the air. Mr. Robert Hunt* draws the following conclusions from his investigations on this subject:

1. The luminous rays prevent the germination of seeds.
2. The chemically active rays quicken germination.
3. Light acts to effect the decomposition of carbonic acid by the growing plant.
4. The luminous and chemical rays are essential to the formation of the colouring matter of leaves.
5. The luminous and chemical rays, independent of the calorific rays, prevent the development of the reproductive organs of plants.
6. The heat-radiations corresponding with the extreme red rays of the spectrum facilitate the flowering of plants and the perfecting of their reproductive organs.

Photography.

The first well-authenticated attempts to produce pictures by means of the chemical action of sun-light were made by Thomas Wedgwood and Sir H. Davy in the year 1802;† but it would appear probable from recent investigations that Boulton and Watt actually obtained sun-pictures at the Soho Works so early as the year 1799. No written statement of the method employed in their experiments has, however, as yet been found, and we must therefore still give to the former experimenters the credit of having first described a mode of obtaining pictures by the means of sun-light. The method adopted by Wedgwood was that of moistening white paper or leather with a solution of nitrate of silver. By this means he copied leaves and paintings on glass, and took profiles, and Davy even succeeded in obtaining pictures of objects seen in the solar microscope; but neither of these chemists was able to prevent the unshaded portions of the picture from being coloured by exposure to diffused light. In the year 1814 M. Niépce examined the action of light on certain resinous substances with the object of obtaining an unalterable image in the camera. In this he succeeded to a certain extent, inasmuch as the light rendered the resin insoluble in the usual solvents, so that, by the subsequent action of an acid on the exposed metallic plate, those parts upon which the light had not fallen were etched. In 1827 M. Niépce communicated an account of his experiments to the Royal Society, and in the same year he informed M. Daguerre, who had been previously but unsuccessfully engaged in the same pursuit, of the particulars of his process. The two investigators continued their researches in common, proposing many different modes of producing the "Heliographic pictures," as they were termed, without great success, until the death of Niépce in 1833. Daguerre, continuing his experiments after this event with the son of Niépce, was fortunate enough to discover, in 1839, the method which bears his name, and to obtain a prize and pension offered by the French government for the discovery of a method for permanently fixing the image formed in the camera. The process of Daguerre consisted essentially in allowing the vapour of iodine to act upon a plate of polished silver, which thus becomes coated with a thin film of iodide of silver; the plate prepared in this way

* See Report by Robert Hunt "On the present state of our knowledge of the Chemical Action of the Solar Radiation," Brit. Assoc. Reports for 1850.

† Journal of Royal Institution, June 1802.

was next exposed to light in the camera, so arranged that the image of the object to be copied fell upon the iodised surface, which thereby undergoes a change, not however visible on withdrawing the plate from the camera. In order to develop the latent image, the plate was exposed to the action of the vapour of mercury, which produces different effects on various parts of the plate, according as the iodide has been more or less altered by the action of the light. The undecomposed iodide was then dissolved by placing the plate in a strong solution of hyposulphite of sodium, and the picture was thereby permanently fixed. Since Daguerre's time, this process has undergone considerable improvements; amongst these, we may mention the exposure of the plate to the vapour of bromine, by which the sensitiveness of the film is greatly increased, and the reduction of metallic gold upon the surface of the film during the process of fixing, by which the lights and shades of the picture are rendered more effective. For the details of the process, as now practised, we must refer the reader to photographic text-books.

The nature of the invisible chemical change effected by the light on the iodobromide of silver is not understood, but it is evidently analogous to the change produced by the light on the mixture of chlorine and hydrogen before combination ensues, which has been termed photochemical induction, the film being so modified as to render it susceptible of decomposition when brought into contact with the vapour of mercury. The amalgam thus produced varies in thickness according to the intensity and duration of the action of the light, and different shades are therefore seen, when the picture is viewed by reflected light, corresponding to the lights and shades of the real object.

The subject of the production of sun-pictures on paper attracted but little attention from the time of Wedgwood until the year 1839, when Mr. Fox Talbot published his plan of "photogenic drawing." This consisted in exposing in the camera a paper soaked in a weak solution of common salt, and afterwards washed over with a strong solution of nitrate of silver; the image thus obtained was a negative one, the light being dark and the shadows light, and the pictures were fixed by immersion in a solution of common salt.

Many improvements have been made in this process. In 1841 Fox Talbot patented the beautiful process known as the "Talbotype or Calotype process," in which the paper is coated with iodide of silver by dipping it first in nitrate of silver, then in iodide of potassium. Paper thus prepared is not sensitive *per se* to the action of light, but may be rendered so by washing it over with a mixture of nitrate of silver and gallic or acetic acid. If it be exposed to the camera for two or three minutes, it does not receive a visible image (unless the light has been very strong); but still the compound has undergone a certain change by the influence of the light: for, on subsequently washing it over with the mixture of aceto-nitrate of silver and gallic acid, and gently warming it, a negative image comes out on it with great distinctness. This image is fixed by washing the paper with hyposulphite of sodium, which removes the whole of the iodide of silver not acted upon by the light, and thus protects the picture from further change by exposure to light. The negative picture thus obtained is rendered transparent by placing it between two sheets of blotting-paper saturated with white wax, and passing a moderately heated smoothing-iron over the whole. It may then be used for printing *positive pictures*, by laying it on a sheet of paper prepared with chloride or iodide of silver, and exposing it to the sun.

A most important step in the progress of photography is the substitution, by Mr. Archer, of a transparent film of iodised collodion spread upon glass for the iodised paper used in Talbot's process, to receive the negative image in the camera. The process is thus rendered so much more certain and rapid, and the positive pictures obtained by transferring the negative by printing on paper are found to be so much sharper in outline, than when the transference occurs through paper, as in the Talbotype process, that this method is now universally employed. In this process, as in that of the Calotype, the image produced in the camera is a latent one, and requires development with substances such as pyrogallie acid, or protosulphate of iron, which, having a tendency to absorb oxygen, induces, in presence of nitrate of silver, the reduction of the chloride or iodide to the metallic state. For a description of the best apparatus and latest processes used in the Collodion method, the reader may consult Hardwich's "Manual of Photographic Chemistry."

A large number of other metallic salts besides the salts of silver are acted upon by light. The photochemical relations of many of these salts have been specially studied by Sir John Herschel (Phil. Trans. 1840), in his celebrated Memoir "On the Chemical Action of the Rays of the Solar Spectrum;" and, founded upon these different actions, a number of methods of producing pictures have been described, all of which are of secondary interest. For a full description of these methods, we may refer the reader to Hunt's "Researches on Light."

Nature of the Chemical Change effected by Light on Silver Salts.—Although the exact chemical decomposition effected by light on the chloride, bromide, and iodide of silver has long been a subject of experimental discussion, still much remains to be learnt concerning the composition of the photographic image. The general result of investigations upon this subject may be stated to be that, in the first place, a sub-salt of silver of a grey or violet colour is formed, whilst by a further action of the light the silver is probably reduced to the metallic state. It appears, however,* most difficult to prepare the sub-salts of silver in a pure state, either by the action of light, or by other chemical methods, the evidence of the presence of such a salt in the violet-coloured chloride depending upon the well-known fact that this substance is unacted upon by nitric acid, but decomposed by ammonia into chloride and metal. The recent experiments of Vogel (Pogg. Ann. cxvi. 497) confirm this result, as he shows that when pure and dry chloride and bromide of silver are insolated, chlorine and bromine are liberated, and a substance insoluble in nitric acid, in each case, produced: he was unable to detect free iodine when pure iodide of silver is exposed to light, and hence he concludes that this salt is not decomposed by light. Vogel has likewise observed that the results obtained when the above-mentioned salts are prepared with an excess of silver-salt, instead of an excess of the precipitant, are somewhat different: thus, whilst the iodide prepared with excess of iodide of potassium shows no change of colour, that prepared with excess of silver becomes decidedly grey on exposure to light.

A singular effect produced by the red rays upon a blackened silvered paper was observed long ago by Ritter, and confirmed by Herschel. If prepared paper soaked in nitrate of silver solution be blackened by exposure to light, and then submitted to the action of the solar spectrum, those portions upon which the violet rays fall become darker, whilst those exposed to the red rays become lighter, and assume a brick-red colour; hence it would appear that the least refrangible rays exert opposite actions upon the sensitive silver-salts. Claudet has also shown (Phil. Trans. 1847) that exposure to the red rays neutralises the effect previously produced on a sensitised daguerreotype plate by white light.

We are as yet quite unacquainted with the essential nature of the change brought about by the action of light. Thus, we do not know whether, in the blackening of chloride of silver, the light used up in the decomposition is equivalent to the work done, as in the case of the decomposition of water by the galvanic current where the force needed to separate the molecules of oxygen and hydrogen is as large as that evolved by the combinations of the gases; or, whether the chemical actions of light resemble that sudden splitting up which occurs in certain compounds (the chloride of nitrogen, for example) where they are placed in circumstances under which they can no longer exist, and where the force establishing the change bears no equivalent relation to the forces developed in the resulting decomposition.

Chromo-photography.—Many attempts have been made to reproduce in the photograph the colours of natural bodies; and although these attempts have not succeeded to the full extent of fixing the coloured picture, yet a certain degree of progress in the production of tinted images has been made. Thus, for instance, Becquerel (Ann. Ch. Phys. [3] xlii. 81) has described a method by which a coloured image of the solar spectrum can be prepared, as well as representations of the coloured rings formed in crystals by polarised light. In order to obtain these coloured images, a polished plate of silver is immersed in dilute hydrochloric acid, and a film of sub-chloride formed upon the silver by allowing the plate to form the positive electrode of a Bunsen's battery. The plate thus prepared becomes variously tinted when exposed to the solar spectrum, some of the rays being reproduced with their distinctive colours, whilst others either produce no effect or give rise to tints differing from their own. Other experimenters, especially Niépce de St. Victor and Campbell, have obtained somewhat analogous results; but, as yet, the coloured images produced by these and similar processes have resisted all attempts to render them permanent.

Photographic Engraving, Lithography, and Galvanography.—The original photographic process proposed in 1827 by Niépce has been lately modified by M. Niépce de St. Victor, for the production of photographic engraving on steel. A plate of steel is covered with a layer of prepared bitumen, and being placed under an ordinary positive photograph, is exposed to light; on treating the bitumen with naphtha and benzol, those portions which have not been insolated dissolve, leaving the steel plate exposed for the subsequent action of acid. The plate thus prepared is then submitted to the usual processes employed in aqua-tint engraving. A somewhat similar process was patented by Mr. Fox Talbot, in 1858, for etching by chemical means a positive photograph on a copper plate. This method has recently been modified,

* See Report on the Nature of the Photographic Image, Brit. Assoc. Reports, 1859, p. 106.

and applied independently by Sir H. James and Mr. Osborne of Melbourne, to the production of lithographs and zincographs from photographs. Mr. Osborne's process consists in coating a sheet of paper with a solution of acid chromate of potassium in gelatin, and exposing the prepared paper to light by placing a negative photograph over it. After a few minutes' exposure, the paper is placed in water; the unchanged portions are then easily washed away, and those parts which have been acted upon by the light remain. This picture is then coated with lithographic ink, and transferred to the lithographic stone by pressure; the prints, obtained by transfer in the usual way, are remarkably sharp and delicate.

A process of photogalvanography, founded on the decomposition of gelatin and acid chromate of potassium, has likewise been proposed. The action of light on this mixture produces a change in the gelatin, rendered evident on immersing the plate in water, by a difference of level of the various parts. A mould of this raised picture is then taken in gutta percha, and a copper plate is made from the gutta-percha mould by the electrolytic process; this plate is again copied by electrolysis, and from this second copper plate the prints are struck off. This process gives the means of making an infinite number of multiplications of the same subject, but the impressions obtained are not very distinct.

H. E. R.

LIGNIN. Syn. with CELLULOSE (i. 818).

LIGNITE. See COAL (i. 1032) and FUEL (ii. 721).

LIGNOIN. $C^{20}H^{20}NO^6$.—A brown substance obtained by Reichel (*Ueber Chinarine und deren chemische Bestandtheile*, Leipzig, 1856) from old Huanoco cinchona-bark, and further examined by Hesse (Ann. Ch. Pharm. cix. 341). It is very soluble in alkaline carbonates; the solution does not absorb oxygen from the air at common temperatures. The brown substance, boiled with caustic potash, gives off ammonia; and the substance then remaining in solution appears to have the composition $C^{20}H^{20}O^6$, agreeing with quinoxa-red and phlobaphene, and resembling a substance obtained by Reichel from red cinchona-bark. Hesse is of opinion that a brown humus-like substance, having also the composition $C^{20}H^{20}O^6$, and essentially different from Schwartz's cinchona-red (i. 969), is deposited in the barks of cinchona and other allied species.

LIGNONE or XYLITE. These names were applied to a volatile liquid of variable composition, and boiling at about 60° , obtained from crude wood-spirit by treatment with chloride of calcium, and subsequent rectification. Völekel (Pogg. Ann. lxxxiii. 272, 557) assigned to it the composition $C^{12}H^{12}O^2$; but the analyses made of it by other chemists, viz. Weidemann and Schweizer, Liebig, Kane, and L. Gmelin, exhibit great discrepancies (the percentage of carbon differing by about 10 per cent.), and Dancer (Chem. Soc. J. xvii. 222), by a more careful investigation of crude wood-spirit, has shown that it is a mixture, in variable proportions, of methylic alcohol, acetone, acetate of methyl, and dimethyl-acetal, $C^{11}H^{10}O^2 = \frac{(C^{11}H^{10})}{(CH^3)^2}O^2$, and that the supposed lignone or xylite has no existence. (See METHYL-ACETAL and METHYL-ALCOHOL.)

LIGULIN. See LIGUSTRUM.

LIGURITE. A mineral having the angles and character of sphene (Dufrenoy), found in a talcose rock in the Apennines.

LIGUSTRIN. See the next article.

LIGUSTRUM VULGARE. *Privet*.—The ripe berries of this plant contain, according to Nicklès (J. Pharm. [3] xxxv. 328), a crimson colouring matter, ligulin, soluble in water and in alcohol, either pure or etherised, but insoluble in ether. It does not contain nitrogen, is not decomposed by 48 hours' boiling with pure water, is coloured green by alkalis (Nicklès recommends this reaction for detecting acid carbonate of calcium in water), and reddened again by acids. It has not been obtained pure.

The leaves of privet yield, according to Pollex (Arch. Pharm. [2] xvii. 75), a yellow, hygroscopic, bitter extract, called ligustrin, insoluble in ether and in absolute alcohol, but soluble in water and in dilute alcohol, forming solutions which do not give distinct reactions with any metallic salts. Strong sulphuric acid gives, with ligustrin, a deep indigo-blue colour, changing on dilution to a cornflower-blue or violet.

The leaves and bark of privet contain mannite. (Pollex, *loc. cit.* Kromayer, *ibid.* ci. 281.)

LILLITE. A silicate of iron from Przibram in Bohemia, having the appearance of green earth or glauconite, and probably a product of the decomposition of iron pyrites. It is a dull, amorphous, earthy substance of blackish-green colour, and in fine powder, appearing translucent with leek-green colour under the microscope. Hardness

— about 2. Specific gravity = 3.043. A specimen, as pure as could be obtained (it is often mixed with iron pyrites and ferric hydrate), gave, by analysis, 32.48 silica, 51.52 iron and oxygen, and 10.20 water (= 94.20, including 1.96 carbonate of calcium, and 0.63 iron pyrites), agreeing approximately with the formula $(2\text{FeO} \cdot 3\text{SiO}_2 \cdot \text{H}_2\text{O}) \cdot (\text{Fe}^{2+}) \cdot \text{H}_2\text{O}^4$.

LIMACIN. A substance obtained by Braconnot (Ann. Ch. Phys. [3] x. 319) from the garden-snail (*Limax agrestis*). When dry it forms a white earthy mass, easily crumbled between the fingers. It is somewhat soluble in cold, more soluble in boiling water, soluble in boiling alcohol, in concentrated hydrochloric acid, and easily in alkaline liquors. The solution in cold water is precipitated by tannic acid, corrosive sublimate, neutral lead-acetate, ferrous sulphate, and the acetates of copper and manganese, but not by oxalate of ammonium. By dry distillation it yields carbonate of ammonium, and leaves charcoal with a small quantity of alkaline ash.

LIMAX. According to A. Vogel and C. Reischauer (N. Jahrb. Pharm. ix. 179), many coloured snails of the genus *Limax* contain a colouring matter which appears violet in dilute acid solution, brown or black in more concentrated solution. It is obtained by macerating the animals, freed from their viscera, with dilute nitric acid, and precipitating the solution with ammonia. The brown or black iridescent precipitate is insoluble in water and in alcohol. The nitric acid solution gradually assumes a crimson colour, then becomes colourless. The colouring matter, when ignited, leaves a large quantity of phosphate of calcium.

LIMBELITE. Syn. with CHRYSOLITE (i. 958).

LIME. Oxide of calcium (see CALCIUM, i. 718).

LIME, CHLORIDE OF. See CHLORINE (i. 904, 908) and HYPOCHLORITES (iii. 237).

LIME, OIL OF. $\text{C}^{10}\text{H}^{16}$.—The volatile oil of *Citrus Limetta*, obtained by distilling the torn and pressed rinds with water (i. 1003).

LIME-FLOWER, OIL OF. A volatile oil, obtained from the flowers of *Tilia europæa*, by distillation with water (Brossat, J. Pharm. vi. 396), or by exhaustion with ether in a percolator. The amount does not exceed 0.1 per cent. It is lighter than water, very volatile, and has a strong odour of lime-flowers. (Gm. xiv. 378.)

LIMESTONE. The generic name of all rocks having carbonate of calcium for their principal constituent. The principal accessory constituents are as follows:—1. Silica and alumina. The former occurs in crystalline limestones, sometimes as crystalline quartz; in compact limestones, sometimes as sand in small quantity; most frequently combined with alumina, in the form of clay. Nearly all limestones contain small quantities of clay, and in some the quantity amounts to several units per cent., the limestone then passing into marl. Limestones also occur containing silicate of calcium, as at Gjellebæk in South Norway.—2. Iron: sometimes as ferric oxide, sometimes as ferrous carbonate; generally only in small quantities and traces.—3. Manganese: either as manganic oxide or as manganeous carbonate. In still smaller quantity than the iron, and often absent altogether.—4. Magnesia, as carbonate: a very frequent accessory constituent of limestones, but in true limestones not exceeding 0.5 to 1.0 per cent. When the proportion is larger, the limestone passes into dolomitic limestone and dolomite.—5. Phosphoric acid: appears to occur only occasionally, and in very inconsiderable quantity, no limestone having yet been found to contain more than 0.2 per cent. of it.—6. Alkalis, namely potash and soda, have been found in a considerable number of limestones by Schramm (J. pr. Chem. xlvii. 440) and Fehling (*ibid.* 446). Schramm found from 0.1 to 0.3 per cent. alkali, for the most part as carbonate, in smaller quantity as chloride. Fehling obtained from aluminous limestones about 3 per cent. alkaline carbonate. According to Schramm, soda always occurs in larger quantity than potash, about in the ratio of 2 at. soda to 1 at. potash.—7. Organic (bituminous) matter, probably in all limestones, excepting a few crystalline ones; sometimes in mere traces, sometimes in more considerable quantities. In anthraconite, stinkstone, and bituminous limestone, the presence of organic matter is very conspicuous.

The following enumeration of the sub-species and varieties of limestone is taken from *Ure's Dictionary of Chemistry*, and originally from *Jamson's Mineralogy*:

1. Foliated limestone; of which there are two kinds—*calcspar*, and *foliated granular limestone*. The first will be found in its alphabetical place in this Dictionary.

Granular foliated limestone.—Colour white, of various shades, sometimes spotted; massive, and in distinct angulo-granular concretions; lustre glistening, between pearly and vitreous; fracture foliated; translucent; hard as calcspar; brittle; specific gravity (of Carrara marble) 2.717. It generally phosphoresces when pounded, or when thrown on glowing coals; infusible; effervesces with acids. It is a pure carbonate of

calcium. Occurs in beds in granite, gneiss, &c., and rarely in secondary rocks; it is found in all the great ranges of primitive rocks in Europe, and affords the finest marbles. Parian marble, Pentelic marble, the Marmo Greco, the white marble of Luni, of Carrara and of Mount Hymettus, the translucent white marble of statuaries, and flexible white marble, are the chief of the white marbles which the ancients used for sculpture and architecture. The red antique marble, *Rosso antico* of the Italians, and Egyptian of the ancients; the *Verde antico*, an indeterminate mixture of white marble and green serpentine; yellow antique marble; the antique Cipolin marble, marked with green-coloured zones, caused by talc or chlorite; and African breccia marble, are the principal coloured marbles of the ancients. The Scottish marbles are—the red and white Tires, the former of which contains hornblende, sahlite, mica, and green earth; the Iona marble, harder than most others, consisting of limestone and tremolite, or occasionally a dolomite; the Skye marble; the Assynt in Sutherland, introduced into commerce by Mr. Joplin, of Gateshead: it is white and grey, of various shades. The Glentilt marble; the Balachulish; the Boyne; the Blairgowrie; and the Glenavon. Hitherto, but few marbles of granular foliated limestone have been quarried in England. The *Mona marble* is not unlike *Verde antico*. The black marbles of Ireland, now so generally used by architects, are lucullites. The Torven, in the county of Waterford, is a fine variegated sort; and a grey marble, beautifully clouded with white, has been found near Kilerump, in the same county. At Loughlougher, in Tipperary, a fine purple marble is found. The county of Kerry affords several variegated marbles. Of the Continental marbles, a copious account is given by Professor Jameson, *Mineralogy*, vol. ii. p. 502.

2. Compact limestone; of which there are three kinds—common compact limestone, blue Vesuvian limestone, and roestone.

a. Common compact limestone has usually a grey colour, with coloured delineations. Massive, corroded, and in various extraneous shapes; dull; fracture fine splintery; translucent on the edges; softer than the preceding sub-species; easily frangible; streak greyish-white; specific gravity 2.6 to 2.7. It effervesces with acids, and burns into quicklime. It is a carbonate of calcium, with variable and generally minute proportions of silica, alumina, iron, magnesia, and manganese. It occurs principally in secondary formations, along with sandstone, gypsum, and coal. Many animal petrifications, and some vegetable, are found in it. It is rich in ores of lead and zinc, the English mines of the former metal being situated in limestone. When it is so hard as to take a polish, it is worked as a marble, under the name of shell, or *tumacella* marble. It abounds in the sandstone and coal formations, both in Scotland and England; and in Ireland it is a very abundant mineral in all the districts where clay-slate and red sandstone occur. The Florentine marble, or *ruin marble*, is a compact limestone. Seen at a distance, slabs of this stone resemble drawings done in bistre.

b. Blue Vesuvian Limestone. Colour dark bluish-grey, partly veined with white; rolled and uneven on the surface; fracture fine earthy; opaque; streak white; semihard in a low degree; feels heavy. Its constituents are, lime 58, carbonic acid 28.5, water somewhat ammoniacal 11, magnesia 0.5, oxide of iron 0.25, carbon 0.25, and silica 1.25 (Klaproth). It is found in loose masses among unaltered ejected minerals, in the neighbourhood of Vesuvius. In mosaic work, it is used for representing the sky.

c. Roestone. Colours brown and grey; massive, and in distinct concretions, which are round granular; dull; opaque; fracture of the mass round granular; approaching to soft; brittle; specific gravity, 2.6 to 2.68. It dissolves with effervescence in acids. It occurs along with red sandstone and lias limestone. In England this rock is called Bath-stone, Ketton-stone, Portland-stone, and Oolite. It extends, with but little interruption, from Somersetshire to the banks of the Humber in Lincolnshire. It is used in architecture, but is porous, and apt to moulder away, as is seen in the ornamented work of the chapel of Henry VII.

3. Chalk, already described (i. 845).

4. Agaric mineral, or Rock-milk. Colour white; in crusts or tuberos pieces; dull; composed of fine dusty particles; soils strongly; feels meagre; adheres slightly to the tongue; light, almost supernatant. It dissolves in hydrochloric acid with effervescence, being a pure carbonate of calcium. It is found on the north side of Oxford, between the lias and the Cherwell, and near Clipping Norton; as also in the fissures of limestone caves on the Continent. It is formed by the attrition of water on limestone rocks.

5. Fibrous limestone, of which there are two kinds—satin-spar, or the common fibrous; and fibrous calc-sinter. *Satin-spar*. White of various shades; massive, and in distinct fibrous concretions; lustre glistening and pearly; fragments splintery;

feebly translucent; as hard as calcareous spar; easily frangible; specific gravity 2.7. Its constituents are, lime 50.8, carbonic acid, 47.6? Stromeyer says it contains small quantities of gypsum. It occurs in thin layers in clay-slate at Alston Moor in Cumberland; in layers and veins in the middle district of Scotland, as in Fifeshire. It is sometimes cut into necklaces, &c.

Fibrous calc-sinter. Used as marble; the ancients formed it into unguent vases, the alabaster-box of Scripture. See CALC-SINTER (i. 720).

6. Tufaceous limestone, or Calc-tuff. Colour grey; massive, and in imitative shapes; enclosing leaves, bones, shells, &c.; dull; fracture fine-grained uneven; opaque; soft; feels rough; brittle. It is pure carbonate of calcium. It occurs in beds, generally in the neighbourhood of rivers; near Starly-burn in Fifeshire, and other places. Used for lime.

7. Pisiform limestone, or Peastone. Colour yellowish-white; massive, and in distinct concretions, which are round granular, composed of others which are very thin and concentric lamellar. In the centre there is a bubble of air, a grain of sand, or of some mineral matter; dull; fracture even; opaque; soft; brittle; specific gravity 2.532. It is carbonate of calcium. It is found in great masses in the vicinity of Carlsbad in Bohemia.

8. Slate-spar; *Schieferepath*. Colour white of various shades; massive, and in distinct curved lamellar concretions; lustre glistening and pearly; feebly translucent; soft; between sectile and brittle; feels rather greasy; specific gravity 2.63. Its constituents are, carbonate of calcium, with three per cent. of oxide of manganese. It occurs in primitive limestone, in metalliferous beds, and in veins. It is found in Glentilt; in Assynt; in Cornwall; and near Granard in Ireland.

9. Aphrite (i. 349).

10. Lucullite; of which there are three kinds—compact, prismatic, and foliated.

a. Compact lucullite is subdivided into common or black marble; and stinkstone.

a. *The common compact.* Colour greyish-black; massive; glimmering; fracture fine-grained, uneven; opaque; semi-hard; streak dark ash-grey; brittle; specific gravity 3. When two pieces are rubbed together, a fetid urinous odour is exhaled, which is increased by breathing on them. It burns white, but forms a black-coloured mass with sulphuric acid. Its constituents are, lime 53.38, carbonic acid 41.5, carbon 0.75, magnesia and oxide of manganese 0.12, oxide of iron 0.25, silica 1.13, sulphur 0.25, chloride and sulphate of potassium with water 2.62 (John). It is said to occur in beds in primitive and older secondary rocks. Hills of this mineral occur in the district of Assynt in Sutherland. Varieties of it are met with in Derbyshire; at Kilkenny; in the counties of Cork and Galway. It is the *Nero antico* of the Italians.

β. *Stinkstone or Swinestone.* Colour white of many shades, cream-yellow, grey, black, and brown; massive, disseminated, and in distinct granular concretions; dull; fracture splintery; opaque; semi-hard; streak greyish-white; emits a fetid odour on friction; brittle; specific gravity 2.7. The same chemical characters as the preceding. Its constituents are, 88 carbonate of calcium, 4.13 silica, 3.1 alumina, 1.47 oxide of iron, 0.58 oxide of manganese, 0.30 carbon, 0.58 lime; sulphur, alkali, salt, water, 2.20 (John). It occurs in beds, in secondary limestone, alternating occasionally with secondary gypsum and beds of clay. It is found in the vicinity of North Berwick, resting on red sandstone, and in the parish of Kirbean in Galloway. It is employed for burning into lime.

b. *Prismatic lucullite.* Colours black, grey, and brown; massive, in balls, and in distinct concretions; external surface sometimes streaked, internal lustre shining; cleavage threefold; translucent on the edges; semi-hard; streak grey; brittle; when rubbed it emits a strongly fetid urinous smell; specific gravity 2.67. When its powder is boiled in water, it gives out a transient hepatic odour. The water becomes slightly alkaline. It dissolves with effervescence in hydrochloric acid, leaving a charcoaly residuum. Its constituents resemble those of the preceding. It occurs in balls, in brown dolomite, at Building-hill near Sunderland. It was at one time called *madrepore*.

c. *Foliated or sparry lucullite.* Colours white, grey, and black; massive; disseminated and crystallised in acute six-sided pyramids; internal lustre glimmering; fragments rhomboidal; translucent; semi-hard; brittle; emits on friction a urinous smell; specific gravity 2.65. In other respects similar to the preceding. It is found in veins at Andreasberg in the Hartz.

11. Marl; of which there are two kinds, earthy and compact. *Earthy marl* has a grey colour; consists of fine dusty particles, feebly coherent; dull; soils slightly; is light; effervesces with acids; and emits a urinous smell when first dug up. Its constituents are, carbonate of calcium, with a little alumina, silica, and bitumen. It occurs

in beds in the secondary limestone and gypsum formations in Thuringia and Mansfeld. *Compact marl* has a grey colour; is massive, vesicular, or in flattened balls; contains petrifications; dull; fracture earthy, but in the large masses slaty; yields to the nail; opaque; streak greyish-white; brittle; feels meagre; specific gravity 2.4. It intensifies before the blowpipe, and melts into a greenish-black slag. It effervesces with acids. Its constituents are, carbonate of calcium 50, silica 12, alumina 32, iron and oxide of manganese 2 (Kirwan). It occurs in beds in the secondary floetz limestone. It is frequent in the coal-formations of Scotland and England.

12. Bituminous marl-slate. Colour greyish-black; massive, and frequently with impressions of fishes and plants; lustre glistening; fracture slaty; opaque; shining streak; soft; sectile; frangible; specific gravity 2.66. It is said to be carbonate of calcium, with albumin, iron, and bitumen. It occurs in floetz limestone. It frequently contains cupreous minerals, petrified fishes, and fossil remains of cryptogamous plants. It abounds in the Hartz. (Jameson.)

LIMETTIC ACID. $\text{C}^{\text{H}}\text{O}^{\text{A}}$ (H. Vohl, N. Ber. Arch. lxxiv. 16).—An acid produced, together with formic and acetic acids, by treating oil of lime, or oil of rosemary, with acid chromate of potassium and sulphuric acid. As soon as the action is finished, the liquid is diluted with water, and the limettic acid, which separates as a resin, is washed and purified by repeated solution in aqueous carbonate of potassium, precipitation with nitric acid, and recrystallisation from alcohol.

Limettic acid is white, crystalline; volatilises when heated, and forms a crystalline deposit on cold bodies. It has neither taste nor smell; dissolves sparingly in water, easily in alcohol.

The silver-salt, $\text{C}^{\text{H}}\text{Ag}^{\text{O}}$, obtained by adding nitrate of silver to the acid neutralised with ammonia, forms a powder sparingly soluble in water and blackening on exposure to light.

LIMONIN. The bitter principle contained in the pips of oranges and lemons. It forms small, bitter crystals, sparingly soluble in water, ether, and ammonia; easily in alcohol, acetic acid, and potash; from the potash-solution it is precipitated by acids. Sulphuric acid dissolves it, forming a red liquid, from which the limonin is precipitated by water. Nitric acid dissolves it without alteration. It melts at 124° , and solidifies to an amorphous mass on cooling. According to Schmidt's analysis (calculated with the old atomic weight of carbon), it contains 66.04 65.62 per cent. carbon, and 6.32–6.49 hydrogen, whence Schmidt deduced the formula $\text{C}^{24}\text{H}^{10}\text{O}^{12}$. (Bernays, Buchner's Rep. [3] xxi. 306.—Schmidt, Ann. Ch. Pharm. li. 338.)

LIMONITE. Brown Hematite. Hydrated Sesquioxide of Iron (See IRON, OXIDES OF, p. 395.)

LINARITE. $\text{PbSO}_4 \cdot \text{CuH}^{\text{O}}_2$. Cupreous Sulphate of Lead. Cupreous Anglesite. Bleisatz. Kupferbleispath.—Occurs in crystals belonging to the monoclinic system. Specific gravity 5.2–5.5. Hardness 2.5–3. Lustre vitreous or adamantine. Colour deep azure-blue. Streak pale blue. Translucent. Fracture conchoidal. Analysis by Brooke, 75.4 sulphate of lead, 18.0 oxide of copper, 4.7 water = 98.1; by Thomson, 74.8 sulphate of lead, 19.7 oxide of copper, and 5.5 water. It occurs at Leadhills, also at Roughton Gill in Cumberland, in crystals sometimes an inch long; at Linares in Spain, and near Ems. It occurs altered to cerussite, a change like that of anglesite to cerussite. (Brooke, Ann. Phil. [2] iv. 117.—Thomson, Phil. Mag. 1840; see p. 402.—Dana, ii. 391.)

LINCOLNITE. See STILBITE.

LINDACKERITE. A mineral consisting of arsenite of copper with basic sulphate of nickel, and water; and containing, according to Lindacker's analysis (Jahrb. K. K. Geol. Reichs. iv. 552), 28.58 As^{O}_3 , 6.44 SO_4 , 16.15 NiO , 2.90 FeO , and 9.32 water (= 99.73), agreeing nearly with the formula $2\text{Cu}(\text{AsO}_3)_2 \cdot \text{NiSO}_4 \cdot 2\text{NiO} \cdot 8\text{H}^{\text{O}}$. Specific gravity 2–2.5. Hardness 2–2.5. Lustre vitreous. Colour verdigris to apple-green. Streak pale green to white. It dissolves after longer heating in hydrochloric acid. (Dana, ii. 500.)

LININ. A crystallisable substance from *Linum catharticum* (Pagenstecher, Ann. Ch. Pharm. xl. 322.—Handw. d. Chem. iv. 924). According to C. Schröder (N. Repert. Pharm. x. 11), the best mode of preparing it is to digest a considerable quantity of the plant with dilute milk of lime; mix the filtered yellow liquid with hydrochloric acid, which forms a precipitate remaining suspended in the liquid; agitate with ether, and leave the linin to crystallise from the ethereal solution. It forms small white crystals, having a silky lustre, heavier than water, dissolving very sparingly in water, very easily in alcohol and ether, somewhat less easily in acetic acid and in chloroform. The aqueous solution tastes slightly, the alcoholic solution intensely and persistently.

bitter. Linin melts and decomposes when heated. It gives by analysis 61.92 per cent. carbon and 4.72 hydrogen; does not evolve ammonia when boiled with milk of lime.

LINNÆITE. Native sulphide of cobalt.

LINOLEIC ACID. *Papaveroleic acid. Trockenölsäure.*— $C^{18}H^{32}O^2$. (Pelouze and Boudet, Ann. Ch. Phys. [2] lix. 43.—Laurent, *ibid.* lxx. 150 and 298.—Liebig, Ann. Ch. Pharm. xxxiii. 113.—Sacc, *ibid.* li. 214.—Schüler, *ibid.* ci. 252.—A. C. Oudemans, Jun. Scheik. Onderzoek. i. Stuk. 184.—Gm. xvi. 306).—An oily acid occurring in linseed and poppy oils, and perhaps also in other drying oils. To prepare it, linseed oil (or poppy oil) is saponified, and the soap purified by repeated salting out, after which it is dissolved in a large quantity of water, and thrown down by an excess of chloride of calcium. The precipitated calcium-salt is washed, pressed, and digested in ether, which dissolves out the linoleate of calcium, and leaves the salts of the solid fatty acids undissolved. The ethereal solution is decomposed by cold hydrochloric acid, whereby the linoleic acid is separated, and remains dissolved in the ether; the solution is drawn off, and the ether distilled at as low a temperature as possible, in a stream of hydrogen. There then remains dark-yellow linoleic acid, which is dissolved in alcohol, and precipitated by ammonia and chloride of barium. The barium-salt, after being washed and pressed, is dissolved in ether, and the warts and granules, gradually formed in the solution, are repeatedly recrystallised from ether. From the barium-salt the acid is separated by agitating with ether and hydrochloric acid, pipetting off the ethereal layer of liquid, and distilling off the ether; it is dried in a vacuum over oil of vitriol and a mixture of lime and sulphate of iron (Schüler). A similar method is employed by Oudemans, who, however, prefers precipitating the linoleate of sodium by chloride of calcium in a strongly ammoniacal solution. Sacc digests linseed oil with oxide of lead and water, at a gentle heat; exhausts the pale-grey, greasy soap with ether, which leaves margarate (palmitate according to Schüler) and a little basic linoleate of lead undissolved; evaporates the ethereal solution; and decomposes the residue with hydrochloric acid. The acid thus obtained is washed with boiling water, dissolved in ether, and recovered by evaporating the solution. Or he decomposes the lead-salt with sulphydric acid, and extracts the linoleic acid with ether.

Properties.—Linoleic acid is a faint-yellow, limpid oil, of specific gravity 0.9206 at 14° , having a high refractive power, and a weak acid reaction. It does not solidify at 18° ; tastes mild at first, afterwards harsh (Schüler). It is more limpid than poppy oil (Oudemans). It is insoluble in water, but dissolves readily in ether, less easily in alcohol.

Decompositions.—1. On standing in the air for ten weeks, the acid absorbs 2 per cent. oxygen, and becomes viscid and tough (Schüler). It takes up more oxygen the fresher it is, and thickens, so that at last it will scarcely flow, but remains colourless, and does not evolve carbonic acid (Oudemans). A thin layer on wood exposed to the air forms a varnish; on glass it only becomes tough (Schüler). Linoleate of potassium or sodium, containing an excess of alkali, exposed in the finely divided state to the air, absorbs oxygen greedily, and becomes yellow and dry; it then dissolves in water with dark brown-red colour, and deposits, on addition of hydrochloric acid, a brown greasy resin, similar to that produced by the action of nitric acid (Sacc).—2. By dry distillation, products are formed, different from those yielded by oleic acid (Laurent).—3. With nitric acid, the acid swells up considerably, and yields a greasy resin, suberic acid, and a little oxalic acid, the last probably derived from adhering ether (Sacc). Nitrous acid and mercurous nitrate do not form elaidic acid with linoleic acid. (Pelouze and Boudet; Laurent; Schüler; Oudemans.)

Linoleates.—The mono-acid salts are difficult to obtain pure, and generally contain too small a proportion of base, on account of their easy conversion into acid salts (Schüler, Oudemans). They are white, for the most part uncrystallisable, and separate from their hot solutions in flakes; by spontaneous evaporation they are obtained in the form of a jelly. When exposed to the air, they become coloured and odorous. They are soluble in alcohol and ether. (Oudemans.)

Barium-salt.—The salt produced by mixing chloride of barium with the acid to which a large excess of ammonia has been added, contains a portion of baryta, varying from 12.04 to 24 per cent. ($C^{18}H^{30}BaO^2 = 23.46$ per cent. BaO). It is white; separates from alcohol on cooling in microscopic crystals, and from ether on spontaneous evaporation, in more distinct crystals. When exposed to the air, or when kept, and also on boiling with alcohol, it becomes yellow and sticky. It dissolves very easily in ether, less easily in alcohol; and is insoluble in water. (Oudemans.)

The calcium-salt resembles the barium-salt. It was only once obtained of the com-

position $C^{18}H^{14}Ca^{10}O^4$ (containing 9.72 per cent. CaO), and mostly contained a smaller proportion of lime. (Oudemanna.)

The *cupric salt* is bluish-green, insoluble in water, and nearly so in alcohol. (Oudemanna.)

Lead-salt.—The acid dissolves a large quantity of oxide of lead, and forms therewith a solid, plaster-like mass; with a smaller quantity of oxide of lead it forms a thick liquid which, on exposure to the air, remains for a long time greasy, and of the consistence of ointment (Liebig). The ethereal solution of the lead-salt becomes resinised during evaporation, and throws down a white basic salt, upon which an acid, red-brown, jelly-like salt is deposited; this last smells like linseed-oil, and shows a varying composition on analysis. Exposed to the air in thin layers upon wood, linoleate of lead does not form a varnish, but strips off in scales. (Sacc.)

The *magnesium-salt* is insoluble in water.

Silver-salt.—Nitrate of silver throws down, from the sodium-salt, a white precipitate, which easily blackens from reduction of silver. It dissolves readily in aqueous ammonia, and, on evaporating the solution, a portion crystallises out; another portion is decomposed and colours the liquid black. (Oudemanna.)

Sodium-salt.—When the acid is dissolved in caustic soda, salted out with chloride of sodium, and dried, and the residue is freed from chloride of sodium by dissolving it in ether and evaporating the solution, an acid salt is obtained containing 7.5 per cent. Na^2O , and agreeing with the formula $2C^{18}H^{14}NaO^2 \cdot C^{18}H^{14}O^2$; by calculation, 7.75 per cent. Na^2O .

The *zinc-salt* is insoluble in water.

LINSEED. The seed of the flax plant (*Linum usitatissimum*). The following analyses of it are given by Way (Journ. Roy. Agr. Soc. x. pt. 2.):

Composition of Linseed.

	Nitrogen, per cent.	Fat, per cent.	Ash, per cent.	Water, per cent.
From Riga	3.60	34.70	5.25	9.45
" Memel	3.33	36.00	3.66	8.74
" the Black Sea	3.31	38.42	5.64	10.22
English, 1847	4.60	36.66	2.68	12.33
" "	5.28	32.77	3.30	11.00
" "	4.25	33.50	4.08	10.58
" 1848	4.29	38.11	4.03	8.57

33 samples of oil-cake, obtained by expressing the fixed oil from linseed grown in various countries, exhibited an amount of nitrogen varying from 3.92 to 5.25 per cent., fat from 6.60 to 15.32 per cent., ash from 5.45 to 22.66 per cent., water from 6.66 to 10.26 per cent. The quantity of albuminous substances calculated from that of the nitrogen varies in the 33 samples from 25 to above 36 per cent.

Anderson (Highland Agr. Soc. J. new series, No. 69, p. 376) found in linseed, 24.44 albuminous substance; 34.00 oil; 30.73 gum, sugar, and cellulose; 3.33; ash and 7.50 water.

Meurein (J. Pharm. [3] xx. 96) has analysed the several parts of linseed with the following results:

Episperm 21	Gum and soluble salts	14
	Soft resin and fixed oil	1
	Water	2
	Matter insoluble in water and in ether	4
Endosperm 23	Soft resin and fixed oil	6
	Water	2
	Matter soluble in water	3
	Matter insoluble in water and in ether	12
	Fixed oil	30
	Water	5
	Matter soluble in water	3
	Matter insoluble in water and in ether	18

100

For analysis of the ash of linseed, see FLAX (ii. 657).

Linseed also contains a large quantity of mucilage, which is deposited in the outer layers of cells of the epidermis, and swells up when the seed is macerated with water, so much as to burst the cell-walls. 1 pt. of linseed boiled with 16 pts. water yields a mucilage thick enough to be drawn out into threads, and forming a dark-coloured

MUCILAGE. This crude mucilage contains, in addition to the true vegetable mucilage, mucous albumin, an organic acid, perhaps malic acid, and ash-constituents, such as potash and iron, partly as phosphates, partly united in the ash with carbonic acid. Linseed mucilage, precipitated by alcohol, gave 41 per cent. ash, containing 4 per cent. carbonic acid (Schmidt, Ann. Ch. Pharm. k. 29). See MUCILAGE.

LINSEED OIL. The fixed oil expressed from the seeds of *Linum catenatum* is taken as the type of the class of oils called drying oils, from their property of drying up, when exposed to the air, to a transparent resinous, not brittle mass. They probably all resemble linseed oil in containing a glyceride of linoleic acid, together with palmitin (and perhaps stearin), by the varying proportions of which their differences are determined. In the impure state, they contain also mucus, gum, and albumin, together with a yellow colouring principle possessed of taste and smell.

The cold-pressed oil of fresh linseed is pale yellow, and without disagreeable taste. The commercial oil is dark yellow, and has a sharp penetrating smell and taste. Specific gravity at 13° = 0.9347 (Schüler, Schübler), 0.9337 (van Kerchoff, Jahrbuch, 1859, p. 701); other statements vary between 0.928 and 0.952. Specific gravity at 12° = 0.9395; at 25° = 0.931; at 50° = 0.9125; at 94° = 0.8815, that of water at 15° being taken as unity (Saussure). It does not solidify at -15° to -16° (Gusserow), nor at -28° (Brandis); according to Schüler, it deposits a little solid fat at -18°. It contains, on an average, 78.11 per cent. C, 10.98 H, and 10.93 O (Sacco); the cold-drawn oil contains, on an average, 75.17 per cent. C, 10.98 H, and 18.85 O, corresponding to the formula $C^{18}H^{26}O^8$ (Lefort). (See Saussure's analysis, Ann. Ch. Phys. [2] xiii. 338.)

It contains margaric (palmitic, according to Schüler; stearic, according to Unverdorben), and a glyceride of linoleic acid (Sacc). By saponification, it yields 1/10th margarate, and 9/10ths linoleate of lead (Gusserow, Kastn. Arch. xix. 80).

Linseed oil exposed to sunshine for some weeks, in contact with an aqueous solution of an equal weight of protosulphate of iron, becomes limpid and colourless. Exposed to the air in thin layers, it dries up to a transparent, resinous, moderately elastic mass, resembling caoutchouc; when heated, however, it does not melt, but carbonises and burns (Leucho, Kastn. Arch. iii. 197). A peculiar fat is produced at the same time, together with a crumbly substance, insoluble in ether (Hoppe, J. pr. Chem. lxxx. 117). Mixed with chalk so as to form a powder, and exposed to the air for four weeks, it dries up completely, and on dissolving out the carbonate of calcium with hydrochloric acid and exhausting the residue with ether, a white mass of the consistence of tar is obtained, which behaves like oleic acid altered by exposure to the air. There remains behind resinous linseed oil in the form of a yellowish conglomerate mass, which is insoluble in alcohol, ether, volatile and fixed oils, is converted by alcoholic hydrochloric acid into a tarry substance, and dissolves in caustic potash (Unverdorben, Schw. J. xvii. 245).

Impure oil, containing mucus or albumin, becomes rancid in the air, more quickly in sunshine, and has then a repulsive odour and taste, a dark colour, and acid reaction. Concerning the formation of ozonised oxygen in the oxidation of linseed oil, see Schönbein (J. pr. Chem. lxxiv. 338). When the oil is boiled for some time, till it loses about 1/5 of its weight, it becomes thicker, tenacious, and viscid, and dries up still more readily than in the fresh state to a tough, turpentine-like mass, scarcely soluble in oils: *Printers' varnish*. (See IX, p. 272.)

Linseed oil (also nut or poppy oil), heated to about 323°—375°, takes fire and burns quietly, without further heating from without, till tar or charcoal remains. If the burning be interrupted by closing the vessel, there remains a brown, turpentine-like body which may be used as *birdlime*. When this substance is boiled continuously with water containing nitric acid (water being added to prevent the too violent action of the acid), an odour of acrolein is constantly evolved, and the substance becomes solid, of the consistence of plastic, resembles India-rubber, and no longer sticks to the fingers. It is then not completely fusible, dissolves to an emulsion in sulphide of carbon, shrinks when boiled with concentrated caustic potash, dissolves only on addition of water, and is again precipitated from the solution.

This substance is soluble in alcoholic potash and precipitable by acids; it is soluble in ether free from alcohol, and partly dissolves in a larger quantity of ether; it precipitates it from the solution. In rock-oil it swells without dissolving; it dissolves a little oil of turpentine, but dissolves completely in a larger quantity, and remains unaltered on evaporation. Linseed and nut oils yield eight or ten times as much of this caoutchouc-like substance as poppy oil (Jonas, N. Br. Arch. xli. 169; J. pr. Chem. xxxvii. 381).

Linseed oil submitted to *dry distillation* gives off, without boiling, white vapours, which condense to a colourless oil, having an odour of bread; on the disappearance of

these vapours, it begins to boil, expands, and yields a distillate of empyreumatic products until a mass resembling jolly and caoutchouc remains (Sacc.)

Sulphur dissolves in hot linseed oil with red colour, partially dissolving on cooling; on longer heating, the oil takes up, with evolution of sulphydric acid, 1 weight of sulphur, and forms therewith a brown viscous mass: *fatty balsam of sulphur* (See Radig, Horst and Ulex, N. Br. Arch. ii. 15; also Reinsch. J. pr. Chem. 136.) Linseed oil dissolves *selenium* (Berselius); it dissolves nearly 1/4th arsenic acid, whereby it is rendered heavier, precipitable by oil of vitriol and hydrochloric acid, and coagulable by alkalis (W. Henry, Schw. J. ii. 636). *Phosphorus* boiled with linseed oil acquires a scarlet colour (Reinsch. J. pr. Chem. xiv. 267). Heated with 1/4th its weight of phosphorus to 75°, the oil becomes brown-black, and after cooling forms a leathery substance insoluble in linseed oil; 1/4th phosphorus forms a thin tar, which mixes with the drying oils. (Jonas, N. Br. Arch. lxx. 139.)

When linseed oil is heated with 1/4th iodine, there pass over, first iodine, then an empyreumatic oil coloured brown by iodine; afterwards white vapours of hydriodic acid are evolved, followed by a thick yellowish oil, and at last charcoal, containing iodine, remains. (Reinsch. J. pr. Chem. xiv. 263.)

Brominated linseed oil is obtained by drenching the oil with 8 or 10 parts of water, heating it to between 50° and 80°, and adding bromine by drops as long as the colour disappears, removing the excess of bromine, if necessary, by further addition of oil. The product is then washed with warm water and dissolved in ether; the solution is shaken up with warm water, and the brominated oil thus freed is dried at 120°. It is brown, smells like linseed oil when heated, has a specific gravity of 1.345 at 14.5°, and contains 40.77 per cent. bromine, corresponding to the formula $C^{18}Br^8H^{26}O^2$. **Chlorinated linseed oil**, prepared in like manner, is a dark-yellow, thick liquid, of specific gravity 1.088 at 6.5°, and contains 22.62 per cent. chlorine ($C^{18}Cl^{12}H^{26}O^2$). (Lefort, J. Pharm. [3] xxiii. 343.)

On mixing from 15 to 25 pts. *chloride of sulphur* with 100 pts. linseed oil, caoutchouc-like products are obtained, which are the harder the more chloride of sulphur they contain, and are not attacked by moderately dilute acids and aqueous alkalis, but are ultimately saponified by concentrated alkalis. They become brown at 120°, and blacken and melt at a higher temperature. The addition of 5 per cent. chloride of sulphur thickens linseed oil, but does not cause it to harden; the product still retains the solubility of the fatty oils. When to a solution of 1 pt. linseed oil in 30 or 40 pts. sulphide of carbon, a quantity of chloride of sulphur is added equal to 1/4th the weight of the oil, the mixture remains fluid for some days, and dries up to a tarnish on wood. (Perra, Compt. rend. xviii. 878; see also Compt. rend. xvii. 972.)

With 1/4th its volume of *syrrupy phosphoric acid*, linseed oil becomes brownish-yellow or green. (Calvert.)

Cold strong *sulphuric acid* colours it yellowish-brown (Gaultier de Claubry), dark red-brown (Heidenreich, van Kerckhoff); it coagulates the oil, colours it purple-red, violet, and black, and evolves sulphurous and formic acids; and there remains at last a tough, black, ropy, saponifiable mass (Sacc). From this last, water and alcohol take up substances which precipitate gelatin: *Hatchett's artificial tannin*. A mixture of 5 volumes linseed oil with 1 volume sulphuric acid of specific gravity 1.478 to 1.635, shaken vigorously, becomes green in 15 minutes (Calvert). When 15 grs. linseed oil are mixed with 7 1/2 grs. sulphuric acid containing 90 per cent. H^2SO^4 , the temperature rises to 75°. (Fehling, Dingl. pol. J. cxxix. 53.)

Linseed oil takes fire with fuming *nitric acid*. Linseed, hemp, and poppy oils take fire more easily than nut-oil; with dilute nitric acid an addition of sulphuric acid is necessary (Rouelle). A vigorously shaken mixture of linseed oil with 1/4th its volume of nitric acid of specific gravity 1.18 to 1.22, becomes yellow in 5 minutes; with acid of specific gravity 1.33, green to brown; with nitro-sulphuric (equal parts of oil of vitriol and nitric acid), green (Calvert, Phil. Mag. [4] vii. 101; J. pr. Chem. lxi. 554). See also Lescallier, J. Pharm. xiii. 203. Linseed oil shaken with water and very dilute nitric acid, is decolorised after some time, and converted into a varnish (Ann. 1782, 49). On dropping 2 to 4 drams of strong nitric acid into a hundredweight of not linseed oil, a slimy sediment is formed, with frothing, and the oil is changed to a varnish, as with oxide of lead (Jonas, Ann. Ch. Pharm. xxxix. 238).—A mixture of 1 pt. linseed oil and 2 pts. commercial nitric acid, heated with 4 times its bulk of water, acquires a red colour, swells up, evolves nitric oxide, and forms a tough, elastic resin. This last contains margaric acid, and the mother-liquor oxalic and suberic acids. The resin, heated with nitric acid, again becomes oily, and is then decomposed (the margaric acid only remaining), with formation of suberic and pimelic acids and a volatile

fatty substance having the odour of butyric acid (Saccé).—With nitrous acid linseed oil does not form elaidic acid. (Pelouze and Boudet.)

In contact with aqueous ammonia and alcohol, it is attacked with difficulty, and yields a small quantity of warty crystals of an amide which melts at 100° , solidifies at 97° , and dissolves easily in alcohol; it contains, on an average, 75.25 per cent. C, 13.02 H, and 5.03 N, and has therefore the composition of margaramide, with which it is identical. (Rowney, J. pr. Chem. lxxvii. 159.)

Linseed oil yields, with alkalis, a very soft soap. On heating with 4th its volume of caustic soda of specific gravity 1.34, it turns yellow and remains fluid (Calvert). By distillation with an excess of alkali, it evolves hydrogen, together with a fishy odour, and yields a green distillate. (A. Müller, *Handwörterb.*, vi. 874.)

Potassium and sodium oxidise in linseed oil somewhat more quickly than in volatile oils, with formation of soap. (Gay-Lussac and Thénard.)

Linseed oil is oxidised with peculiar facility by acid chromate of potassium and dilute sulphuric acid, and yields an acid, strongly-smelling distillate. (Arzbücher, *Ann. Ch. Pharm.* lxxiii. 199.)

It dissolves oxide of lead when heated, and is decolorised thereby and rendered more easily drying, forming what is called *boiled oil* (see Liebig, *Ann. Ch. Pharm.* xxxiii. 110; W. Henry, *Seher. J.* ii. 636; Schindler, *N. Br. Arch.* xli. 146; Varrentrapp *Handwörterb.* iii. 123). When shaken with basic acetate of lead and left at rest, it throws down a turbid mucus containing oxide of lead, above which is a yellow varnish containing 4 or 5 per cent. oxide of lead. Exposed to the sun in contact with mercuric oxide, it reduces the mercury to a liquid mass (Fuchs, *Ann. Ch. Pharm.* xx. 200); partial reduction takes place in strong sunshine, the oxide becoming blackish-grey; but it is only when heat is applied, that a small quantity of metal is obtained. (*Ann. Ch. Pharm.* xx. 200.)

Linseed oil dissolves, according to Bucholz, in about 5 pts. of boiling and 40 pts. of cold alcohol; according to Brandes (Gilb. *Ann.* xlv. 289), in 32 pts. alcohol of specific gravity 0.82 and in 1.6 pt. ether.

LIPARITE. Syn. with FLUOR SPAR (ii. 677).

LIPIC ACID. $C^8H^{10}O^4 = C^8H^9O^4 \cdot H^2O$ according to Laurent (*Ann. Ch. Phys.* lxxvi. 169); $C^8H^9O^4$ according to Wirz (*Ann. Ch. Pharm.* cv. 257); the latter formula places it among the homologues of oxalic acid, included in the general formula $C^mH^{2m-2}O^4$. This acid, discovered by Laurent, is produced, together with pimelic, suberic, adipic, and other acids, by the action of nitric acid upon oleic, stearic, or palmitic acid, and is contained in the mother-liquor which remains after the pimelic and suberic acids have been separated.

The best mode of preparing it, is to heat oleic acid in a retort for about 12 hours with an equal weight of nitric acid of ordinary strength, then add fresh nitric acid, and repeat the operation four or five times. The united solutions are then to be evaporated to a fourth of their bulk, and the concentrated liquid left at rest, till pimelic and suberic acids crystallise out. The remainder of the nitric acid must then be removed from the mother-liquor by evaporation as completely as possible, taking care that the mass does not blacken from too great concentration; the crystals which separate from it, consisting of adipic and lipic acids, are dried and dissolved in hot ether, which leaves a few brown impurities undissolved; the solution is left to evaporate to half its bulk, and the liquid which covers the crystals is evaporated. The two products thus obtained, by evaporating the ether are separately dissolved in boiling alcohol, and the solutions are left to evaporate in the air. By repeating these operations several times, two acids are obtained, viz. adipic acid crystallised in rounded tuberculous aggregated grains, and lipic acid in slightly elongated laminae (Laurent), in translucent crusts made up of nodular groups of small prisms. (Wirz.)

Lipic acid is moderately soluble in cold water. When a few grains of it are heated on a watch-glass, till partial fusion takes place, the acid crystallises on cooling in a fibrous mass, while a portion volatilises and condenses on the non-melted mass in beautiful needles having the form of prisms with rectangular base.

The acid crystallised from water, contains 1 at. water, which it loses by sublimation, the anhydrous acid then condensing in long shining needles (Wirz). Its vapour is very suffocating and excites coughing. When deprived of its water of crystallisation, it does not melt below 140° or 145° (Laurent); according to Wirz it melts at 150° . It is very soluble in alcohol and ether.

Lipic acid is dibasic, the formula of its salts being $C^8H^8M^2O^4$, which is the same as that of the itaconates (Laurent); $C^8H^8M^2O^4$ (Wirz). The salts when heated with sulphuric acid give off lipic acid.

The ammonium-salt crystallises in long prisms (Laurent).—The barium-salt separates after a while from a mixed solution of chloride of barium and lipate of am-

prism in quadratic prisms, passing into the octahedron (Laurent).—The calcium-salt is precipitated in like manner in square-based prisms, containing, according to Wirtz, $\text{C}^2\text{H}^2\text{Ca}^2\text{O}^4\cdot\text{H}^2\text{O}$.—The cupric salt, $\text{C}^2\text{H}^2\text{Cu}^2\text{O}^4$, is obtained, by boiling cupric carbonate with the acid, in green crystalline scales, which may be freed from adhering acid by heating to 150° — 200° (Wirtz).—The silver-salt contains $\text{C}^2\text{H}^2\text{Ag}^2\text{O}^4$ (Laurent); $\text{C}^2\text{H}^2\text{Ag}^2\text{O}^4$ (Wirtz).—The sodium-salt crystallises in flat rhombic prisms containing $\text{C}^2\text{H}^2\text{Na}^2\text{O}^4\cdot 6\text{H}^2\text{O}$. (Wirtz.)

The existence of lipic acid must, however, be regarded as somewhat doubtful. Gerhardt regarded it merely as impure succinic acid, and Arppe (Ann. Ch. Pharm. xiv. 143) in his more recent investigation of the products of the action of nitric acid on oleic acid, has arrived at the same conclusion. He prepared the acids by Laurent's process above described, from oleic acid obtained by saponification of the so-called stearin-oil. The yellow solution obtained by evaporating the nitric acid with addition of water, yielded a granular powder, which, after repeated crystallisation, melted at 127° , and was found to consist of suberic acid mixed with another acid which could be extracted by cold ether, and proved to be azelaic acid (p. 572); the same acid was also found in the mother-liquors of the suberic acid.

LIPYL. A hypothetical radicle, C^2H^2 , supposed by Berzelius to exist in the natural fats and fatty acids. At present however these compounds are regarded as derivatives of the triatomic radical *glyceryl*, C^3H^3 . (See ETHERS, ii. 519, and GLYCERIDES, ii. 877.)

LIQUID. This term is applied to bodies in that peculiar state of aggregation, intermediate between the solid and the gaseous, in which the particles are free to move amongst themselves in all directions, but do not exhibit the constant tendency to fly asunder which is characteristic of the gaseous state.* The conditions which are supposed to give rise to this particular state of aggregation have been already considered in connection with the dynamical theory of heat (p. 133).

LIQUIDAMBAR. A balsam produced from a large tree (*Liquidambar styracifolia*) growing in Louisiana, Florida, and Mexico.

Liquid liquidambar, or *Oil of liquidambar*, which is obtained by making incisions in the tree, is received immediately in vessels to protect it from the air, and decanted after a while to separate a portion of the opaque balsam which settles to the bottom. It has the consistence of a thick oil, is transparent, of amber-yellow colour, and has an odour like that of liquid storax, but more agreeable; its taste is aromatic and irritates the throat. It contains a considerable quantity of benzoic or cinnamic acid, and a drop of it reddens litmus strongly. Treated with boiling alcohol, it leaves only a small residue, and the filtered liquid becomes turbid on cooling.

Soft or White Liquidambar proceeds either from the opaque deposit above mentioned, or from parts of the balsam which have run down the stem of the tree, and thickened by exposure to the air. It has the consistence of very thick turpentine or soft pitch; it is opaque and whitish; its odour is less strong and more agreeable than that of the oil just mentioned; taste, sweet and aromatic, but irritating. It contains a large quantity of benzoic or cinnamic acid. By long exposure to the air it solidifies completely and becomes almost transparent. It was formerly sold under the name of *White Peru balsam*. (Gerh., iv. 386.)

LIQUIDS, DIFFUSION OF. When two liquids of different density, and capable of mixing, are placed in contact, diffusion takes place between them, much in the same manner as between gases, excepting that, as the particles of the liquid are less freely mobile than those of the gas, the rate of diffusion is slower. The phenomena of liquid diffusion have been minutely investigated by Graham, in two classical series of researches published in the Philosophical Transactions for 1850 and 1862, also in the Journal of the Chemical Society, iii. 60, 257; iv. 83, and xv. 216; and important contributions to the subject have also been made by Fick, Simmler and Wilde, Beilstein and others.

The rate of diffusion varies with the nature of the liquids, the temperature, and in the case of solutions, with the degree of concentration.

1. Diffusion of Saline Solutions. The apparatus used in Graham's first series of experiments consisted of a set of phials of nearly equal capacity, cast in the same mould, and further adjusted by grinding to a uniform size of aperture. The phials were 3·8 inches high, with a neck 0·5 inch in depth, and aperture 1·25 inch wide; capacity to base of neck equal to 2080 grains of water or between 4 and 5 ounces. For each diffusion-phial a plain glass water-jar was also provided 4 inches in diameter and 7 inches deep. (Fig. 708.)

* Many writers use the term "fluid" as synonymous with liquid; but this is incorrect; fluid is, properly speaking, the correlative of solid, and includes both liquid and gas.

The diffusion-phial was filled with the saline solution, sal-ammoniac for instance, to the base of the neck, or more correctly to a distance of 0.5 inch from the ground surface of the lip. The neck of the phial was then filled up with distilled water, a light float being first placed on the surface of the solution, and care being taken to avoid agitation. After the phial had been placed within the jar, water was poured into the jar, so as to cover the open phial to the depth of an inch, which required about 20 ounces of water. The saline liquid in the phial is thus allowed to communicate freely with the water in the jar. The diffusion is interrupted by placing a small plate of ground glass on the mouth of the phial, and raising the latter out of the jar. The amount of salt diffused, called the diffusion-product, or diffusate, is ascertained by evaporating the water in the jar to dryness, or, in the case of chlorides, by precipitating with nitrate of silver.

Fig. 708.

The results of several series of experiments made in this manner are given in the following table, the second column of which gives the quantity of salt in 100 pts. of the solution, one per cent. of salt amounting to 20.8 grains; the third, the time of diffusion; the fourth, the temperature, on the Fahrenheit scale; the fifth, the quantity of salt diffused in grains:—

TABLE I.—DIFFUSION OF SALINE SOLUTIONS.

	2	11·43	64·1	11·49

These experiments, and a number of others made in a similar manner, lead to the following general conclusions:

1. Different salts, in solutions of equal strength, diffuse unequally in equal times.

2. With each salt, the rate of diffusion increases with the temperature, and at any given temperature, is proportionate to the strength of the solution, at least when the quantity of salt dissolved does not exceed 4 or 5 per cent.

Later experiments (Chem. Soc. J. xv. 236) have shown that diffusion increases at a higher, though not greatly higher, rate than the temperature, and that the more

highly diffusive the substance, the less does it gain in diffusiveness by rate of temperature. For hydrochloric acid the rate of diffusion was found to increase as follows:

Diffusion at 15.55 C. (60° F.)	= 1
" 26.66 C. (80° F.)	= 1.3545
" 37.77 C. (100° F.)	= 1.7732
" 41.88 C. (120° F.)	= 2.1812

3. There exist classes of equidiffusive substances which coincide in many cases with the isomorphous groups, but are, on the whole, more comprehensive than the latter. Thus, the same rate of diffusion is exhibited by hydrochloric, hydrobromic, and hydriodic acid; by the chlorides, iodides, and bromides of the alkali-metals; by the nitrates of barium, strontium, and calcium; the sulphates of magnesium and zinc, &c. &c.

4. For several groups of salts, it is found that the squares of the times of equal diffusion, from solutions of the same strength, stand to one another in a simple numerical relation. Thus, the diffusate from a solution of nitrate of potassium in 7 days, was equal to that obtained from an equally strong solution of carbonate of potassium, in 9.9 days, numbers which are to one another as $1 : \sqrt{2} = 1.414$. Similar results were obtained with 2 per cent. solutions of nitrate and sulphate of potassium, equal diffusates of the two being obtained in 3.5 and 4.95 days, in 7 and 9.9 days, and in 10.6 and 14.85 days; also, with hydrate and nitrate of potassium, and with nitrate and carbonate of sodium. The times of equal diffusion of 1 per cent. solutions of chloride of ammonium and chloride of sodium, were to one another as $\sqrt{2} : \sqrt{3}$. Now, according to Graham's experiments (ii. 812), the squares of the times of equal diffusion of gases are to one another in the ratio of their densities. Hence, by analogy, it may be inferred that the molecules of these several salts, as they exist in solution, possess densities which are to one another as the squares of the times of equal diffusion. Thus the solution-densities of sulphate, nitrate, and hydrate of potassium, are to one another as the squares of the numbers 4, 2 and 1, that is as 16, 4 and 1. These solution-densities appear to relate to a kind of molecules different from the chemical atoms, and the weights of which are either equal, or bear to one another a simple numerical relation.

The diffusion of a salt into the solution of another salt takes place with nearly the same velocity as into pure water; at least, when the solutions are dilute. Graham has shown that the diffusion of a 4 per cent. solution of carbonate of sodium, is not sensibly affected by the presence of 4 per cent. of sulphate of sodium in the liquid atmosphere; nor that of a 4 per cent. solution of nitrate of potassium, by the same proportion of nitrate of ammonium. The presence of 4 per cent. of sulphate of sodium reduced the diffusion of carbonate of sodium by only $\frac{1}{4}$ of the whole. In stronger solutions the retardation would probably be greater. There is, indeed, reason to believe that the phenomena of liquid diffusion are exhibited in their simplest form only by weak solutions, the effect of concentration, like that of compression in gases, being to produce a departure from the normal character.

The rate of diffusion is, however, materially affected when the liquid atmosphere already contains a portion of the diffusing salt. The consideration of this case leads to the general question of the motion of particles of a dissolved substance in a solution of unequal concentration. The general law which regulates such movements appears to be this:—*The velocity with which a soluble salt diffuses from a stronger into a weaker solution, is proportioned to the difference of concentration between two contiguous strata.* This law has not yet been experimentally demonstrated in a sufficient number of cases to establish it completely; but in the case of chloride of sodium, it has been shown to be true by the following experiments of Fick. (Phil. Mag. [4] x. 30.)

A cylindrical glass tube, open at both ends, was cemented into a vessel completely filled with common salt, the cylindrical space filled up with water, and the whole immersed in a large jar containing water. The apparatus was then left to itself for several weeks, the water in the jar being from time to time taken out and renewed. Now, as the lowest stratum of liquid in the tube, being in contact with undissolved salt, must remain constantly saturated, while the uppermost layer, which is in contact with pure water, contains no salt at all, a certain normal state of diffusion will ultimately establish itself throughout the length of the tube, characterised by the condition, that each horizontal stratum will, in a given time, give up to the stratum immediately above it as much salt as it receives from the one below. When this state is attained, the densities of the successive strata decrease from below upwards in arithmetical progression. This law of decrease was verified experimentally by immersing in the liquid, at various depths, a glass bulb suspended from the arm of a balance, and counterpoised by weights in the opposite scale. This law of decrease,

nowever, is true only with regard to cylindrical columns of liquid, or others, in which the horizontal section is of uniform magnitude. In other cases, the law of decrease of density may be calculated according to the form of the vertical section. In funnel-shaped tubes Fick has shown that the results of calculation agree with those of experiment.

Now let K denote the quantity of salt which, in the normal state of diffusion, passes, in a unit of time, through a unit of horizontal section of a cylindrical tube whose height is equal to the unit of length; this quantity is called the *diffusion-coefficient*; also, let Q be the quantity of salt which, in the time t , flows from the mouth of the tube into the water-atmosphere; h , the height of the tube; s , its horizontal section; and d , the density of the liquid at the bottom; then

$$Q = K \cdot d \cdot \frac{h}{s} \cdot t.$$

Hence, with a tube of given dimensions, and a solution of known and constant density at the bottom, the *diffusion-coefficient* K , of any salt may be calculated from the quantity Q , diffused out in a given time.

This method has been applied by Fick only in the case of chloride of sodium. It is, in fact, though simple in principle, somewhat inconvenient of application, on account of the long time—at least fourteen days—which must elapse before the normal state is attained.

Another method of determining the diffusion-coefficient of a salt has been devised by Jolly, and applied in several cases by Beilstein (Ann. Ch. Pharm. xix. 165). The

Fig. 709.

apparatus used consists of a glass tube (fig. 709), about three inches long, bent round at the bottom, and cut off near the bend, so that the level of the orifice is not much more than a millimetre above the bottom of the bend. The upper end of the tube is slightly drawn out and closed with a stopper. This tube is filled with a solution of known concentration, and fixed upright within a jar of water, the orifice of the tube being two or three lines below the level of the water. The salt then immediately begins to diffuse into the water, and as the liquid near the orifice becomes diluted, it passes round the bend to the upper part of the tube, its place being supplied by more concentrated liquid from above. With this apparatus, Beilstein has obtained the following diffusion-coefficients (taking that of chloride of potassium for unity), for solutions containing 4 per cent. of salt, and at the temperature of 6° C. (42·8° F.)

TABLE II.—*Diffusion-coefficients.*

Chloride of potassium . . .	1·0000	Sulphate of potassium . . .	0·6987
Nitrate of potassium . . .	0·9487	Carbonate of sodium . . .	0·5436
Chloride of sodium . . .	0·8337	Sulphate of sodium . . .	0·5369
Bichromate of potassium . .	0·7543	Sulphate of magnesium . .	0·3587
Carbonate of potassium . . .	0·7371	Sulphate of copper . . .	0·3440

Beilstein infers from his experiments, that the rate of diffusion is not exactly proportional to the difference of density of two contiguous strata, but increases in a somewhat greater ratio.

Simmler and Wilde (Pogg. Ann. c. 217) are of opinion that the want of agreement of Beilstein's results with this law arises from a defect in the method of experimenting. Beilstein's calculations, indeed, are based on the supposition that the strength of the solution in the tube (fig. 709), though constantly decreasing, is uniform at any instant of time throughout the entire length; whereas, a little consideration will show that the density near the orifice must be less than that in the larger arm of the tube, and in this arm less than near the bottom of the bend, where the liquid must stagnate to a certain extent. From this source of error, Fick's mode of observation is free. Simmler and Wilde, however, propose other methods, easier of execution than Fick's, and not subject to the necessity of waiting till the normal state of diffusion is established. One of these methods is similar to that adopted by Graham (p. 706), excepting that the vessel containing the solution is perfectly cylindrical, a condition which greatly simplifies the calculations; and, instead of being placed at the bottom of the water-jar, is supported on a stand, so as to bring its mouth within a line or two below the surface of the water; the salt, as it diffuses out, is thus made to flow over the sides of the vessel and fall to the bottom, leaving an atmosphere of pure water above. Another method proposed by the same authors is to place the saline solution in a vessel having the form of a triangular prism, and determine the

variation of density at different depths below the surface by observation of the indices of refraction.

Graham, in his later experiments (Phil. Trans. 1862, part i.; Chem. Soc. J. xv. p. 217) also uses a plain glass jar, in which the salt is allowed to rise from below in a cylindrical column. The jars were 152 mm. (6 inches) in height, and 87 mm. (3.45 inches) in width. In operating, seven-tenths of a litre of water were first placed in the jar, and then one-tenth of a litre of the liquid to be diffused was carefully conveyed to the bottom of the jar by means of a fine pipette. The whole fluid column then measured 127 mm. (5 inches) in height. As much as five or six minutes of time were occupied in emptying the pipette at the bottom of the jar, and extremely little disturbance was occasioned in the superincumbent water, as could be distinctly seen when the liquid introduced by the pipette was coloured. The jar was then left undisturbed, to allow diffusion to proceed, the experiments being always conducted in an apartment of constant, or nearly constant temperature. When a certain time had elapsed, the diffusion was interrupted by drawing off the liquid from the top by means of a small siphon, slowly and deliberately, as the liquid had been first introduced, in portions of 50 cubic centimetres, or one-sixteenth of the whole volume. The open end of the short limb of the siphon was kept in contact with the surface of the liquid in the jar, and the portion of liquid drawn off was received in a graduated measure. By evaporating each fraction separately, the quantity of salt which had risen into equal sections of the liquid column was ascertained. A particular advantage of this method is that it affords the means of ascertaining the absolute rate or velocity of diffusion, rendering it possible to state the distance which a salt travels per second in terms of the meter. Such a constant must enter into all the chronic phenomena of physiology, and holds a place in vital science not unlike the time of the falling of heavy bodies in the physics of gravitation.

2.—Crystalloids and Colloids.

The substances whose diffusion has been considered in the preceding pages, though they exhibit considerable diversities in their diffusive mobility, all belong to the more diffusive class. Opposed to them is another class, which are much less diffusive, and are likewise distinguished from the former by several well-defined physical and chemical characters, especially by the absence of the power to crystallise. Such are hydrated silicic acid, hydrated alumina, and other metallic oxides of the aluminous class, when they exist in the soluble form; also starch, dextrin and the gums, caramel, tannin, albumin, gelatin, vegetable and animal extractive matters. These bodies are also distinguished by the gelatinous character of their hydrates. Although often largely soluble in water, they are held in solution by a most feeble force. They appear singularly inert in the capacity of acids and bases, and in all the ordinary chemical relations. But, on the other hand, their peculiar physical aggregation, together with the chemical indifference referred to, appears to be required in substances that can intervene in the organic processes of life. The plastic elements of the animal body are found in this class. As gelatin appears to be its type, substances of this class may be designated as *colloids* (from κόλλα, glue), and their peculiar form of aggregation, as the *colloidal condition of matter*. Opposed to the colloidal is the crystalline condition. Substances affecting the latter form may be classed as *crystalloids*. The distinction is no doubt one of intimate molecular constitution.

Although chemically inert in the ordinary sense, colloids possess a compensating activity of their own, arising out of their physical properties. While the rigidity of the crystalline structure shuts out external impressions, the softness of the gelatinous colloid partakes of fluidity, and enables the colloid to become a medium for liquid diffusion, like water itself. The same penetrability appears to take the form of cementation in such colloids as can exist at a high temperature. Hence a wide sensibility on the part of colloids to external agents. Another and eminently characteristic quality of colloids, is their mutability. Their existence is a continued metastasis. A colloid may be compared in this respect to water while existing liquid at a temperature under its usual freezing-point, or to a supersaturated saline solution. Fluid colloids appear to have always a *pectous* modification; and they often pass, under the slightest influences, from the first into the second condition. The solution of hydrated silicic acid, for instance, is easily obtained in a state of purity, but it cannot be preserved. It may remain fluid for days or weeks in a sealed tube, but is sure to gelatinise and become insoluble at last. Nor does the change of this colloid appear to stop at that point. For the mineral forms of silicic acid, deposited from water, such as flint, are often found to have passed, during the geological ages of their existence, from the vitreous or colloidal into the crystalline condition (H. Rose). The colloidal is, in fact, a dynamical state of matter; the crystalloidal being the static condition. It may be

looked upon as the probable primary source of the force appearing in the phenomena of vitality. To the gradual manner in which colloidal changes take place (for they always demand time as an element), may the characteristic protraction of chemico-organic changes also be referred.

The following experiments made by the method of jar-diffusion (p. 700), exhibit the difference of diffusibility of colloids, namely gum, tannin, or caramel, as compared with the crystalloidal substances, chloride of sodium, sulphate of magnesium, and cane-sugar.

TABLE III.—Diffusion of 10 per cent. solutions (10 grms. of substance in 100 cubic centimetres of liquid) into pure water, after fourteen days, at 10° (50 Fahr.)

Number of stratum (from above downwards).	Chloride of sodium.	Sulphate of magnesium, at 10°.	Sugar.	Gum.	Tannin.	Albumin at 13°—13° 5.	Caramel at 16°—11°.

	9·999	10·000	10·003	9·999	9·997	10·000	10·000

Here the superimposed column of water being 111 millimetres (4·38 inches) high, the chloride of sodium is found to have diffused in sensible quantity to the top, and could have risen higher. The top of the diffusion-column of sulphate of magnesium, and likewise that of sugar, appear to have just reached the top of the liquid in the fourteen days of the experiment. But the colloids, gum, tannin, albumin and caramel, exhibit a great falling off in the rate of diffusion. Gum and tannin do not appear to be carried by diffusion higher than the seventh stratum, the minute quantities found in the higher strata, which together do not exceed 0·02 gm., being doubtless the result of accidental dispersion, arising probably from a movement of the upper liquid, occasioned by slight inequalities of temperature. The diffusion of albumin and of caramel is still slower.

By continuing the diffusion of different substances till equal quantities had diffused out, the following results were obtained:

Approximate times of Equal Diffusion.

Hydrochloric acid	1
Chloride of sodium	2·33
Sugar	7
Sulphate of magnesium	7
Albumin	49
Caramel	98

The diffusion of hydrochloric acid in three days corresponds with the diffusion of chloride of sodium in seven days. Hydrochloric and the allied hydracids, with other monobasic acids, are the most diffusive substances known.

The diffusion process in alcohol appears to be several times slower than in water. The following table exhibits the results of experiments on three substances dissolved in alcohol, and placed under a column of alcohol, the experiments being conducted exactly as described at p. 700.

3.—*Application of Liquid Diffusion to Chemical Analysis.*

Mixed salts may be more or less separated by their unequal diffusibility. A solution of 1 pt. of carbonate of potassium, and 1 pt. carbonate of sodium in 10 pts. of water placed in a diffusion-phial (*fig.* 708), yielded in 10 days at 16° a diffusate containing 63·6 pts. carbonate of potassium to 36·4 pts. carbonate of sodium; the diffusate in 25 days contained the same salts in nearly the same proportion. Inequality of diffusion is indeed somewhat increased by mixture, so that the actual separation is greater than that calculated from the relative diffusibilities of the mixed substances.

Similar results were obtained by the method of jar-diffusion at p. 700; when a mixture of two salts was placed at the bottom of the jar, the more diffusive salt travelled upwards the most rapidly, showing itself first, and always most largely, in the upper strata. The following table shows the results obtained with a mixture of equal parts of the chlorides of potassium and sodium.

TABLE V.—*Diffusion of a mixture of 5 per cent. of Chloride of Potassium, and 5 per cent. of Chloride of Sodium, for seven days at 12°—13°.*

13	·552	·684	1·236
14	·615	·772	1·387
15 and 16	1·385	1·551	2·936
	5·001	4·999	10·000

The first six strata contain together 561 milligrammes, of which 404 milligrammes, or 72 per cent., that is nearly three-fourths, are chloride of potassium. We have to

descend to the tenth stratum before the salts are found in equal proportions. The progression is then inverted, and chloride of sodium comes to preponderate in the lower strata.

It is evident that the preceding experiment might be so conducted as to diffuse away the chloride of potassium, and leave below a mixture containing chloride of sodium in relative excess, to as great an extent as the chloride of potassium is found above, in the last experiment.

Further, the mixture in which chloride of potassium was concentrated in the experiment described, so as to form 72 per cent. of the whole mixture, might be again subjected to diffusion in the same manner. In an experiment upon a mixture of 7.5 grms. of chloride of potassium and 2.5 grms. of chloride of sodium, the six upper strata gave 640 milligrams. of salt, of which 610 milligrams., or 95.3 per cent., were chloride of potassium. It is obvious that, by repeating this diffusive rectification a sufficient number of times, a portion of the more diffusive salt might be obtained at last in a state of sensible purity.

The preceding example illustrates the separation of unequally diffusive metals or bases; the following example represents, on the other hand, the separation of unequally diffusive acids united with a common base. Chloride and sulphate of sodium diffuse separately in the phial experiments in the proportion of 1 to 0.707.

TABLE VI.—Diffusion of 5 per cent. of Chloride of Sodium and 5 per cent. of anhydrous Sulphate of Sodium, for 7 days, at 10°—10°-75.

Number of stratum.	Chloride of sodium in grammes.	Sulphate of sodium in grammes.	Total diffuse in grammes.
1	.009	.	.009

14	.713	.909	1.627
15 and 16	1.390	2.141	3.531
	4.999	5.000	9.999

Here the separation is still more sensible than with the bases. The six upper strata contain 263 milligrammes of salt, of which 239 milligrammes, that is 90.8 per cent., are chloride of sodium. The salt of the upper eight strata amounts to 695 milligrammes, of which 583 milligrammes, or 83.9 per cent., are chloride.

On comparing the diffusion of a mixture of equivalent quantities of chloride of sodium and sulphate of potassium with that of a mixture, also in equivalent proportions, of chloride of potassium and sulphate of sodium, it was found that the diffusion of the metals is not affected by the acid with which each of them is originally combined. This result is quite in harmony with Berthelot's view, that the acids and bases are indifferently combined, or that a mixture of chloride of potassium and sulphate of sodium is the same thing as a mixture of chloride of sodium and sulphate of potassium, when both mixtures are in the state of solution. With two acids greatly unequal in their affinity for bases, however, the result might possibly be different.

In some cases, diffusion is also capable of effecting the decomposition of chemical compounds. Thus, when a solution of common alum is allowed to diffuse into water, the sulphate of potassium passes out more rapidly than the sulphate of aluminium. A solution of sulphate of potassium in lime-water left to diffuse into lime-water yields a diffusate containing hydrate of potassium; similarly with sulphate of sodium. The sulphates of potassium and sodium are also decomposed by carbonate of calcium dissolved in carbonic acid water, when the liquid is allowed to diffuse into pure water. The chlorides of potassium and sodium are not sensibly decomposed by lime-water in

this manner. When saturated solutions of lime-water and sulphate of calcium are mixed in equal volumes, 1 per cent. of chloride of sodium dissolved in the mixture, and the solution left to diffuse into pure water, scarcely a trace of hydrate of sodium is obtained; but when the solution of sulphate of calcium, with an addition of 2 per cent. of chloride of sodium, is kept at the boiling point for half an hour, and the solution mixed two or three days afterwards with an equal volume of lime-water, and diffused into pure water for $3\frac{1}{2}$ days, the diffusate in three cells is found to contain 0.234 grains hydrate of sodium and 0.371 sulphate of sodium. It appears, then, that more than one condition of equilibrium is possible for mixed solutions of sulphate of calcium and chloride of sodium. Cold solutions of these salts may be mixed without decomposition, or without sensible formation of sulphate; but, on heating, this change is induced, and is permanent, sulphate of sodium being formed, and continuing to exist in the cold solution; for it is the decomposition of that salt alone by hydrate of calcium which appears to yield the diffused hydrate of soda. As the effects of time and temperature are often convertible, it is possible that the same decomposition might take place at ordinary temperatures after a considerable time. If such be the case, we have an agency in the soil by which the alkaline carbonates required by plants may be formed from the chlorides of potassium and sodium, as well as from the sulphates; for the sulphate of calcium, generally present, will convert those chlorides into sulphates. The mode in which the soil of the earth is moistened by rain is peculiarly favourable to separations by diffusion. The soluble salts of the soil may be supposed to be carried down together, to a certain depth, by the first portion of rain which falls, while they find afterwards an atmosphere of nearly pure water, in the moisture which falls last and occupies the surface stratum of the soil. Diffusion of the salts upwards into the water, with its separations and decompositions, must necessarily ensue. The salts of potassium and ammonium, which are most required for vegetation, possess the highest diffusibility, and will rise first. The pre-eminent diffusibility of the alkaline hydrates may also be called into action in the soil by hydrate of calcium, particularly as quicklime is applied as a top-dressing to grass-lands. (Graham.)

4. Dialysis.

Membranes or septa of the colloid class (p. 710) possess a property which is very useful in assisting diffusive separations. The jelly of starch, that of animal mucus, of pectin, of Payen's vegetable gelose (ii. 826), and other solid colloidal hydrates, all of which are strictly speaking insoluble in cold water, are themselves permeable when in mass, as water is, by the more highly diffusive substances. But such jellies greatly resist the passage of the less diffusive substances, and cut off entirely other colloid substances like themselves that may be in solution: in this respect they resemble animal membrane. This mode of separation by diffusion through a septum is called dialysis. A mere film of the colloidal septum produces this separating effect. Thus, if a sheet of very thin letter-paper, well sized with starch, and having no porosity, be laid on the surface of water, a depression made in its centre, and a mixed solution of cane-sugar and gum-arabic containing 5 per cent. of each substance poured upon it, the sugar diffuses through into the water while the gum remains above, so that, after twenty-four hours, the water below is found to contain about three-fourths of the whole sugar, in a condition so pure as to crystallise when the liquid is evaporated over the water-bath. Now the sized paper has no power to act as a filter; it is mechanically impenetrable, and refuses a passage to the mixed liquid as a whole. Molecules only permeate this septum, and not masses. The molecules also are moved by the force of diffusion. But the water of the gelatinous starch with which the paper is sized, is not directly available as a medium for the diffusion of either the sugar or the gum, being in a state of real though feeble chemical combination. The hydrated compound itself is solid, and also insoluble. Sugar, however, with other crystalloids, can separate water, molecule after molecule, from any hydrated colloid, such as starch. The sugar thus obtains the liquid medium required for diffusion, and makes its way through the gelatinous septum. Gum, on the other hand, presenting, as a colloid, an affinity for water of the feeblest description, is unable to separate that liquid from the gelatinous starch, and so fails to open the door for its own passage outwards by diffusion.

Diffusion of a crystalloid through a firm jelly appears to proceed at nearly the same rate as into pure water. This is strikingly shown by the following experiment.

Ten grammes of chloride of sodium and 2 grammes of the Japanese gelatin, or gelose of Payen, were dissolved together in so much hot water as to form 100 cub. cents. of liquid. Introduced into the empty diffusion-jar and allowed to cool, this liquid set into a firm jelly, occupying the lower part of the jar, and containing of course 10 per cent. of chloride of sodium. Instead of placing pure water over this jelly, it was covered by 700 cub. cents. of water containing 2 per cent. of the same gelose, cooled so

far as to be on the point of gelatinising, the jar at the same time being placed in a cooling mixture in order to expedite that change. The jar with its contents was now left undisturbed for eight days at the temperature 10° . After the lapse of this time, the jelly was removed from the jar in successive portions of 50 cub. cents. each from the top, and the proportion of chloride of sodium in the various strata ascertained. The results were very similar to those obtained in diffusing the same salt in a jar of pure water, excepting that the diffusion in the gelose appeared more advanced in eight days than diffusion in water for seven days. With a coloured crystalloid, such as acid chromate of potassium, the gradual elevation of the salt to the top of the jar is very plainly seen. On the other hand, the diffusion of a coloured colloid, such as caramel, through the jelly, appears scarcely to have begun after the lapse of eight days. The diffusion of a salt into the solid jelly may be regarded as cementation in its simplest form.

The most suitable of all substances for a dialytic septum is De la Rue's vegetable parchment or parchment-paper (i. 819), which is unsized paper, altered by a short immersion in sulphuric acid, or in chloride of zinc. Paper so metamorphosed acquires considerable tenacity, and when wetted, expands and becomes translucent, evidently admitting of hydration. In the wetted state, parchment-paper can easily be applied to a light hoop of wood, or better, to a hoop made of sheet gutta percha, 2 inches in depth and 8 or 10 inches in diameter, so as to form a vessel like a sieve in form (fig. 710). The disc of parchment-paper used should exceed in diameter the hoop to be covered by 4 inches, so as to rise well round the hoop. It may be bound

Fig. 710.

to the hoop by string, or by an elastic band, but should not be finally secured. The parchment-paper must not be porous. Its soundness will be ascertained by sponging the upper surface with pure water, and then observing that no wet spots show themselves on the opposite side. Such defects may be remedied by applying liquid albumin, and then coagulating the same by heat. Mr.

De la Rue recommends the use of albumin in cementing parchment-paper, which may thus be formed into cells and bags very useful in dialytic experiments. The mixed fluid to be dialysed is poured into the hoop upon the surface of the parchment-paper to a small depth only, such as half an inch. The vessel described (*dialyser*) is then floated in a basin containing a considerable volume of water, in order to induce the egress of the diffusive constituents of the mixture. Half a litre of urine, dialysed for twenty-four hours, gave its crystalloid constituents to the external water. The latter, evaporated by a water-bath, yielded a white saline mass. From this mass urea was extracted by alcohol in so pure a condition as to appear in crystalline tufts upon the evaporation of the alcohol.

For operating on smaller quantities of liquid, a small glass bell jar, tied round at the bottom, as shown in fig. 711, may be used. Figs. 712, 713 show convenient modes of supporting the instrument in a basin or a jar of water. In Mr. Graham's experiments

Fig. 711.

Fig. 712.

Fig. 713.

two sizes of bulb were employed, 3.14 and 4.41 inches in diameter, the dialytic septa having areas very nearly of $\frac{1}{100}$ and $\frac{1}{250}$ of a square metre (15.6 and 7.8 square inches). With 100 cub. cents. of liquid (the quantity usually employed) the septum of the smaller instruments was covered to the depth of 20 mm. (0.8 inch) and the septum of the larger to a depth of 10 mm. (0.4 inch). The thinner the stratum, the more exhaustive the diffusion in a given time. When a considerable diffusion is desired within 24 hours, it is generally inadvisable to cover the septum deeper than 10 or 12 mm. (half an inch).

Numerous experiments on the diffusion of crystalloids through various dialytic septa, such as gelatinous starch, coagulated albumin, gum-tragacanth, besides animal

mucus and parchment-paper, all tended to prove how little the diffusive process is interfered with by the intervention of colloid matter. Salts appear to preserve their usual relative diffusibility unchanged. The same partial separation of mixed salts is observed as in the water-jar (p. 713). With a mixture, for instance, of equal parts of chlorides of potassium and sodium in a dialyser, the first tenth part of the mixture which passed through was found to consist of 59·17 per cent. of chloride of potassium and 40·83 per cent. of chloride of sodium. Double salts also, such as alum, and the sulphate of copper and potassium, which admit of being resolved into pairs of unequally diffusive salts, were largely decomposed upon the dialyser, as they are in the water-jar. The effect of heat in promoting diffusion appears, however, to be diminished in dialysis, at least with a parchment-paper septum. Thus the diffusion from a 2 per cent. solution of chloride of sodium, in a constant period of three hours, was—

The rate of diffusion in water alone, without the septum, would have been doubled by an equal rise of temperature, instead of being increased one-third only as above.

The following table exhibits the rate of diffusion of several substances, both crystalloids and colloids, compared with chloride of sodium as a standard. The larger bell-jar (p. 716) was used, and the parchment-paper was changed in each experiment. The substance in solution amounted to 2 grms., the depth of liquid in the dialyser to 10 mm. (0·4 of an inch), and the surface of the septum to 0·01 square metre (15·6 square inches).

TABLE VII.—*Dialysis through Parchment-paper during twenty-four hours, at 12°.*

Two per cent. solutions.	Diffusate in grammes.	Proportional diffusate.
Chloride of sodium	1·657	1·000
Picric acid	1·690	1·020
Ammonia	1·404	·847
Theine	1·166	·703
Salicin	·835	·503
Cane-sugar	·783	·472
Amygdalin	·517	·311
Extract of quercitron	·305	·184
Extract of logwood	·280	·168
Catechu	·265	·159
Extract of cochineal	·086	·051
Gallotannic acid	·050	·030
Extract of litmus	·033	·019
Purified caramel	·009	·005

The picric acid and theine were actually diffused from 1 per cent. solutions, and the numbers observed are multiplied by 2. The crystallisable principles, theine, salicin, and amygdalin, appear greatly more diffusible than gallo-tannic acid, or than gum, as has been already seen. Such inequality of rate is likely to facilitate the separation of vegetable principles by the agency of dialysis.

Preparation of Colloid Substances by Dialysis.

The purification of many colloid substances may be effected with great advantage by placing them on the dialyser. Accompanying crystalloids are eliminated, and the colloid is left behind in a state of purity. The purification of soluble colloids can rarely be effected by any other known means, and dialysis is evidently the appropriate mode of preparing such bodies free from crystalloids.

When the mixed solution obtained by pouring silicate of sodium into water acidulated with hydrochloric acid, was placed upon a parchment-paper dialyser, and allowed to diffuse into water, the latter being occasionally changed, a quantity of silicic acid was left upon the septum, amounting, after the lapse of five days, to seven-eighths of the original silicic acid, and the solution of silicic acid which subsequently passes through, is so free from hydrochloric acid and chloride of sodium as not to give a precipitate with nitrate of silver.

Soluble silicic acid forms a peculiar class of compounds, which like itself, are colloidal, and differ entirely from the ordinary silicates. These compounds, which may

be called *collisilicates* or *co-silicates*, appear to contain an acid of higher atomic weight than ordinary silicic acid. *Cosilicic acid*, like *gallotannic*, *gummic*, and other colloidal acids, unites with *gelatin*, forming a *cosilicate* of *gelatin*, which is precipitated on mixing the solutions of silicic acid and *gelatin*; but, like the *gallotannate* (i. 828), varies in composition according as the one or the other constituent is present in excess. *Cosilicic acid* also precipitates both *albuminic acid* and pure *casein*.

The true hydrated alumina, also *Crum's metalumina* (i. 159), are obtained soluble by dialysing solutions of these oxides in the chloride and acetate of the same metal; so, likewise, hydrated ferric oxide, and the peculiar ferric hydrate (*metaferric hydrate*) discovered by Péan de St.-Gilles (p. 395), and soluble *chromic hydrate* (ii. 949). The several varieties of *Prussian blue* (ii. 229, 244) are obtained soluble by dialysing their solutions in oxalate of ammonium, the latter salt diffusing away. *Stannic* and *metastannic acids* both give soluble modifications when dialysed from alkaline solutions; *titanic acid*, when dialysed from a solution in dilute hydrochloric acid; *tungstic acid* and *molybdic acids*, when the tungstate and molybdate of sodium in dilute solution are repeatedly dialysed with a slight excess of hydrochloric acid. (Chem. Soc. J. [2] ii. 318.)

A solution of *gum-arabic* (*gummate* of calcium) dialysed after addition of hydrochloric acid, gave at once the pure *gummic acid* of Frémy (ii. 955). Soluble albumin is obtained in a state of purity by dialysing albumin with addition of acetic acid.

Caramel of sugar purified by repeated precipitation with alcohol, and afterwards by dialysis, contains the proportion of carbon in the highest of the *caramelic bodies* of Gélis (ii. 748); it forms a tremulous jelly when concentrated, and appears decidedly colloidal. Like all other colloids, it has a soluble and an insoluble modification. The latter has its solubility restored by the action of alkalis, followed by that of acetic acid and subsequent dialysis.

For further details on the preparation of colloids by dialysis, see Chem. Soc. J. xv. 243—260; also the descriptions of the several substances in their alphabetical order in this Dictionary.

Separation of Arsenious Acid from Colloidal Liquids.—Dialysis may be advantageously applied to the separation of *arsenious acid* and *metallic salts* from organic solutions in medico-legal enquiries. The process has the advantage of introducing no metallic substance or chemical reagent of any kind into the organic fluid. The arrangement for operating is also of the simplest nature.

The organic liquid is placed, to the depth of half an inch, on a dialyser formed of a hoop of gutta percha 10 or 12 inches in diameter, covered with parchment-paper (fig. 710, p. 716). The dialyser is then floated in a basin containing a volume of water about four times greater than the volume of organic fluid in the dialyser. The water of the basin is generally found to remain colourless after the lapse of 24 hours; and after being concentrated by evaporation, it admits of the application of the proper reagents to precipitate and remove a metal from solution. One-half to three-fourths of the crystalloidal and diffusible constituents of the organic liquid will generally be found in the water of the basin.

Tartar-emetic and *strychnine* may be separated from viscid organic matter in a similar manner: indeed, all soluble poisonous substances appear to be crystalloids, and therefore pass through colloidal septa.

LIQUIDS, DISPERSIVE POWERS OF. See LIGHT (p. 624).

LIQUIDS, EXPANSION OF. See HEAT (p. 52).

LIQUIDS, INDICES OF REFRACTION OF. See LIGHT (pp. 615, 627).

LIQUIDS, OSMOSE OF. When two liquids are separated by the intervention of a porous diaphragm, a flow of liquid takes place from one side of the septum to the other, or sometimes an unequal flow of the two liquids in opposite directions, so that the quantity of liquid increases on one side of the septum and diminishes on the other. This phenomenon was originally designated by the correlative terms *Endosmose* and *Exosmose*, but it is better expressed by the shorter word (*Osmose*, from *ωσμός*, impulsion), which includes the two former.

The passage of liquids through porous septa was first studied by Dutochet, whose apparatus, called an *endosmometer*, consisted of a narrow glass tube, having a funnel-shaped expansion at the bottom, and closed at that end by a piece of bladder. This tube was filled with a saline solution, and placed in a vertical position in a jar containing water. The flow of liquid in the one direction or the other was measured by the rise or fall of the liquid in the tube. Dutochet inferred, from his experiments, that the velocity of the osmotic current is proportionate to the quantity of salt or other solid substance originally contained in the saline solution. The experiments were, however, inexact, because no allowance was made for the alteration of hydrostatic pressure caused by the rise or fall of the liquid in the tube. Vierordt (Pogg. Ann. lxxxiii. 79),

who used a modification of Dütrochet's apparatus, in which this source of error was removed, found that the velocity of the current increases with the initial concentration of the solution, but in a lower ratio.

Professor Jolly, of Heidelberg, has examined the osmose of water and saline solutions by a different method. The saline solution containing a known quantity of salt is contained in a glass tube closed at the bottom with bladder, and plunged into water, which is frequently changed, so as to keep it nearly pure. The tube with its contents is taken out from time to time and weighed, and these operations are repeated till the weight becomes constant, showing that the whole of the salt has passed out from the tube, and nothing but water remains.

In this manner it is found that a given quantity of any salt which passes through the septum into the water is always replaced by a definite quantity of water. The quantity of water which is thus replaced by a unit of weight of the salt, is called the *endosmotic* (or *osmotic*) *equivalent* of that salt. This quantity varies with the nature of the salt, and with the temperature, increasing as the temperature rises; but it is independent of the density of the solution. At temperatures near 0° C., the endosmotic equivalent of hydrate of potassium was found to be 200; of chloride of sodium, between 4.3 and 4.6; of sulphate of sodium, between 11 and 12; of neutral sulphate of potassium, 12; of acid sulphate of potassium, 2.3; and of hydrated sulphuric acid (at 18° C.), 0.35.

These results point to the conclusion, that the osmose between water and saline solutions consists, not in the opposite passage of two liquid currents, but in the passage of particles of the salt in one direction, and of pure water in the other. This conclusion is strengthened by Graham's observation, that common salt diffuses into water, through a thin membrane of ox-bladder deprived of its outer muscular coating, at the same rate as when no membrane is interposed.

The flow of water into the saline solution is the only one of the two movements which can be correctly described as a current. This is, in fact, the true osmose, and depends essentially on the action of the membrane or other porous septum; for the quantity of water which thus passes into the solution is often much greater than would be introduced by mere liquid diffusion, amounting in some cases to several hundred times that of the salt displaced.

This action of the septum has been explained in various ways. By Dütrochet and others, it was attributed to capillarity; but this force is quite insufficient to account for the great inequality of ascension which different liquids exhibit in the osmotic apparatus: in fact, Graham has shown, that solutions of the most different character exhibit very nearly equal ascension in tubes of equal diameter.

Osmose has likewise been attributed to the unequal absorption of the two liquids by the porous septum. Suppose the septum to be of such a nature as to absorb only one of the liquids,—the water, for instance. The water will then penetrate the septum, and coming in contact with the saline solution, will diffuse into it. More water will then be absorbed, and subsequently diffused, and thus a continuous current will be set up. If both liquids are absorbed by the septum, but in different degrees, and each is capable of diffusing into the other, like water and alcohol, the result will be the formation of two unequal currents in opposite directions. Water is absorbed by animal membrane much more rapidly than most other liquids, and accordingly, when a septum of this kind is used, the direction of the current is in most cases from the water to the other liquid. According to Liebig, a given weight of dried ox-bladder absorbs in the same time, 200 vols. of water, 133 vols. of a saturated solution of common salt, 38 vols. of alcohol of the strength of 84 per cent., and 17 vols. of bone-oil. When water and alcohol are separated by an animal membrane, the quantity of water which passes into the alcohol is greater than the quantity of alcohol which passes into the water; but when the same liquids are divided by a thin film of collodion, which absorbs alcohol more quickly than water, the contrary effect is produced.

On the other hand, the numerous experiments recently made by Graham (Phil. Trans. 1855, p. 177; Chem. Soc. J. vii. 43) lead to the conclusion that osmose depends essentially on the chemical action of the liquid on the septum. These experiments were made partly with porous mineral septa, partly with animal membrane. The earthenware osmometer consisted of the porous cylinders employed in voltaic batteries, about five inches in depth, surmounted by a glass tube 9 inches in diameter, attached to the mouth of the cylinder by means of a cap of gutta serena. The cylinder was filled to the base of the glass tube with a saline solution, and immediately placed in a jar of distilled water; and as the liquid within the instrument rose during the experiment, water was added to the jar to equalize the pressure. The rise (or fall) of the liquid in the tube was very regular, as observed from hour to hour, and the experiment was generally terminated in five hours. From experiments made on solutions of every variety of soluble substance, it appeared that the rise or osmose is quite

insignificant with neutral organic substances in general, such as sugar, alcohol, urea, tannin, &c.; so likewise with neutral salts of the earths and ordinary metals, with the chlorides and nitrates of potassium and sodium, and with chloride of mercury. A more sensible but still very moderate osmose is exhibited by hydrochloric, nitric, acetic, sulphurous, citric, and tartaric acids. These are surpassed by the stronger mineral acids, such as sulphuric acid, phosphoric, and by sulphate of potassium, which are again exceeded by salts of potassium and sodium, possessing a decided acid or alkaline reaction, such as dioxalate of potassium, phosphate of sodium, or the carbonates of potassium and sodium. The highly osmotic substances were also found to act with most advantage in small proportions—producing, in fact, the largest osmose in the proportion of one-quarter per cent. dissolved. The same substances are likewise always chemically active bodies, and possess affinities which enable them to act on the material of the earthenware septum. Lime and alumina were always found in solution after osmose, and the corrosion of the septum appeared to be a necessary condition of the flow. Septa of other materials, such as pure carbonate of calcium, gypsum, compressed charcoal, and tanned sole-leather, although not deficient in porosity, gave no osmose apparently, because they are not chemically acted on by the saline solutions.

Similar results were obtained with septa of animal membrane. Ox-bladder was found to act with much greater strength and regularity when divested of its outer muscular coat. Cotton calico, impregnated with liquid albumin, and afterwards heated to coagulate the albumin, formed an excellent septum, resembling membrane in

Fig. 714.

every respect. The osmometer (*fig. 714*) used in these experiments was arranged like the original instrument of Dutrochet; but the membrane was supported by a plate of perforated zinc, and the tube was of considerable diameter, viz. one-tenth of that of the mouth of the bulb, or of the disc of membrane exposed to the liquids.

Osmose in membrane presents many points of similarity to that in earthenware. The membrane is constantly undergoing decomposition, and its osmotic action is exhaustible. Salts and other substances capable of determining a large osmose are all chemically active substances, while the great mass of neutral organic substances and perfectly neutral monobasic salts of the metals, such as chloride of sodium, possess only a low degree of action, or are wholly inert. The active substances are also most efficient in small proportions.* With a solution containing $\frac{1}{10}$ per cent. of carbonate of potash, the rise in the osmometer was 167 millimetres; and with 1 per cent. of the same salt, 206 millimetres in five hours. With another membrane and a stronger solution, the rise was 863 millimetres, or upwards of 38 inches in the same time. To induce osmose, the chemical action on the membrane must be different on the two sides, and apparently not in degree only, but in kind, viz. an alkaline action on the albuminous substance of the membrane on the one side and an acid action on the other. The water appears always to accumulate on the alkaline or basic side of the membrane.

Hence with an alkaline salt, such as carbonate of sodium, in the osmometer, and water outside, the flow is inwards; but with an acid in the osmometer, there is negative osmose, or the flow is outwards, the liquid then falling in the tube. The chlorides of barium, sodium, and magnesium, and similar neutral salts, are wholly indifferent, or appear to act merely in a subordinate manner to some other active acid or basic substance, which may be present in the solution or the membrane in the most minute quantity. Salts which admit of division into a basic salt and free acid exhibit an osmotic activity of the highest order, *e.g.* the acetate and various other salts of alumina, ferric oxide and chromic oxide, cuprous chloride, stannous chloride, nitrate of lead, &c. The acid travels outwards by diffusion, superinducing a basic condition of the inner surface of the membrane, and an acid condition of the outer surface, the most favourable condition for a high positive osmose. Again, the dibasic salts of potassium and sodium, such as the sulphate and tartrate, though strictly neutral in properties, begin to exhibit a positive osmose, in consequence, perhaps, of their resolution into an acid supersalt and free alkaline base.

The following table exhibits the osmose of substances of all classes through membrane, the degree being a rise or fall of 1 millimetre:—

* The action increases with the strength of the solution up to a certain point, as the above examples show. With stronger solutions the pores of the membrane probably becomes topped up with particles of salt, and the action consequently diminishes.

OSMOSE OF 1 PER CENT. SOLUTIONS IN MEMBRANE.

	Degrees.		Degrees.
Oxalic acid	- 148	Chloride of zinc	+ 54
Hydrochloric acid (0·1 per cent.)	- 92	Chloride of nickel	88
Trichloride of gold	- 54	Nitrate of lead	125 to 211
Stannic chloride	- 46	Nitrate of cadmium	137
Platinic chloride	- 30	Nitrate of uranium	234 to 458
Chloride of magnesium	- 3	Nitrate of copper	204
Chloride of sodium	+ 2	Chloride of copper	351
Chloride of potassium	18	Stannous chloride	289
Nitrate of sodium	2	Ferrous chloride	435
Nitrate of silver	31	Mercuric chloride	121
Sulphate of potassium	21 to 60	Mercurous nitrate	356
Sulphate of magnesium	14	Mercuric nitrate	476
Chloride of calcium	20	Ferrie acetate	194
Chloride of barium	21	Acetate of aluminium	280 to 393
Chloride of strontium	26	Chloride of aluminium	640
Chloride of cobalt	26	Phosphate of sodium	311
Chloride of manganese	31	Carbonate of potassium	439

The osmotic action of carbonate of potassium and other alkaline salts is interfered with in an extraordinary manner by the presence of chloride of sodium, being reduced to almost nothing by an equal proportion of that salt. The moderate positive osmose of sulphate of potassium is converted into a very sensible negative osmose by the presence of the merest trace of a strong acid, while the positive osmose of the same salt is singularly promoted by a small proportion of alkaline carbonate: thus, a 1 per cent. solution of sulphate of potassium gives an osmose of 21°, but the addition of 0·1 per cent. of carbonate of potassium raises it to between 254 and 204 degrees. (Graham.)

If a glass tube, bent in the form of a siphon, and having its shorter leg closed with bladder, be partially filled with salt water, the shorter leg then immersed in a vessel of pure water, and mercury poured into the longer leg, so that its pressure may not in opposition to the force with which the water tends to enter the saline solution through the bladder, it will be found that, when the column of mercury attains a certain height, the two liquids will mix without change of volume, the force of the osmotic current being then exactly balanced by the weight of the mercurial column. In this way the mechanical force of the osmotic current may be measured. (Liebig.)

Osmose appears to play an important part in the functions of life. We have seen that it is peculiarly excited by dilute saline solutions, such as the animal and vegetable juices are, and that the acid or alkaline property which these juices possess is another favourable condition for their action on membrane. The natural excitation of osmose in the substance of the membranes or cell-walls dividing such solutions seems therefore almost inevitable.

In osmose there is also a remarkably direct substitution of one of the great forces of nature by its equivalent in another force,—the conversion, namely, of chemical action into mechanical power. Viewed in this light, the osmotic injection of fluids may, perhaps, supply the deficient link which intervenes between chemical decomposition and muscular movement. The ascent of the sap in plants appears to depend upon a similar conversion of chemical, or, at least, molecular action into mechanical force. The juices of plants are constantly permeating the coatings of the superficial vessels in the leaves and other organs; and as these evaporate into the air, a fresh portion of liquid is absorbed by the membrane and evaporates; and thus a regular upward current is established, by which the sap is transferred from the roots to the highest parts of the tree. In a similar manner, the evaporation constantly taking place from the skin and lungs of animals, causes a continuous flow of the animal juices from the interior towards the surface.

From his recent experiments on the passage of liquids through colloidal septa, Graham infers that the water movement in osmose is an affair of hydration and of dehydration in the substance of the membrane or other colloidal septum, and that the diffusion of the saline solution placed within the osmometer has little or nothing to do with the osmotic result, otherwise than as it affects the state of hydration of the septum.

Osmose is generally considerable through membranous and other highly hydrated septa, with the solution of any colloid (gum, for instance) contained in the osmometer. Yet the diffusion outwards of the colloid is always minute, and may sometimes amount to nothing. Indeed, an insoluble colloid, such as gum-tragacanth, placed in powder within the osmometer, was found to indicate the rapid entrance of water, to convert the gum into a bulky gelatinous hydrate. Here no outward or double movement is possible.

The degree of hydration of any gelatinous body is much affected by the liquid medium in which it is placed. This is very obvious in fibrin and animal membrane. Placed in pure water, such colloids are hydrated to a higher degree than they are in neutral saline solutions. Hence the equilibrium of hydration is different on the two sides of the membrane of an osmometer. The outer surface of the membrane being in contact with pure water, tends to hydrate itself in a higher degree than the inner surface does, the latter surface being supposed to be in contact with a saline solution. When the full hydration of the outer surface extends through the thickness of the membrane and reaches the inner surface, it there receives a check. The degree of hydration is lowered, and water must be given up by the inner layer of the membrane, and it forms the osmose. The contact of the saline fluid is thus attended by a continuous catalysis of the gelatinous hydrate, by which it is resolved into a lower gelatinous hydrate and free water. The inner surface of the membrane of the osmometer contracts by contact with the saline solution, while the outer surface dilates by contact with pure water. Far from promoting this separation of water, the diffusion of the salt throughout the substance of the membrane appears to impede osmose, by equalising the condition as to saline matter of the membrane through its whole thickness. The advantage which colloidal solutions have in inducing osmose, appears to depend in part upon the low diffusibility of such solutions, and their want of power to penetrate the colloidal septum.

The substances fibrin, albumin, and animal membrane swell greatly when immersed in water containing minute proportions of acid or of alkali, as is well known. On the other hand, when the proportion of acid or alkali is carried beyond a point peculiar to each substance, contraction of the colloid takes place. Such colloids as have been named, acquire the power of combining with an increased proportion of water, and of forming superior gelatinous hydrates, in consequence of contact with dilute acid or alkaline reagents. Even parchment-paper is more elongated in an alkaline solution than in pure water. When so hydrated and diluted, the colloids present an extreme osmotic sensibility. Used as septa, they appear to assume or resign their water of gelatination under influences apparently the most feeble. It is not attempted to explain this varying hydration of colloids with the osmotic effects thence arising. Such phenomena belong to colloidal chemistry, where the prevailing changes in composition appear to be of the kind vaguely described as catalytic. To the future investigation of catalytic affinity, therefore, must we look for the further elucidation of osmose. (Graham, Chem. Soc. J. xv. 268.)

LIQUIDS, TRANSPIRATION OF. (Poiseuille, Ann. Ch. Phys. [3] vii. 60; xxi. 76; Jahresber. 1847-8, p. 139; Graham, Phil. Trans. 1861, p. 373; Chem. Soc. J. xv. 427.)—This term is applied to the passage of liquids through capillary tubes under pressure, in accordance with the analogy of gaseous transpiration (ii. 820). The first experiments on the subject were made by Poiseuille, who determined the manner in which the flow of the liquid is related to the pressure, and to the length and diameter of the tubes; also, in many cases, the manner in which it is affected by the nature of the liquid. Graham's enquiries were directed chiefly to the relation between the rate of transpiration and the chemical composition of the liquid.

The apparatus used by both these enquirers consists essentially of a small but rather stout glass bulb, A (*fig. 715*), about two-thirds of an inch in diameter, having a capacity of from 4 to 8 c. c., blown upon a thick glass tube, with a bore of about 2 millimetres.

Fig. 715.

A scratch *c* is made upon the glass tube above, and another *d* below the bulb, to indicate the available capacity of the instrument. The lower tube is bent at a right angle to the upper, and a fine capillary tube, B, from 3 to 4 inches in length, is sealed to the curved extremity of the tube. The bulb and capillary are immersed in a vessel of water during the experiment, to secure uniformity of temperature. The force employed to impel the liquid through the capillary is obtained from compressed air contained in a large reservoir provided with a mercurial gauge. The time is noted in seconds.

The liquid may be introduced into the bulb through the open upper tube by means of a tube-funnel; but it is more convenient, although requiring a much longer time, to fill the bulb by aspiration through the capillary. With this view, the compressed air is shut off by a stop-cock, and the upper tube of the bulb allowed to communicate with the receiver of an air-pump instead, whereby exhaustion is produced, while the open end of the capillary is immersed in a portion of the liquid. The liquid which enters the bulb in this manner is sure to be free from

any solid matter that could cause obstruction in the capillary during the subsequent passage of the liquid outwards, while the disconnecting of the bulb from the rest of the apparatus, for the purpose of filling the former, is also avoided.

From the experiments of Poiseuille it appears that when a tube exceeds a certain length (which is greater as the diameter increases), the rate of efflux is regulated by the following laws:—

1. The flow increases directly as the pressure.
2. With tubes of equal diameter, the quantities discharged in equal times are inversely as the lengths.
3. In tubes of equal length, but different diameters, the rate of efflux is as the fourth powers of the diameters.

The material of which the tube is made does not appear to influence the result, but the nature of the liquid employed exercises a marked effect. The liquids used in Poiseuille's experiments were in most cases aqueous solutions of various bodies, especially of salts. In the majority of instances, the flow of the solution was slower than that of distilled water. All the alkalis occasioned this retardation. In a few instances, no sensible alteration was produced; thus neither nitrate of silver, mercuric chloride, iodide of sodium, iodide of iron, nitric, hydriodic, bromic, nor hydrobromic acid seemed to have any influence, whilst sulphydric and prussic acids, the nitrates and chlorides of potassium and ammonium, and the iodide, bromide, and cyanide of potassium, increased the rapidity of the flow; it is remarkable, however, that concentrated solutions of iodide of potassium, at temperatures above 60° , and of nitrate of potassium above 40° , actually flow more slowly than distilled water. Strict attention to the temperature at which these comparisons are made is absolutely necessary; for both with water and with dilute solutions generally, a slight elevation of temperature produces a great increase in the rapidity of efflux. Water, for instance, at 45° escapes through the same tube $2\frac{1}{2}$ times as fast as it does at 5° .

No connection has hitherto been traced between the rate of efflux of a liquid and its density, capillarity, or fluidity. The capillarity of alcohol, as well as its density, increases in proportion as it is diluted with water, whilst its fluidity diminishes; but a mixture of equal parts of alcohol and water flows out with considerably less than half the rapidity of pure alcohol, and with less than a third of that of distilled water. The dilution of alcohol therefore, to a great extent, retards its efflux, and beyond that point increases it: the minimum rate of efflux corresponds with that particular mixture of alcohol and water, which is attended with the maximum contraction after the admixture of the two liquids.

The degree of solubility of a body in water appears to exercise but a secondary influence on the result. Poiseuille shows it to be highly probable that various solutions, when introduced into the blood of a living animal, provided they do not cause the serum to coagulate, produce effects of acceleration and retardation on the capillary circulation corresponding with those which are observed in the same liquids in capillary tubes of glass. He has shown this to be the case, by direct experiment, with iodide of potassium when injected into the veins of the horse; and that when various salts are mingled with the serum, and the liquids are allowed to flow out through small tubes, retardation or acceleration occurs, as in the corresponding cases, with their aqueous solutions.

The following tables contain the numerical results of Poiseuille's experiments.

The salts are arranged according to the acids, which appear to have the greatest influence on the rate of efflux. The letters *A, B, C, &c.*, designate the tubes employed. *L* is the length, *D* the diameter of the tube, *H* the pressure, measured by a column of water in millimetres, *T* the temperature (centigrade), *M* the quantity of substance in 100 pts. of water, *S* the time of efflux in seconds. The figures printed in the thicker type denote the time of efflux of pure water in each case.

It is remarked by Graham that the flow of a liquid is greatly retarded by the presence of a small quantity of a soluble colloid; so much so that the transpiration tube may be used as a colloidoscope. The transpirability of different salts appear also generally to follow their ratio of diffusibility in water.

The isolated fact discovered by Poiseuille that aqueous alcohol has a point of maximum retardation, coincident with the degree of dilution at which the greatest con-

densation of the mixed liquids occurs,—which degree of dilution corresponds with the hydrate, $C^2H^4O.3H^2O$, has been made by Graham the starting-point of an important series of experiments on the relation between capillary transpiration and chemical composition. The 3-atom hydrate of methylic alcohol, $CH^3O.3H^2O$, though not distinguished by any particular degree of condensation in volume, exhibits a peculiarity in its transpiration rate, similar to that of dilute ethylic alcohol. The hydrated acids also, in many cases, exhibit a characteristic retardation of transpiration at a particular degree of hydration. In hydrated substances generally, the extent to which transpiration is affected by annexation of water, is by no means in proportion to the intensity of combination. In sulphuric acid, for instance, the maximum transpiration-time occurs with the hydrate $H^2SO^4.H^2O$; in acetic acid, with the compound $C^2H^4O^2.H^2O$; of nitric acid with $2HNO^3.3H^2O$; and with alcohol, as above observed, with the hydrate $C^2H^4O.3H^2O$. The transpiration-times of these hydrates are given, amongst other results, in the following table, in which the transpiration-time of water at the same temperature is taken as the unit of comparison :

Transpiration-times of Acids, Alcohols, and Ethers. (Graham.)

Liquid (undiluted).	Transpiration-time.	Degree of hydration.	Transpiration-time.
Water	1.0000		
Methylic alcohol C^2H^4O	0.6300	+ $3H^2O$	1.8021
Ethylic alcohol C^2H^4O	1.1950	+ $3H^2O$	2.7582
Amylic alcohol C^3H^7O	3.6490		
Formate of ethyl $C^2H^4O^2$	0.5110		
Acetate of ethyl $C^2H^4O^2$	0.5530		
Butyrate of ethyl $C^4H^8O^2$	0.7500		
Valerate of ethyl $C^5H^{10}O^2$	0.8270		
Acetic acid $C^2H^4O^2$	1.2801	+ H^2O	2.7400
Butyric acid $C^4H^8O^2$	1.5650	+ H^2O	3.2790
Valerianic acid $C^5H^{10}O^2$	2.1550	+ H^2O	3.8390
Nitric acid NH^5O^3	0.9899	+ $\frac{3}{2}H^2O$	2.1034
Sulphuric acid H^2SO^4	21.6514	+ H^2O	23.7706
Acetone C^3H^6O	0.4010	+ $6H^2O$	1.6040

On comparing the transpiration-times of the several alcohols, ethers, and acids in this table, it will be seen that, so far as these observations extend, the order of succession of individual substances in any homologous series is indicated by their degree of transpirability as clearly as by their comparative volatility, the heaviest molecules having the slowest rate of efflux. It may also be observed that the transpiration rate of an acid is slower than that of an ether with which it is metameric; butyric acid, for example, is slower than acetate of ethyl.

LIQUORICE. See GLYCYRRHIZIN (ii. 920).

LIRIODENDRIN. A neutral substance, existing, according to Emmet, in the stem of the tulip-tree (*Liriodendron tulipifera*). It is obtained by exhausting the bark with water, concentrating to one-fifth, washing the impure substance which separates with weak potash, and crystallising from boiling dilute alcohol. It crystallises in scales or in radiating needles. It is bitter, melts at 83° , is partly volatile, sparingly soluble in water, very soluble in alcohol and ether. It is decomposed by strong hydrochloric or sulphuric acid, the latter converting it into a brown resin. Iodine colours it yellow.

LIROCONITE. *Octahedral Arsenate of Copper, Chalcophacite, Linsenger.*—This mineral occurs in trimetric crystals, exhibiting the combination $\infty P : \bar{P}\infty$, occasionally an inch in diameter, but usually minute. Angle $\infty P : \infty P = 119^\circ 20'$; $P\infty : P\infty = 72^\circ 22'$. Cleavage lateral, but obtained with difficulty. Rarely granular. Hardness = 2 to 2.5. Specific gravity = 2.882 to 2.985. Lustre vitreous, inclining to resinous. Colour and streak sky-blue. Fracture imperfectly conchoidal, uneven. Imperfectly sectile.

When heated it turns green and begins to glow, then becoming dark brown. On charcoal before the blow-pipe it melts slowly, and forms a red brittle bead; when reduced with carbonate of sodium, it yields white scales of arsenide of copper (Damour). It is completely dissolved by acids, and even by ammonia.

The following are analyses of liroconite from Cornwall; *a.* by Hermann (J. pr. Chem. xxxiii. 296)—*b.* by Damour (Ann. Ch. Phys. [3] xiii. 401)—*c.* by Trolle Wachtmeister (Kongl. Vet. Acad. Förhandl. 1832, p. 80):—

	As ² O ³	P ² O ⁵	CuO	Al ² O ³	H ² O	
a.	23.05	3.73	36.38	10.85	25.01	= 99.02
b.	22.40	3.24	37.40	10.09	25.44	= 98.57
c.	23.14	2.98	39.16	8.94	25.78	= 100.00

These results may be represented by the following formulæ:

- a. $(4\text{Al}^2\text{O}^3 \cdot \text{P}^2\text{O}^5) \cdot 3(5\text{CuO} \cdot \text{As}^2\text{O}^3) \cdot 48\text{H}^2\text{O}$
- b. $(4\text{Al}^2\text{O}^3 \cdot \text{P}^2\text{O}^5) \cdot 4(5\text{CuO} \cdot \text{As}^2\text{O}^3) \cdot 60\text{H}^2\text{O}$
- c. $(4\text{Al}^2\text{O}^3 \cdot \text{P}^2\text{O}^5) \cdot 5(5\text{CuO} \cdot \text{As}^2\text{O}^3) \cdot 72\text{H}^2\text{O}$

Liroconite occurs, with various ores of copper, pyrites, and quartz, at Huel Gorland and Huel Unity, in Cornwall; also in minute crystals at Herrangrund in Hungary, and in Voightland. (Dana, ii. 429.)

LITHEOSPORE. Syn. with HEAVY SPAR.

LITHIUM. Atomic weight 7, Symbol, Li.—Lithia, the oxide of this metal, was discovered by Arfvedson in 1817. It was first obtained from petalite (silicate of aluminium and lithium), in which it exists to the amount of 5 per cent.; it exists also in lithia-spodumeno (8 per cent.), amblygonite (11 per cent.), triphylite (3.4 per cent.), lepidolite (3.6 per cent.), apyrite, and the tourmaline of Uton in Sweden. The most abundant source of lithium yet discovered is a mineral spring in Cornwall, analysed by W. A. Miller (*Reports of the British Association*, 1864). In smaller quantities it is very widely diffused, being found in sea-water, in many micas and feldspars, in the ash of various kinds of tobacco, in sea-water, and in many mineral springs.—Bunsen has lately detected it in the meteorite of Juvenas in France, and in that of Parnallee in South Hindostan (Ann. Ch. Pharm. cxx. 263), and Engelbach has found it in the meteorite of the Cape. (Pogg. Ann. cxvi. 512.)

Brandes (Scherer's Annalen, viii. 120) stated that a white combustible metal is obtained from lithia by the action of the electric current, but metallic lithium was first obtained in definite form by Bunsen (Pogg. Ann. xciv. 107). The process is as follows:

Pure chloride of lithium is fused over a spirit-lamp in a small porcelain crucible, and decomposed by a zinc-carbon battery of 4 to 6 cells. The positive pole is a small splinter of gas coke (the hard carbon deposited in gas-retorts), and the negative pole an iron wire about the thickness of a knitting-needle. After a few seconds, a small silver-white regulus is formed under the fused chloride, round the iron wire and adhering to it, and after two or three minutes attains the size of a small pea. To obtain the metal, the wire pole and regulus are lifted out of the fused mass, by a small, flat, spoon-shaped iron spatula. The wire may then be withdrawn from the still melted metal, which is protected from oxidation by a coating of chloride of lithium. The metal may now be easily removed from the spatula with a pen-knife, after having been cooled under rock-oil. These operations may be repeated every three minutes; and thus an ounce of the chloride may be reduced in a very short time.

Lithium, on a freshly-cut surface, has the colour of silver, but quickly tarnishes on exposure to the air, becoming slightly yellow. It melts at 180°, and if pressed at that temperature between two glass plates, exhibits the colour and brightness of polished silver. It is harder than potassium or sodium, but softer than lead, and may, like that metal, be drawn out into wire. It tears much more easily than a lead wire of the same dimensions. It may be welded by pressure at ordinary temperatures. It floats on rock-oil, and is the lightest of all known solids, its specific gravity being 0.589—0.578. (Bunsen.)

Lithium is much less oxidable than potassium or sodium. It makes a lead-grey streak on paper. It ignites at a temperature much higher than its melting point, burning quietly, and with an intense white light. It burns when heated in oxygen, chlorine, bromine, iodine, or carbonic anhydride, and with great brilliancy on boiling sulphur. When thrown on water, it oxidises, but does not fuse like sodium. Nitric acid acts on it so violently that it melts and often takes fire. Strong sulphuric acid attacks it slowly; dilute sulphuric acid and hydrochloric acid quickly. Silica, glass, and porcelain are attacked by lithium at temperatures below 200°. (Bunsen, Ann. Ch. Pharm. xciv. 107.)

LITHIUM, CHLORIDE OF. LiCl. Produced when lithium burns in chlorine gas; also by dissolving lithia or carbonate of lithium in hydrochloric acid. By evaporating the aqueous solution at temperatures above 155°, or an alcoholic solution over sulphuric acid, the anhydrous chloride is obtained in cubes having the taste of common salt (C. Gmelin). According to Troost, it crystallises in regular octahedrons. According to H. Rose, it is more volatile than chloride of potassium, less volatile than chloride of sodium. In open vessels it volatilises even below a red heat, and is partially converted into carbonate.

The *hydrated chloride*, $\text{LiCl} \cdot \text{H}_2\text{O}$ according to Rammelsberg, $\text{LiCl} \cdot 2\text{H}_2\text{O}$ according to Hermann and Troost, is formed when the anhydrous chloride deliquesces in the air, or when the aqueous solution is evaporated at a rather low temperature (below 10°), and crystallises in large rectangular prisms with four-sided summits resting on the lateral edges: it is probably isomorphous with hydrated chloride of sodium. By rapid crystallisation, it forms needles grouped in feathery tufts like sal-ammoniac (Hermann). Both the anhydrous and the hydrated chloride deliquesce rapidly in the air, and dissolve very readily in water and in alcohol. (C. Gmelin.)

LITHIUM, DETECTION AND ESTIMATION OF. 1. *Reactions in the dry way.*—Lithium salts are white, excepting those which contain a coloured acid, such as chromic acid. They are more readily fusible than the corresponding salts of potassium and sodium, and are permanent in the fire, if the acid is not too volatile or easily decomposed. Fused with *carbonate of sodium* on platinum foil, they cause a dark yellow stain round the circumference, whilst carbonate of sodium by itself produces this effect to a much smaller degree only (Berzelius). Fused on platinum wire they colour the blowpipe flame carmine-red. An excess of a potassium-salt does not interfere with the production of this colour, but the presence of a small quantity of soda gives rise to the yellow flame (H. Rose). Alcohol, in which a salt of lithium is dissolved or diffused in the state of fine powder, also burns with a carmine-red flame (C. Gmelin). The same occurs also with paper saturated with a solution of a salt of lithium, or the wick of a taper saturated with moistened phosphate or acetate of lithium (Turner, Ed. Phil. J. of Sc. ii. 267; iv. 113). By means of the spectroscope, the occurrence of very minute traces of lithium may be detected, by a brilliant crimson band, having a refrangibility between those of the lines B and C of the solar spectrum, and a faint yellow band somewhat less refrangible than the line D. In these two lines the whole light of the lithium spectrum is contained, when formed by the gas-flame of a Bunsen's burner. At very high temperatures, however, such as that of a hydrogen-flame, a blue line also makes its appearance.

2. *Reactions in Solution.*—All salts of lithium are soluble in water; but the carbonate and phosphate, and the double phosphate of lithium and sodium are but slightly soluble. Hence the other salts of lithium, when not dissolved in too much water, yield difficultly soluble precipitates with *carbonate of ammonium*, *potassium*, or *sodium*, and with *phosphate of sodium*. *Carbonate of sodium* precipitates the salts of lithium after some time only. Common *disodic phosphate* does not precipitate them in the cold, even after a long time, except on the addition of ammonia, which gradually gives rise to an abundant precipitate. But a mixture of a salt of lithium with phosphate of sodium becomes turbid by boiling or evaporation, and the dry residue, on being treated with water, leaves the difficultly soluble phosphate of lithium and sodium.

Phosphate of potassium gives no precipitate, even on boiling or evaporation; but on the addition of *ammonia*, an abundant precipitate after some time (H. Rose). *Hydrofluosilicic acid* throws down from salts of lithium the almost insoluble fluoride of silicon and lithium (Berzelius), and *picric acid* precipitates picrate of lithium (H. Rose). Solutions of lithium-salts, even when concentrated, are not precipitated by perchloric acid, sulphate of aluminium, dichloride of platinum, oxalic acid, or tartaric acid.

A solution of a salt, which is not clouded by caustic soda in the cold, or by carbonate of sodium at a boiling heat, but yields with phosphate of sodium, on evaporation, an almost insoluble white powder, contains lithia. (Berzelius.)

3. *Quantitative Estimation and Separation.*—Lithium, after separation from other metals, may be estimated as carbonate, sulphate, or chloride. The hydrate and the organic salts of lithium are converted into carbonate, Li_2CO_3 , when ignited in contact with the air. All lithium-salts containing volatile acids, may be converted into sulphate by heating them with sulphuric acid: the excess of acid may be expelled by simple ignition, without addition of carbonate of ammonia, because lithium does not form an acid sulphate. The chloride is not so well adapted for quantitative estimation as the sulphate, on account of its hygroscopic qualities; but as lithium is generally obtained as chloride, in the process of separating it from sodium, it is convenient to estimate it directly in this form: it must be ignited in a well-covered crucible, and weighed immediately after cooling.

Lithium may also be estimated as phosphate, Li_3PO_4 , by evaporating the solution of a lithium-salt with phosphate of sodium, adding a quantity of hydrate or carbonate of sodium sufficient to keep the liquid alkaline; digesting the residue with ammonia, and washing the precipitate with a mixture of equal volumes of water and ammonia, then drying at 100° , and igniting. The determination may be rendered more exact by repeatedly evaporating the filtrate and wash-water, and treating the small quantities of lithium-phosphate thereby separated, as before (W. Mayer, Ann. Ch. Pharm. xviii. 193; Jahresb. 1856, p. 739). According to Rammelsberg (Pogg. Ann. cii.

441; Jahresb. 1857, p. 141), solutions of lithium treated with phosphate and carbonate of sodium yield salts of the form M^2PO^4 , containing variable quantities of lithium and sodium; but Fresenius (Zeitschr. Annal. Chem. i. 42) finds that the precipitate obtained as above always has the composition Li^2PO^4 , and, accordingly, that Mayer's process is capable of yielding correct results.

Lithium is separated from the earth-metals and heavy metals in the same manner as the other alkalis, namely, by sulphydric acid, sulphide of ammonium, or carbonate of ammonium, &c. From potassium it may be separated by *dichloride of platinum*, which precipitates potassium, but not lithium; and from sodium, by converting the two alkalis into chlorides, and treating the dried chlorides, in a well closed bottle, with a mixture of *ether* and *absolute alcohol*, which, in the course of a few days, dissolves the chloride of lithium, and leaves the chloride of sodium.

As, however, this last process is somewhat tedious, and is apt to be rendered inexact by the presence of moisture, Bunsen (Ann. Ch. Pharm. cxvii. 348) recommends the following indirect method of estimating lithium, when it exists in the state of mixture or combination with other alkali-metals. The anhydrous mixture of the chlorides of the alkali-metals is repeatedly exhausted with ether-alcohol; the residue obtained by evaporating this solution is again treated in the same manner; and the evaporated residue of this extract is ignited and weighed. It is then dissolved in water; the total amount of chlorine is determined by precipitation with nitrate of silver; the filtrate is then freed from excess of silver by hydrochloric acid, and the potassium contained in it is precipitated by chloride of platinum. The quantity of chloride of potassium thus determined gives, when deducted from the total weight of the chlorides, a remainder $A = x$ chloride of lithium + y chloride of sodium; and the quantity of chloride of silver equivalent to the known quantity of chloride of potassium, gives, when deducted from the total weight of the chloride of silver, a weight B , whence the quantity of chloride of lithium is calculated by the formula—

$$x = 1.0823 B - 2.6525 A.$$

4. *Atomic weight of Lithium.* The earlier determinations of this number by Arfvedson, Vauquelin, C. G. Gmelin, and Kralovansky, were much too high, having been made with lithium-salts containing sodium. Hermann, Berzelius, and Hagen, prepared carbonate of lithium free from sodium by precipitation with carbonate of ammonium, and converted it into sulphate, which was then analysed by precipitation with baryta. In this manner Berzelius obtained the number 6.5. The numbers obtained by Hermann and Hagen were lower, and even that of Berzelius has been shown by subsequent experiments to be too low, the error probably arising from partial decomposition of the carbonate of lithium during fusion.

Mallet (Sill. Am. J. xxii. 349), by decomposing chloride of lithium with nitrate of silver, obtained the numbers 6.92 and 6.96. Diehl (Ann. Ch. Pharm. cxi. 93), by the analysis of carbonate of lithium, the purity of which had been tested by spectral analysis, found the atomic weight of the metal = 7.026. Troost (*ibid.* cxviii. 384), by decomposing the pure carbonate with silicic acid, obtained the number 7.01; the analysis of the chloride gave the same result; and the decomposition of the carbonate by sulphuric acid yielded the number 7.06. From all these results, the number 7 is adopted as the true atomic weight of lithium.

LITHIUM, FLUORIDE OF. This compound crystallises from the aqueous solution in very small opaque grains, which, at the temperature of commencing redness, fuse to a clear mass, again becoming cloudy as it solidifies. It is very slightly soluble in water. (Berzelius.)

LITHIUM, OXIDE OF. *Lithia*, Li^2O .—*Anhydrous lithia* is obtained as a yellowish-white spongy mass, containing a certain quantity of peroxide, by burning lithium in oxygen, and leaving the product to cool in a stream of the gas. (Troost, Ann. Ch. Phys. [3] li. 703.)

The *hydrate* may be obtained from petalite, spodumene, or lepidolite, which are silicates containing lithium (most advantageously from lepidolite), or from triphylite, which is a phosphate of lithium, manganese, iron and aluminium, by the following processes:—

1. Lepidolite, petalite, or lithia-spodumene, reduced to fine powder by careful levigation, is ignited with twice its weight of quicklime; the mass is treated with hydrochloric acid, then with sulphuric acid; the resulting sulphate of lithium is dissolved out from the sulphate of calcium; and the last traces of calcium are removed by precipitation with oxalate of ammonium. The solution of sulphate of lithium is then treated with a quantity of baryta-water just sufficient to throw down the sulphuric acid, and the filtrate on evaporation yields hydrate of lithium.

2. Troost (Ann. Ch. Phys. [3] li. 121) heats 10 pts. of finely-powdered lepidolite

with 10 pts. of carbonate of barium, 5 pts. sulphate of barium, and 3 pts. sulphate of potassium. The fused mass separates on cooling into a heavy transparent glass and a supernatant white crystalline slag, consisting of the sulphates of barium, lithium, potassium, and sodium, and containing nearly all the lithium. The alkaline sulphates are dissolved out by water, and converted into chlorides by chloride of barium; the potassium is precipitated by chloride of platinum, and the chlorides of lithium and sodium are separated by means of alcohol and ether. In operating on a large scale, the double sulphate of lithium and potassium may be separated by fractional crystallisation.

3. Triphyline is dissolved in strong hydrochloric acid, nitric acid being added to bring the iron to the state of ferric oxide; the solution is evaporated to dryness; and the residue is treated with water, which leaves all the iron as insoluble phosphate. The solution containing the chlorides of lithium and manganese and a little phosphoric acid, is treated with sulphide of barium, which removes the two latter substances; the excess of barium is removed by sulphuric acid (or better, by carbonate of ammonium), and the filtrate is evaporated to dryness and ignited. Chloride of lithium thus obtained frequently contains chloride of sodium, which may be separated by alcohol and ether. The chloride is then converted into sulphate, and from this salt caustic lithia is obtained as above. (Müller, Ann. Ch. Phys. [3] xlv. 350.)

Hydrate of Lithium, LiHO , separates from the aqueous solution in small crystalline grains. It has the same taste, causticity, and alkaline action on vegetable colours as potash and soda, but is much less soluble in water. It melts easily below redness, forming a fused mass which has a crystalline fracture. It does not appear to volatilise at a white heat.

Fused lithia, as commonly prepared, corrodes platinum vessels powerfully, so that silver vessels should always be used for heating it. This action upon platinum is said, indeed, to be one of the best indications of the presence of lithium; but, according to Troost (Ann. Ch. Pharm. exxiii. 384), it is not produced by pure lithia, or by any pure lithium-salt, but only by such as contain cesium and rubidium.

Peroxide of Lithium is said by Troost to be formed, together with lithia, when lithium is burned in oxygen gas.

LITHIUM, SULPHIDE OF. Li_2S . This compound is formed when lithium is thrown on melted sulphur; also when sulphate of lithium is heated to redness with charcoal. It dissolves in water and alcohol more easily than lithia.

LITHOGRAPHY. See PRINTING, CHEMICAL.

LITHOMARGE. *Stone-marrow* (Stinnmark). A kind of clay, of which there are two varieties, the friable and the indurated.

Friable Lithomarge.—Colour white. Massive and sometimes in crusts; particles acely and feebly glimmering; streak shining. Slightly cohering. Soils slightly. Feels rather greasy; adheres to the tongue. Light. Phosphoresces in the dark. Its constituents are, according to Klaproth, silica 32, alumina 26.5, iron 21, chloride of sodium 1.5, and water 17.0. It occurs sometimes in tin-stone veins.

Indurated Lithomarge. Colours yellowish and reddish-white. Massive and amygdaloidal. Dull, opaque. Fracture fine earthy. Streak shiny. Soft, sectile, and easily frangible; adheres strongly to the tongue; greasy to the touch. Specific gravity 2.44. Infusible before the blowpipe. Some varieties phosphoresce, and others, when moistened, afford an agreeable smell like that of nuts. Its constituents are, silica 45.25, alumina 36.5, oxide of iron 2.75, water 14, and a trace of potash (Klaproth). It occurs in veins in porphyry, gneiss, &c., at Rochlitz in Saxony, and at Zöblitz. (Jameson.)

LITHOSPERMUM. The root-bark of *Lithospermum arvense* contains a red colouring matter, which reacts with water, alcohol, ether, and alkalis, in the same way as that of alkanet (i. 128), excepting that the lithosperm-red forms a blue solution with ether, whereas alkanet-red forms a dark red solution. (Ludwig and Kromayer, Rép. Chim. ap. 1859, p. 211.)

LITMUS. *Lackmus*. *Tournesol en pains*.—A blue colouring matter, used chiefly for preparing test-papers. It is obtained from various species of *Roccella*, *Variolaria*, and *Lecanora*, the same lichens in fact that yield archil (i. 355). It appears from the experiments of Gélis (Revue Scient. vi. 50) that the blue colouring matter is developed in the lichens by fermentation, when the proximate principles contained in them are metamorphosed in presence of an alkaline carbonate. Under the influence of the air and ammonia alone, these lichens yield nothing but archil; but if an alkaline carbonate is likewise present, the lichens undergo a totally different alteration, and the product of the fermentation, instead of being red or violet, has then a pure blue colour. This blue coloration is due to the combination of the new colouring matter with the

alkali: for acids, as is well known, reddened litmus, that is to say, they unite with the alkali, and liberate the colouring matter of the litmus, which in this state is red, like that of archil. When 2 pts. of *Rocella tinctoria* and 1 pt. carbonate of potassium are repeatedly moistened with carbonate of ammonium, or with urine which is saturated with that salt, the mass acquires in three days a brown or dirty red colour; in 20 or 25 days a purple red; in 30 days a blue colour; and in 40 days yields litmus of the finest colour (Gélie, J. Pharm. xxiv. 277). Litmus is prepared in Holland from *Lecanora tartarea* and *Rocella tinctoria* from the Canary Isles, the coloured mass obtained as above being thickened with chalk or gypsum.

Our knowledge of the colouring matters of litmus is not very exact, but they are probably derived directly from orcein, like orcein, the colouring principle of archil. The principal of these colouring matters is azolitmin, and three others have been distinguished, namely, Spaniolitmin, erythrolein, and erythrolitmin. The following mode of preparation of these colouring matters is given by Kane (Phil. Trans. 1840, p. 298):

a. Commercial litmus in powder is exhausted with boiling water, and the pale blue residue, which contains the greater part of the colouring matter, is made up into a thin paste with water, and hydrochloric acid is added till effervescence ceases and the liquid exhibits a strong alkaline reaction. The mass is then thrown on a filter; and the residue, after being freed from excess of acid by washing with water, is well dried and repeatedly boiled with alcohol, as long as that liquid extracts anything from it. The alcoholic solution is evaporated to dryness over the water-bath, and the residue digested with warm ether as long as the ether is coloured by it. The ethereal solution, distilled in the water-bath to remove the ether, leaves Erythrolein in the form of a purple semi-fluid oil. The portion of the alcoholic extract which is insoluble in ether consists of Erythrolitmin.

The red-brown powder which remains after the boiling with alcohol (*vid. sup.*) consists of impure Azolitmin. This substance is either boiled with pure water, and pure azolitmin obtained by evaporating the strongly coloured solution; — or the residue insoluble in alcohol is boiled with ammoniacal water, and the blue solution evaporated to dryness, during which operation the greater part of the ammonia escapes; the remainder is separated by moistening the mass with hydrochloric acid, and washing the resulting sal-ammoniac with alcohol.

b. The strongly coloured liquid obtained by boiling litmus with water is precipitated with neutral acetate of lead; the precipitate washed with water, treated while still moist with sulphydric acid, and suspended in warm ammoniacal water; the dark blue liquid is evaporated to dryness, and moistened with hydrochloric acid; and the sal-ammoniac is separated by means of warm alcohol. The residue is but of small amount in proportion to the deep colour of the solution; it sometimes consists of pure azolitmin, more rarely of Spaniolitmin, a substance not containing nitrogen.

Azolitmin is a red-brown amorphous powder which dissolves with blue colour in ammonia, and forms blue and violet lakes.

Spaniolitmin has only been obtained mixed with azolitmin, but it appears to be of a light red colour.

Erythrolein is a semi-fluid mass of a fine red colour, and dissolves in ammonia, forming a purple liquid.

Erythrolitmin forms crystalline grains of a fine deep red colour, coloured blue by potash, and forming, with ammonia, a blue compound insoluble in water.

The following are the analytical results obtained by Kane with these substances, and calculated with the old atomic weight of carbon (6.12 or 12.24):

	Erythrolein.	Erythrolitmin.	Azolitmin.	Spaniolitmin.		
Carbon . . .	74.27	55.78	55.3	49.50	50.05	44.54
Hydrogen . .	10.68	8.69	8.1	5.35	5.52	3.11

Of these four substances, azolitmin is the only one which contains nitrogen. Kane determined the nitrogen only by the comparative method which gave proportions of N : CO₂ varying from 1 : 17.3 to 1 : 18.3.

The composition of azolitmin approaches pretty nearly to the formula C⁷H⁴NO⁴ (carbon 49.6, hydrogen 4.1, nitrogen 8.2), according to which azolitmin would contain 1 at. oxygen more than orcein, and might be derived from orcein in the manner shown by the equation,

If this be true, the action of the alkaline carbonates in the formation of litmus may be explained by supposing that these salts accelerate the absorption of oxygen by orcein subjected to the influence of air and ammonia, so as to produce a new compound more highly oxygenated than orcein.

The ammoniacal solution of azolitmin forms with the salts of the heavy metals, precipitates which are red or blue, according to the quantity of metal contained in them. The azolitminates of barium and calcium are blue. The lead-compound, which has a fine violet colour when recently prepared, but becomes blue when dried at 120° , appears to contain $2\text{C}_2\text{H}_3\text{PbNO}_4 \cdot \text{PbO}$. The stannous salt is a lake of a fine violet colour; by exposure to the air in the moist state it is converted into a stannic compound of a splendid scarlet colour.

Azolitmin suspended in water through which chlorine gas is passed yields yellow chlorazolitmin.

Azolitmin subjected to the action of nascent hydrogen, is dissolved, and converted into a compound called by Kane, leuc azolitmin, which, however, cannot be obtained pure, because it oxidises immediately and becomes coloured when exposed to the air. A white compound of leuc azolitmin with stannic oxide is formed by boiling the stannous compound of azolitmin with water; on exposure to the air, it is immediately converted into the scarlet stannic compound of azolitmin.

LIVER, GLYCOGENIC FUNCTION OF. See GLYCOGEN (ii. 906).

LIVER OF SULPHUR. An old term applied to a mixture of the higher sulphides of potassium, obtained by heating sulphur with carbonate of potassium in a covered vessel. (See POTASSIUM, SULPHIDES OF.)

LIXIVIATION. The application of water to the fixed residues of bodies, for the purpose of extracting the saline part.

LIXIVIUM. A solution obtained by lixiviation.

LOADSTONE. Magnetic iron ore (p. 397): see also MAGNETISM.

LOAM. See CLAY (i. 1023).

LOBELINE. An alkaloid existing, according to Bastick and Procter (Pharm. J. Trans. x. 270, 456) in *Lobelia inflata*. It is oily; cannot be volatilised without decomposition; dissolves very readily in water, alcohol, and ether; and forms crystallisable salts with hydrochloric, sulphuric, nitric, and oxalic acids. The solutions are precipitated by tannin. It acts as a narcotic when taken internally.

LOBOSITE. A magnesian vesuvian from Norway. (See VESUVIAN.)

LOLINGITE. Syn. with LEUCOPYRITE (p. 585).

LEWITE. A sulphate of magnesium and sodium, $\text{Mg}^2\text{Na}_2(\text{SO}_4)_2 \cdot 2\frac{1}{2}\text{H}_2\text{O}$, from Ischl, approaching astrachanite in composition. It is of yellowish colour, specific gravity 2.376, and gives by analysis 52.35 SO_4 , 12.78 MgO , 18.97 Na_2O , 14.46 H_2O , and 0.66 Fe_2O_3 and $\text{Al}_2\text{O}_3 = 99.21$. (Karafiat, Haid. Ber. 1846, p. 266.)

LOGANITE. A variety of pyrochlorite from Calumet Island on the Ottawa, Canada, where it occurs associated with serpentine, phlogopite, pyrites, and apatite, in crystalline limestone. It has a weak subresinous lustre, pale or dark brownish colour, and greyish streak. Hardness = 3. Specific gravity = 2.6–2.64. Sometimes in crystals with rounded angles, which appear to be pseudomorphs; one gave the angle 124° , near that of hornblende. Contains 32.49 per cent. silica, 13.18 alumina, 35.77 magnesia, 0.95 lime, 2.14 protoxide of iron, and 16.92 water (including carbonic acid) = 101.45. (T. S. Hunt, Phil. Mag. [4] ii. 65.)

LOGWOOD. *Bois de Campêche*. *Blancholz*.—The tree which yields this wood is called by Linnæus, *Hæmatoxylum campechianum*.

Logwood is so heavy as to sink in water, hard, compact, of a fine grain, capable of being polished, and scarcely susceptible of decay. Its predominant colour is red, tinged with orange, yellow, and black.

It yields its colour both to spirituous and watery solvents. Alcohol extracts it more readily and copiously than water. The colour of its dye is a fine red, inclining a little to violet or purple, which is principally observable in its watery decoction. This, left to itself, becomes in time yellowish, and at length black. Acids turn it yellow; alkalis deepen its colour, and give it a purple or violet hue.

Stuffs would take only a slight and fading colour from decoction of logwood, if they were not previously prepared with alum and tartar. A little alum is also added to the bath. By these means they acquire a pretty good violet.

A blue colour may be obtained from logwood, by mixing verdigris with the bath, and dipping the cloth till it has acquired the proper shade.

The great consumption of logwood is for blacks, to which it gives a lustre and velvety cast, and for greys of certain shades. It is also of very extensive use for different compound colours, which it would be difficult to obtain of equal beauty and variety by means of drugs affording a more permanent dye.

Decoction of logwood is frequently mixed with that of brazil-wood, to render colours deeper, their proportion being varied according to the shade desired.

Logwood is used for dyeing silk violet. For this, the silk must be scoured, alumed, and washed; because, without aluming, it would take only a reddish tinge that would not stand wetting. To dye silk thus, it must be turned in a cold decoction of logwood till it has acquired the proper colour; if the decoction were used hot, the colour would be in stripes and uneven.

Bergmann observed, that a fine violet might be produced from logwood by impregnating the silk with solution of tin. In fact we may thus obtain, particularly by mixing logwood and brazil-wood in various proportions, a great number of fine shades, more or less inclined to red, from lilac to violet. See *HÆMATOXYLIN* (p. 4). U.

LOMONITE. Syn. with LAUMONTITE (p. 472).

LÖNCHIDITE. A variety of manganite or white iron pyrites, found at Freiberg, Schneeberg, and in Cornwall. Hardness = 6.5. Specific gravity = 4.925—5. Colour, tin-white, sometimes greenish or greyish. Streak, black. According to Plattner's analysis, it contains 49.61 per cent. S, 4.40 As, 44.23 Fe, 0.35 Co, 0.75 Cu, and 0.20 Pb (= 99.24). (Breithaupt and Plattner, Pogg. Ann. lxxvii. 135.)

LOPEZ-ROOT. The root of *Toddalia aculeata*. By successive treatment with ether, alcohol, water, and dilute hydrochloric acid, it yields about 40 per cent. of soluble matter, consisting of a bitter principle, a tasteless resin, gum, tannin, starch, and oxalate of calcium. (H. Weber, Jahresber. 1859, p. 572. See also Schnitzer, *ibid.* 1862, p. 525.)

LOPHINE. $C^{21}H^{18}N^2$. *Pyrobenzoline*, (Laurent, Ann. Ch. Phys. [3] xix. 369. —Fownes, Ann. Ch. Pharm. liv. 365 and 368. —Gössmann, *ibid.* xxiii. 331. —Gössmann and Atkinson, *ibid.* xevii. 283; Chem. Soc. J. ix. 220. —Gm. xii. 199. —Gerh. iii. 179; iv. 1010.)—An organic base produced by the dry distillation of hydrobenzamide, benzoylazotide, or azosulphide of benzylene (Laurent), of amarine (Fownes), and by heating sulphite of benzoyl and ammonium with slaked lime (Gössmann). Its formation from hydrobenzamide (p. 183), or from the isomeric compound amarine, may be represented by the equation,

The compound $C^{21}H^{18} = 3C^7H^6$ (polymeric with stilbene) is probably the only matter which distils over with the lophine. (Gerhardt.)

Preparation.—1. When hydrobenzamide is heated, ammonia escapes, together with a mobile fragrant oil, and there remains a fused mass which may be distilled at a high temperature, but is more advantageously treated by pouring it out, pulverising it when cold, and digesting it in hot ether, which extracts a small quantity of a body crystallising in shining laminae as the solution cools. The residue is heated with alcohol to the boiling point, and hot caustic potash added to it till the whole is dissolved; the liquid on cooling deposits thread-like crystals which may be washed with alcohol. It is better, however, to boil the residue insoluble in ether, with alcohol containing hydrochloric acid, mix the solution at the boiling heat with ammonia, and leave it to cool (Laurent).—2. From the mixture of lophine and amarine obtained by distilling benzoylazotide, the amarine is extracted by boiling with rock-oil, or the lophine by boiling with alcohol containing hydrochloric acid (Laurent).—3. From the distillate obtained by heating azosulphide of benzylene, the oily products are extracted by ether, the stilbene by boiling alcohol, and the thionessal by rock-oil, and the residue, consisting of lophine, is dissolved by boiling with alcohol and potash, or with alcohol containing hydrochloric acid. A similar process is adopted with the product resulting from distilling the mixture obtained by treating bitter-almond oil for two or three weeks with sulphurate of ammonium, which mixture also contains picril (Laurent).—4. The needle-shaped crystals which sublime in the neck of the retort during the distillation of sulphite of benzoyl and ammonium with hydrate of calcium, are dissolved in hot alcohol, and recrystallised after being treated with animal charcoal. The formation of the lophine is facilitated by heating the retort very quickly and covering the upper part, at the commencement of the distillation, with red-hot coals (Gössmann). The best mode of conducting the process is to add a quantity of quicklime, equal in weight to the hydrate, introduce the mixture into a rather shallow globular retort coated with clay, and cover the retort, as far as it is filled with the mixture, with live coals, from the very beginning of the operation. Only small quantities should be operated on at once, from 10 to 15 grms. of the benzoyl-compound, with about 4 to 6 times the quantity of the lime mixture. When the operation is thus conducted, only a small quantity of amarine forms at first; and when this has melted down, the upper

part of the retort begins to be covered with radiant masses of lophine, and the formation of secondary products ceases, nothing being formed but lophine and free ammonia. At the commencement, a small quantity of an aromatic oil accompanies the lophine, apparently resulting from the decomposition of the amarine into lophine and other products, the principal of which is amarone (Gössmann and Atkinson). Purification as in Laurent's method (1).

Properties.—Lophine forms colourless needles, often an inch long, grouped in tufts, and having a lustre similar to that of caffeine; they become opalescent after a while, but retain their lustre. At 250° the compound sublimes, gradually but completely, without previous fusion, and without decomposition. It melts at 265° , forming a transparent liquid, which at 260° solidifies in a radiating crystalline mass. It is tasteless and inodorous, with scarcely any alkaline reaction. The alcoholic solution exhibits fluorescence like quinine, but not in so high a degree. It has no action upon polarised light (Gössmann and Atkinson). G. Kühn (Chem. Centr. 1861, p. 237) obtained, by the dry distillation of hydrochlorate of hydrobenzamide (p. 184), two modifications of lophine, one crystallising in needles which melted at 230° , the other (likewise obtained by Ekman, Ann. Ch. Pharm. cxii. 151) in needles which melted at 170° .

The composition of lophine has been variously represented by the formulæ $C^{21}H^{10}N^2$ and $C^{22}H^{10}N^2$ (Laurent), $C^{21}H^{10}N^2$ (Fownes), $C^{21}H^{11}N^2$ (Gössmann and Atkinson), $C^{22}H^{10}N^2$ (Liszt). Fownes's formula, $C^{21}H^{10}N^2$, agrees best, on the whole, with the analyses, and likewise affords the best representation of the formation of the compound from hydrobenzamide (or from amarine):

	Calculation.		Laurent.		Fownes.	Gössmann.	Gössmann and Atkinson.
C^{21}	252	85.1	85.6	86.0	85.2	85.7	84.7
H^{10}	16	5.4	5.4	5.1	5.4	5.5	5.6
N^2	28	9.5	9.2	.	9.1	.	9.5
$C^{21}H^{10}N^2$	296	100.0	100.2		99.7		99.8

Laurent's second analysis, which differs considerably from all the rest, was probably made with impure material.

Lophine is insoluble in water, very sparingly soluble in boiling alcohol and ether, crystallising in needles on cooling. It dissolves to about the same amount in rock-oil, and in oil of turpentine, whence it separates in a crystalline powder on cooling. It dissolves easily and without decomposition in boiling alcoholic potash. (Laurent.)

According to Ekman (Ann. Ch. Pharm. cxii. 151), 100 pts. of absolute alcohol at 19° dissolve 0.81 pt. of lophine, and at 21° from 0.84 to 0.91 pt.; at the boiling point, 2.70 to 2.75 pts.; and 100 pts. ether dissolve 0.26 pt. lophine at 19° , 0.32 to 0.33 at 20° , and 0.32 at 21° . Of an indifferent substance, having nearly the composition of lophine, and formed, together with the latter, by the decomposition of hydrochlorate of hydrobenzamide at 160° – 200° (p. 183), 100 pts. absolute alcohol dissolve 0.07 pt. at 16° , and 0.33 to 0.37 pt. at the boiling point; and 100 pts. ether at the boiling point dissolve 0.69 to 0.74 pt. of the same substance.

Decompositions.—Lophine boiled with nitric acid forms nitrolophine (Laurent). It is dissolved by bromine, without evolution of vapours of hydrobromic acid. When the mass is dissolved in ether, and the solution mixed with alcohol and abandoned to spontaneous evaporation, beautiful yellow prisms with rectangular base separate out; these crystals give off bromine when heated, and, when water is poured upon them, turn white and fall to powder (Laurent). Lophine in contact with iodide of ethyl does not form any substitution-compound not even when the two bodies are heated together to 100° in a sealed tube for several weeks. A portion of the iodide of ethyl is decomposed into alcohol and hydriodic acid, which combines with the lophine. (Gössmann and Atkinson.)

The lophine-salts are for the most part insoluble in water, and sparingly soluble in alcohol.—They are rather unstable, having a tendency when recrystallised to give up part of their acid and form basic compounds; this is particularly the case with the sulphate. (Gössmann and Atkinson.)

Iodide of Lophine, $C^{21}H^{10}N^2.HI$, is prepared like the hydrochlorate, and crystallises readily in large needles, which are more soluble in alcohol and ether than the hydrochlorate. From a very acid solution, it separates in granular crystals. It dissolves very easily in iodide of ethyl. In other respects it resembles the hydrochlorate. (Gössmann and Atkinson.)

Hydrochlorate of Lophine, $C^{21}H^{10}N^2.HCl$, separates quickly on cooling from a solution of lophine in boiling alcohol containing hydrochloric acid. If a solution in a sufficient quantity of boiling alcohol be mixed with such a quantity of hot water that no immediate precipitate is formed, the liquid on cooling yields well defined crystalline

laminae (Laurent). The second modification of lophine, obtained by Kühn (p. 184), forms a hydrochlorate, also containing $C^{21}H^{16}N^2.HCl$, which crystallises in interlaced needles, melting at 160° . When hydrochloric acid is added to a hot saturated alcoholic solution of lophine till the mixture exhibits a decided acid reaction, the hydrochlorate separates on cooling in large transparent needles very much like the crystals of pure lophine. If left for some time in the mother-liquor, they change into small white opaque prisms, an alteration which is probably due to loss of water. Several other lophine-compounds exhibit a similar change. When lophine is treated with strong hydrochloric acid, it becomes resinous, and can only be restored to the crystalline state by removing the acid and crystallising from alcohol (Gössmann and Atkinson). The hydrochlorate is nearly insoluble in water, but dissolves pretty easily in alcohol (Laurent). It has a slight acid reaction, dissolves more readily in water and alcohol than the pure base, and exhibits stronger fluorescence. (Gössmann and Atkinson.)

Hydrochlorate of lophine unites with *tetrachloride of platinum* when the solutions of the two salts in boiling alcohol are mixed together, the double salt separating, as the liquid cools, in orange-coloured crystals, the formula of which is probably $2(C^{21}H^{16}N^2.HCl).PtCl_4$. The chloroplatinate of Kühn's second modification of lophine contains water of crystallisation, the amount of which was found to be different in different preparations.

Nitrate of Lophine, $C^{21}H^{16}N^2.HNO_3$, forms fine light laminae, devoid of lustre. When heated till they soften, they give off 1 at. water (Laurent). From a concentrated alcoholic solution of lophine acidulated with nitric acid, the salt crystallises in small plates, which, if covered with strong nitric acid free from nitrous acid, are converted into an oily mass. (Gössmann and Atkinson.)

Sulphate of Lophine is obtained in small shining rectangular laminae, by heating lophine with alcoholic sulphuric acid, and mixing the solution with hot water, whereupon crystallisation ensues. The alcoholic solution reddens litmus and is precipitated by water, a portion however remaining in solution, so that, on adding ammonia, a precipitate of lophine is still obtained. Laurent found in the dry salt 11.5 and 13.2 per cent. of sulphuric acid; the neutral salt requires 11.21 per cent. of sulphuric acid (Laurent). When a solution of lophine to which excess of sulphuric acid has been added is left to evaporate slowly, the sulphate separates in broad transparent tables, which become opaque and effloresce on exposure to the air. When crystallised more rapidly, the compound separates in large needles, which, if left for some time in the mother-liquor, change into small white opaque needles. At each crystallisation, the salt becomes more basic, and by frequent solution and re-crystallisation, the acid may be almost entirely removed. (Gössmann and Atkinson.)

Lophine also forms crystalline compounds with *nitrate of silver* and *dichloride of platinum*.

LOTALITE. Syn. with **HORNBLende**.

LOXOCLEASE. A name applied by Breithaupt to a variety of felspar closely resembling orthoclase, if not identical with it.

LUBRICANTS. Oleaginous or fatty bodies used for reducing the friction between parts of a machine or carriage. (See *Ure's Dictionary of Arts*, &c. ii. 736; the chapter on Railway and Waggon Grease in *Richardson and Watts's Chemical Technology*, vol. i. pt. 3, p. 742; and the article **PARAFFIN OILS** in this Dictionary.)

LUCIFER MATCHES. See *Ure's Dictionary of Arts*, &c. ii. 737; *Richardson and Watts's Chemical Technology*, vol. i. pt. 4, p. 131; and the article **PHOSPHORUS** in this Dictionary.

LUCULLITE. See **LIMESTONE**, (p. 698).

LUMACELLA. See **LIMESTONE**, (p. 697).

LUNA CORNEA Chloride of silver (see **SILVER**).

LUNAR CAUSTIC. Nitrate of silver fused at a low heat (see **NITRATES**).

LUPININ. A bitter non-nitrogenous substance obtained from lupine-seeds, (Cassol, Ann. Ch. Pharm. xiii. 308.)

LUPULIN. The yellow, granular, aromatic powder situated at the base of the cones of the hop, and forming from 8 to 18 per cent. of the cones. It contains five different substances; viz. a volatile oil, a resin, a nitrogenous substance, a bitter principle, and a gummy substance. The cones contain about 2 per cent. of the volatile oil. This oil and the resin probably give to beer its agreeable aromatic odour, while the bitter substance tends to preserve it. (See **HOP**, p. 165.)

LUPUS METALLORUM. The alchemical name of trisulphide of antimony.

LUTE. The lutes with which the joinings of vessels are closed are of different kinds

according to the nature of the operations to be performed, and of the substances to be distilled in these vessels.

When vapours of watery liquors, and such as are not corrosive, are to be retained, it is sufficient to surround the joining of the receiver to the nose of the alembic, or of the retort, with slips of paper or of linen covered with flour-paste. In such cases also, slips of wet bladder may be conveniently used.

When more penetrating and dissolving vapours are to be retained, a lute is to be employed of quicklime slacked in the air, and beaten into a liquid paste with whites of eggs. This paste is to be spread upon linen slips, which are to be applied exactly to the joining of the vessels. This lute is very convenient, dries easily, becomes solid, and sufficiently firm. Vessels may be formed of it hard enough to bear polishing on the wheel.

Lastly, when acid and corrosive vapours are to be retained, we must have recourse to the lute called *fat lute*. This lute is made by forming into a paste some dried clay finely powdered, sifted through a silken sieve, and moistened with water, then beating this paste well in a mortar with boiled linseed oil, that is, oil which has been rendered drying by litharge dissolved in it, and fit for the use of painters. This lute easily takes and retains the form given to it. It is generally rolled into cylinders of a convenient size. These are to be applied, by flattening them, to the joinings of the vessels, which ought to be perfectly dry, because the least moisture would prevent the lute from adhering. When the joinings are well closed with this fat lute, the whole is to be covered with slips of linen spread with lute of lime and whites of eggs. These slips are to be fastened with packthread. The second lute is necessary to keep on the fat lute, because this latter remains soft, and does not become solid enough to stick on alone.

Gutta percha may be united to glass, in tube apparatus, by fusing the gutta percha at the point of junction by means of a hot iron knife-blade.

Fine porcelain clay, mixed with a solution of borax, is well adapted to iron vessels, the part required into an aperture being smeared with it. U.

LUTEOLIN. The yellow colouring matter of weld (*Rhus luteola*). It was first isolated by Chevreul (J. Chim. méd. vi. 157), and has been more fully examined and analysed by Moldenhauer (Ann. Ch. Pharm. c. 180) and by Schützenberger and Paraf (*ibid.* Suppl. i. 139). Moldenhauer prepares it by exhausting weld with alcohol, distilling off the alcohol from the extract; then washing with water and drying the residue; exhausting it with ether; dissolving the residue left on evaporating the ethereal solution in alcohol; adding a larger quantity of water; heating to the boiling point; filtering hot; and leaving the filtrate to cool. The product may be purified by recrystallisation from boiling very dilute spirit containing 1 or 2 per cent. alcohol. Schützenberger and Paraf exhaust the plant with alcohol, precipitate the extract with water, and heat the precipitate with water to 250° in a steel apparatus; the luteolin then crystallises on the sides of the vessel on cooling, and may be purified by two crystallisations from superheated water.

Luteolin crystallises from solution in boiling dilute alcohol, also from a hot saturated solution in dilute sulphuric or acetic acid, in yellow four-sided needles arranged in radiate groups; it may also be obtained in needles by careful sublimation. It melts at 320° with partial decomposition, to a black-brown mass. It is inodorous, has a slightly bitter, astringent taste; dissolves in 14,000 pts. of cold and 5,000 pts. of boiling water, in 37 pts. alcohol [at what temperature?] and in 625 pts. of ether. It reddens litmus paper slightly, and unites with metallic oxides. It dissolves with deep yellow colour in caustic alkalis and alkaline carbonates, remaining in the pure state when its ammoniacal solution is evaporated (Moldenhauer). By prolonged heating with ammonia, it is completely dissolved, forming a deep yellow solution, and leaving on evaporation a dark coloured residue which gives off ammonia when heated with potash (Schützenberger and Paraf). In cold dilute acids it is but sparingly soluble; more easily in cold concentrated sulphuric acid, forming a yellow solution from which it is separated by water without alteration. It dissolves sparingly in cold concentrated hydrochloric acid, more easily in warm concentrated nitric acid, but is nearly insoluble in that acid when cold. Dilute nitric acid acts upon it only when heated; strong nitric acid dissolves it with deep red colour, the solution being decolorised by prolonged boiling, with formation of oxalic acid (Moldenhauer). Heated to 200° with phosphoric anhydride, it yields a red substance which dissolves with violet colour in ammonia (Schützenberger and Paraf). Distilled with chromate of potassium and sulphuric acid, it yields formic acid. It does not precipitate a solution of gelatin, but forms a green precipitate with a very dilute solution of ferric chloride, and colours a concentrated solution brown-red (Moldenhauer). According to Chevreul, the aqueous extract of weld forms beautiful yellow precipitates with alum,

stannous chloride, and acetate of lead, a blackish-grey precipitate with ferrous sulphate, and brown with sulphate of copper.

According to Mollenhauer, luteolin contains 62.5 to 63.0 per cent. carbon and 3.70 to 4.1 hydrogen, whence he deduces the formula $C^{22}H^{14}O^8$, requiring 62.8 C, 3.7 H, and 33.5 O. According to Schützenberger and Paraf, the air-dried substance heated to 150° gives off 10.23 per cent. water, and that which has been dried over sulphuric acid gives off 7.02 per cent. at the same temperature. Luteolin dried at 150° gave by analysis 61.6 to 62.5 per cent. carbon, and 3.5 to 3.8 hydrogen, whence Schützenberger and Paraf deduce the formula $C^{22}H^{14}O^8$, which requires 62.1 C, 3.4 H, and 34.5 O. To the substance dried over sulphuric acid, they assign the formula $C^{22}H^{14}O^8$, and to the air-dried substance, $2C^{22}H^{14}O^8 \cdot H^2O$. A lead-salt precipitated from the alcoholic solution of luteolin by alcoholic acetate of lead, gave by analysis 30.97 per cent. C, 1.98 H, and 49.33 PbO, agreeing nearly with the formula $C^{22}H^{14}O^8 \cdot Pb^2O$, which requires 31.65 C, 1.76 H, 17.58 O, and 49.0 PbO.

LUTIDINE. C^8H^9N . An organic base isomeric with benzylamine or toluidine (i. 575), discovered by Anderson (Ann. Ch. Pharm. lxxx. v.) in bone-oil. This oil contains a number of oily bases soluble in hydrochloric acid; and on decomposing the resulting solution with potash and rectifying, lutidine passes over at about 146°. The same base is found in coal-tar naphtha and in shale naphtha, the liquid obtained by distilling the bituminous shale of Dorsetshire (Gr. Williams, Chem. Soc. J. vii. 97); also among the volatile bases obtained by the distillation of peat. (Vohl, Jahresb. 1859, p. 742. Church and Owen, Phil. Mag. [4] xx. 110; Jahresber. 1860, p. 359.)

A base isomeric, but not identical with that from bone-oil, occurs among the products of the dry distillation of cinchonine, and passes over in rectification between 160° and 166°. Greville Williams, who discovered this base (i. 869), and has recently instituted a searching comparison between its properties and that of Anderson's base (Proc. Roy. Soc. xiii. 305), distinguishes it as β -lutidine. The properties of the two bases and of many of their salts are essentially different, as will be seen by the following comparative statements.

Physical properties of the Bases.—Both bases when pure are colourless refractive oils, lutidine having a density of 0.9467 at 0°, and β -lutidine of 0.9555 at the same temperature. Lutidine boils at 154°; β -lutidine between 163° and 168°. Vapour-density of lutidine, by experiment (at 200°) = 3.839 (Anderson); of β -lutidine (at 213°) = 3.787 (Williams); by calculation = 3.699. It may be inferred from this that the boiling point of β -lutidine has not been estimated above the truth, because if the fraction had been taken too high, the vapour-density would have erred in excess.

Lutidine has a most characteristic smell, resembling that of its lower homologues, but less pungent, and more approaching the aromatic; this odour is never altered in the least by any method of purification, and after boiling with nitric, chromic, or any other acid, it is still given off on neutralisation with an alkali. All the salts, however purified, emit the same smell on the addition of an alkali. *β -Lutidine* has also a most characteristic smell, quite unlike that of lutidine, and somewhat resembling that of nicotine, but with out the peculiar pungency of that base, and far more pleasant. No treatment with acids, or oxidising agents, and no amount of purification of its salts, makes the least alteration in the smell, or causes it to approach, however distantly, to that of lutidine.

Lutidine dissolves readily when shaken with three or four times its bulk of water, and on warming the liquid, it becomes milky, the base separating from it. *β -Lutidine*, on the contrary, requires not less than 25 parts of water to dissolve it, and the solution does not become turbid when warmed; on the contrary, a mixture of water and lutidine, cloudy from excess of base, becomes clear on warming. Hence it appears that lutidine is less, β -lutidine more soluble in hot than in cold water.

Both lutidine and β -lutidine unite with acids and with salts, forming crystalline compounds, most of which are very soluble.

Compound of β -lutidine with Cupric Sulphate. (C^8H^9N) $^2CuSO^4 \cdot 4H^2O$.—When β -lutidine is gradually added to a solution of cupric sulphate, a copious pale green precipitate is formed, which dissolves in excess, forming a rich blue liquid, which after filtration, soon becomes filled with brilliant blue prisms of considerable size, and having in the air-dried state the composition above given. They give off 2 at. water at 100°, and become anhydrous at 200°. (Williams.)

Gold-salts. $C^8H^9N \cdot HCl \cdot AuCl^3$.—Both bases give salts having this composition; but a mixture of hydrochlorate of β -lutidine with trichloride of gold became nearly solid, whereas with the lutidine-salt the precipitate occupied only half the bulk of the liquid, and did not require more than a fourth of the quantity of water to dissolve it that was necessary in the case of β -lutidine. (Williams.)

Mercuric salt of Lutidine, $C^6H^9N.HgCl^2$. This salt separates from a mixture of the alcoholic solutions of lutidine and mercuric chloride, as a white bulky precipitate; from dilute solutions it is gradually deposited in radiating crystals. It dissolves in boiling water, with partial decomposition; more freely, and without alteration, in boiling alcohol. (Anderson.)

Palladium-salts.—The chloropalladite of β -lutidine, $2(C^6H^9N.HCl).PdCl^2$, is obtained, as a nearly solid mass of garnet-red prisms, on leaving a mixture of the base, hydrochloric acid, and chloride of palladium, to itself for four days. When heated for a long time to 100° , it is decomposed, 1 at. hydrochloric acid being given off from 2 at. of the salt, and leaving the compound:

The chloride of palladio- β -lutidyl-ammonium, $N^2\left\{\frac{2(C^6H^9)^+}{Pd^{++}}\right\}Cl^2$, the base existing in the last-mentioned substance, is easily obtained by acting on chloride of palladium in solution with β -lutidine. This base is not easily soluble, and precipitates at once. (Williams.)

On mixing solutions of hydrochlorate of lutidine and chloride of palladium, exactly similar in concentration to those above employed, no crystals were obtained by the time that the contents of the vessel containing the β -lutidine had nearly solidified: and even after a month's repose, the quantity obtained was much smaller than with β -lutidine.

Platinic salts.—The chloroplatinates of both bases have the composition $2(C^6H^9N.HCl).PtCl^4$, and crystallise in rectangular tablets; but the β -lutidine-salt exhibits the same superior facility of crystallising that is observed in the corresponding gold- and palladium-salts. The presence of hydrochloric acid in excess greatly retards the formation of the lutidine-salt (Anderson); but Williams finds that this is not the case with the β -lutidine-salt, a mixture of the hydrochlorate of β -lutidine with platinic chloride and a large excess of hydrochloric acid instantly becoming nearly solid.

Decomposition of the Platinic salts by boiling.—Chloroplatinate of β -lutidine begins to decompose the instant the solution enters into ebullition, an insoluble yellow powder beginning to deposit, and rapidly increasing in quantity. After boiling with water, this salt has the composition of tetrahydrochlorate of platino-lutidine, $BN^2\left\{\frac{(C^6H^9)^2}{Pt^{++}}\right\}.4HCl$.

The solution of chloroplatinate of lutidine, on the other hand, required $2\frac{1}{2}$ hours' active boiling before any deposit began to form; and even after several hours' boiling, the deposit was very small.

Platinous salts.—When equal weights (1 grm. each) of platinous chloride and β -lutidine were mixed in an apparatus surrounded with a non-conducting medium, the temperature rose from 16° to 84° , and a hard brittle product was obtained, agreeing almost exactly in composition with the formula $2C^6H^9N.PtCl^3$. When lutidine was treated with platinous chloride under exactly the same conditions, the temperature rose two degrees higher; but the product, instead of becoming a hard brittle mass, remained of the consistence of treacle.

Substitution-derivatives of Lutidine.

ETHYL- β -LUTIDINE.—A mixture of 1 vol. β -lutidine and 2 vol. iodide of ethyl heated in a sealed tube to 94° for three minutes, solidified on cooling to a mass of crystals of iodide of ethyl- β -lutidine, $C^8H^{11}(C^2H^5)^+N.HI$.—The platinum-salt prepared therefrom in the usual way, crystallises in superb orange-coloured fronds, containing $2(C^8H^{11}N.HCl).PtCl^4$. This salt when boiled with water turns black, and deposits platinum. After two days' boiling, it yielded 27.5 per cent. of the metal, the original salt containing 28.99 per cent. (Gr. Williams.)

ETHYL-LUTIDINE.—A mixture of lutidine and iodide of ethyl in the above proportions, heated to the same temperature for the same time, showed no signs of crystallisation on cooling. It required an hour's digestion to effect combination; and in twenty-four hours, only half the product had crystallised, the rest remaining in the form of a syrup. (Gr. Williams, Proc. Roy. Soc. xii. 311.)

METHYL- β -LUTIDINE, $C^6H^{11}N = C^6H^8(CH^3)N$.— β -lutidine mixed with iodide of methyl, becomes heated, and forms hydriodate of methyl- β -lutidine, a salt very soluble in water and alcohol, but nearly insoluble in ether. Its alcoholic solution evaporated to a syrup, remains liquid if left at rest; but on touching it, beautiful long needles shoot through the liquid, which soon becomes completely solid. The chloroplatinate, $2(C^6H^{11}N.HCl).PtCl^4$, forms crystals containing 30.29 per cent. platinum. (Gr. Williams, Ed. Phil. Trans. xxi. [2] 317.)

LYCINE. (Husemann and Marmé, Ann. Ch. Pharm. Suppl. ii. 383.)—A base

contained in the box-thorn (*Lycium barbarum*). The leaves are repeatedly boiled with water (the stems yield but a small product); the extracts are precipitated with basic acetate of lead; and the filtrate, freed from lead by sulphydric acid, and neutralised with carbonate of sodium, is evaporated to a third of its original volume. The liquid, very strongly acidulated with sulphuric acid, is then precipitated with a solution of phosphomolybdate of sodium, or a mixture of 30 at. tungstate and 1 at. phosphomolybdate. The light yellow precipitate, after washing with water acidulated with sulphuric acid, is mixed, while still moist, with carbonate of barium, dried over the water-bath, and exhausted with boiling alcohol. The extracts leave, after evaporation of the alcohol, a syrupy residue, from which the base may be dissolved out by dilute hydrochloric acid, while a resinous body remains undissolved. The hydrochlorate, which has a strong acid reaction, is easily soluble in water, sparingly in absolute alcohol, nearly insoluble in ether, and crystallises from alcohol in dazzling white rhombic prisms, sometimes half an inch long, and from water in fern-like groups of crystals. The free base, obtained by treating the hydrochlorate with carbonate of barium and alcohol, is a white, radio-crystalline, deliquescent mass, which has a sharp but not bitter taste, dissolves easily in water and alcohol, very sparingly in ether, and melts with decomposition when heated. Most of its salts are crystallisable, and easily soluble in water; some of them are also deliquescent.

LYCOPodium. The fine dust of lycopodium, or clubmoss, consists of the spores of the plant; when diffused or strewed in the air, it takes fire from a candle, and burns off like a flash of lightning. It is used in theatres.

From 1000 parts of these spores, Bucholz extracted 60 parts of a fixed oil soluble in alcohol, 30 of sugar, 15 of mucilage, 896 of a substance insoluble in water, alcohol, ether, essence of turpentine, and cold alkaline leys.

The leaves contain 5.0 per cent. chlorophyll, 25.0 extractive matter and acetate of aluminium, 6.0 organic salts of calcium, magnesium, manganese, iron, lead (?), and copper (?), and 64.0 cellulose.

The infusion of lycopodium is used as a mordant, on account of the large quantity of acetate of aluminium which it contains. (Pelouze et Frémy, *Traité*, vi. 469.)

LYDIAN STONE, *Touchstone*, or *Basanite*, a velvet-black siliceous stone or flinty jasper, used, on account of its hardness and black colour, for trying the purity of the precious metals. See GOLD (ii. 929).

LYMPH. This liquid, which fills the lymphatic vessels, is colourless or yellowish when pure, red only if blood-corpuscles happen to be mixed with it. It is sometimes transparent, sometimes slightly turbid or opalescent, of a faintly saline taste and mawkish animal odour; its reaction is usually alkaline. It coagulates in from four to twenty minutes after its discharge from the lymphatics, then forming a gelatinous, trembling, colourless coagulum, which gradually contracts more firmly, and encloses a large number of the so-called lymph-corpuscles: this coagulum usually occupies but a very small space in proportion to the serum.

The especial *morphological elements* of lymph, in addition to fat-globules and nucleolar-like formations, are the true lymph-corpuscles, which, however, do not differ essentially from mucus- and pus-corpuscles. In lymph that has been carefully collected, blood-corpuscles are not found, excepting when the liquid has been obtained from the lymphatics of the spleen, or from animals that have been starved to death. (H. Nasse, *Handwört. d. Physiol.* ii. 363-410.)

The *chemical constituents of lymph* are in general similar to those of blood, without the red corpuscles. The spontaneously coagulating substance of the lymph is perfectly identical with the fibrin of blood. In human lymph (obtained in cases of disease or injury), Marchand and Colberg found 0.52 per cent. and L'Héritier 0.32 per cent. fibrin; while in the lymph of the horse, from 0.04 to 0.33 per cent. has been found by different observers. J. Müller found that frogs which had been starved to death during winter yielded a lymph perfectly free from fibrin; whereas Nasse found that the lymph of frogs which had been kept in a heated room still coagulated.

The albumin of the lymph has the same general properties as blood-albumin. Geiger and Schloesberger found, however, that albumin from the lymph of a horse, though it exhibited no reaction with vegetable colours, did not coagulate on boiling, but that, on evaporation, a membrane was formed on the surface of the liquid as if a strongly alkaline albuminate of sodium had been present. This lymph-serum was not rendered turbid by acetic acid, unless boiled after acidification; neither was it coagulated by rennet, whence the absence of casein may be inferred; nor by ether. In human lymph, the albumin has been found to vary from 0.434 to 6.002 per cent., and in that of the horse from 1.2 to 2.75 per cent. In the ash of lymph-albumin, even after repeated extraction with water and spirit, Nasse found an extraordinarily large quantity of alkaline carbonates.

Fat occurs in lymph only in small quantities, and for the most part in a saponified form; in the lymph of the horse, Nasse found 0·0088 per cent. of free fat, and 0·0575 per cent. of alkaline salts of fatty acids; while in human lymph, Marchand and Colberg found 0·264 per cent. of a pale reddish fat.

The lymph also contains lactates.

In horses' lymph, Nasse found 0·0755 per cent. of extractive matters soluble in alcohol, and 0·9877 per cent. soluble in water only; while, according to Geiger and Schlossberger, the whole of the extractive matters amount to 0·27 per cent. Nasse was unable to detect urea in the lymph of the horse.

Mineral constituents.—In lymph, as in all the animal fluids, chloride of sodium is the preponderating mineral constituent: in horses' lymph, it amounts, according to Nasse, to 0·4123 per cent. Alkaline carbonates were found by Nasse in horses' lymph, the quantity being estimated at 0·056 per cent.; but Geiger failed in detecting them: in the ash of the solid constituents of the lymph, however, the latter found an abundance of alkaline carbonates. The presence of ammoniacal salts, which was suspected by Nasse, has been definitely established in horses' lymph by Geiger and Schlossberger. Nasse found that horses' lymph is comparatively rich in sulphuric acid, which exists in it pre-formed; he estimates the quantity of sulphate of potassium at 0·0233 per cent. Alkaline phosphates occur only in very small quantities. The earthy salts, with a small quantity of ferric oxide (arising probably from the presence of a few blood-corpuscles), were found by Nasse to amount to only 0·031 per cent. in horses' lymph.

The quantity of water in lymph appears to be very variable, but never so great as in the blood-plasma. In human lymph, Marchand found 96·926 per cent. and L'Heritier found 92·436 per cent. water; in the lymph of horses, the quantity has been found to vary from 92·6 to 98·37 per cent.

Nasse has instituted an interesting comparison (based on direct analyses) between the composition of the lymph and of the blood-serum of the horse, from which it appears that the individual salts stand to one another in precisely the same ratio in the two liquids, although their absolute quantity is very different, on account of the comparatively larger proportion of water in the lymph.

There are also considerable differences in the proportions in which the mineral constituents stand to the organic matters in the two liquids: while 100 pts. of salts correspond to 1036 pts. of organic matters in the blood-serum, the ratio in the lymph is as 100 to only 785. According to Marchand and Colberg, human lymph contains organic and inorganic matters in nearly equal parts. (*Lehmann's Physiological Chemistry*, translated by Dny, ii. 299.)

LYNCURION. A Greek name for AMBER.

M.

MACE is the *arillus* or envelope of the fruit of the nutmeg (*Myristica moschata*). It forms a somewhat thick, tough, unctuous, reticulated membrane, of a yellowish-brown or orange colour; has a somewhat more agreeable odour than nutmeg, with a warm and pungent taste, and is used as a condiment in cooking.

Mace contains two oils, one of which is unctuous, bland, and of the consistence of butter; the other, which is obtained by distillation with water, is thinner and volatile. By cohobating four times, 4·7 per cent. oil may be obtained (Hoffmann, *Repert. Pharm.* xliii. 296); from old mace, 4·1 per cent. (Bley, *ibid.* xlviii. 91). It is transparent and colourless; of specific gravity 0·931; smells strongly of mace, and has a burning aromatic taste. It forms a permanent liniment with aqueous ammonia.

MACLE is the name given to certain spots in minerals of a deeper hue than the rest; sometimes proceeding from difference of aggregation, sometimes from the presence of a foreign substance: clay-slate, for example, may be maced with iron pyrites.

MACLES. Twin-crystals (ii. 159).

MACLURIN. Syn. with MORINTANNIC ACID (p. 1049).

MADDER. *Garance.* *Krapp.*—The root of *Rubia tinctorum*, extensively used in dyeing for the production of a variety of colours, namely, red, pink, purple, black, and chocolate. Other species of *Rubia* yield similar colouring matters, and are also used as dyeing materials; viz. *R. Mungista*, or *Munjeet*, which grows in the mountainous regions of Hindoostan, and is used in that country for producing the red and chocolate figures seen in the chintz calicoes of the East Indies; and *R. peregrina*, which is cultivated in the Levant, where it is called *Alizari*, and imported into this country under the name of *Turkey-roots*; but *Rubia tinctorum*, or *dyers' madder*, is the only species

cultivated in Europe: it thrives best in a warm climate, and is grown extensively near Avignon in France, also in Alsace and in Naples; in the north of Europe it requires a sheltered situation.

All kinds of madder have a peculiar smell, and a taste between bitter and sweet. Their colour varies extremely, being sometimes yellow, sometimes orange-red, reddish-brown, or brown. They are more or less hygroscopic; so that even when closely packed in casks in the state of powder, they slowly attract moisture, increase in weight, and at length lose their pulverulent condition, forming a firm coherent mass. Some kinds of madder, especially those of Alsace and Holland, when mixed with water and left to stand for a short time, give a thick coagulum or jelly—an effect which does not take place in the same degree with Avignon madder. The madder of Avignon contains so much carbonate of calcium as to effervesce with acids. The herbaceous parts of the plant, when given as fodder to cattle, are found to communicate a red colour to their bones.

The principal advantages which madder presents, as a dye-stuff, are the following:—

1. It is capable of producing, according to the mordants and the method of treatment, a great variety of different colours and shades; such as black; red of different kinds, from a dull brownish red to a bright red and delicate pink, besides the peculiar colour known as Turkey-red: also purple of various shades, from a dull reddish-purple to a delicate bluish-purple or lilac, as well as chocolate of all shades.—2. Its colouring matters have but little affinity for cotton fibre, and a great affinity for mordants; so that it is not difficult to secure a good white on the parts of the tissue to which no mordant has been applied.—3. The compounds which its colouring matter or matters yield with mordants, possess an unusually stable character; so that they may be exposed, without much detriment to the colour, to the action of various agents for the purpose of improving or modifying the shade.

Chemical Constitution of Madder. There is probably no subject connected with the art of dyeing which has given rise to so much discussion as the composition of madder, and the chemical nature of the colouring matters to which it owes its valuable properties. The subject has engaged the attention of a great number of chemists, among whom may be especially mentioned, Robiquet and Colin, Kuhlmann, Gauthier de Claubry and Persoz, Runge, Schunck, Schiel, Higgin, Debus, Streeker, Roehleder, Sacc, and Emile Kopp. Nevertheless, our knowledge of madder, as compared with that which we possess of other colouring principles, is still confused and uncertain. According to some chemists (Sacc, for example) and many manufacturers, madder contains but one colouring principle, while most others admit the existence of at least two, viz. alizarin and purpurin. Moreover, according to some chemists, the colouring matter exists in madder ready formed; whereas others suppose that fresh madder contains merely a colour-generating substance, which subsequently, by a kind of fermentation gives rise to the colouring matter properly so called: the latter, which is Schunck's view, appears to be based on the most trustworthy experiments.

When ordinary commercial madder is exhausted with boiling water, a dark-brown muddy liquid is obtained, having a taste between bitter and sweet. On adding a small quantity of an acid to this liquid, a dark-brown precipitate is produced; while the supernatant liquid becomes clear, and appears of a bright yellow colour. The precipitate consists of alizarin, purpurin, rubiacin, two resinous colouring matters, pectic acid, oxidised extractive matter, and a peculiar nitrogenous substance. The liquid filtered from this precipitate contains the bitter principle and the extractive matter of madder, as well as sugar, and salts of potassium, calcium, and magnesium. No starch, gum, or tannin can be detected in the watery extract. After the madder has been completely exhausted with boiling water, it appears of a dull red colour. It still contains a quantity of colouring matter, which cannot, however, be extracted with hot water, or even by alkalis, since it exists in a state of combination with lime and other bases, forming compounds which are insoluble in those liquids. If, however, the residue be treated with boiling dilute hydrochloric acid, that acid dissolves a quantity of lime, magnesia, alumina, and sesquioxide of iron, as well as some phosphate and oxalate of calcium, which may be discovered in the filtered liquid; and if the remainder, after being well washed, be treated with caustic alkali, a dark-red liquid is obtained, which gives with acids a dark reddish-brown precipitate of alizarin, purpurin, rubiacin, resin, and pectic acid. The portion of the madder left after treatment with hot water, acids, and alkalis, consists almost entirely of woolly fibre. (Schunck.)

Of the substances thus shown to exist in ordinary madder, the most important are undoubtedly alizarin and purpurin, which are in fact the essential red colouring matters of the dye-stuff. They were discovered by Robiquet and Colin, to whom we are indebted for the first memoir of any importance relating to the chemistry of madder. (Ann. Ch. Phys. [2] xxxiv. 225.)

Alizarin, the *Lizaric acid* of Debus, *Madder-red* of Runge, *Matière colorante rouge* of Gauthier de Claubry and Persoz, was obtained by Robiquet and Colin as a sublimate, in beautiful reddish-yellow needles; but the mode of preparation which they adopted left it uncertain whether the alizarin pre-existed in madder, or was a product of decomposition of some other body produced by heat.

It may, however, be extracted from ordinary madder, as used by the dyer, by the action of solvents, and obtained in crystals without sublimation: hence its existence in ordinary madder may be inferred (see i. 114; and for details of preparation, *Gmelin's Handbook*, xiii. 326, and xiv. 130). Its composition cannot be regarded as definitely established. Wolff and Strecker's formula, $C^{16}H^{10}O^4$, is most in accordance with the relation of alizarin to chloronaphthalic acid, $C^{16}H^8ClO^4$, both of these compounds being converted, by the action of nitric acid, into phthalic acid; but Schunck's formula, $C^{14}H^{10}O^4$, appears to explain more clearly the formation of alizarin from rubian (p. 745): it must be remembered, however, that the formula of rubian itself is by no means well established. Alizarin is very little soluble in water, more soluble in alcohol, but nearly insoluble in aluminium-salts. Its alkaline solutions have a beautiful violet or purple colour, and it forms lakes of various colours with the earthy and heavy metallic oxides.

Purpurin, the *Madder-purple* of Runge, *Matière colorante rose* of Gauthier de Claubry and Persoz, *Oxilizaric acid* of Debus, is extracted from madder by the same processes as alizarin, and separated from it by its superior solubility in alum-liquor. It bears considerable resemblance to alizarin, yielding a crystalline sublimate when heated, and being very sparingly soluble in water, but more soluble in alcohol. The properties by which it is distinguished from alizarin, are its easy solubility in boiling alum-liquor, forming a solution of a beautiful pink colour, with yellow fluorescence; and secondly, the colour of its alkaline solutions, which are cherry-red or bright red; whereas alizarin forms violet solutions with alkalis. These differences might, however, be produced by the admixture of some foreign substance with alizarin; and accordingly some chemists, as already observed, do not regard purpurin as a distinct substance, but attribute all the colouring power of madder to alizarin. There are, however, other characters which show beyond doubt that purpurin is a distinct substance: viz.—1. Its decomposition when exposed to the air in alkaline solution, the colour of the liquid then changing from bright red to reddish-yellow, and ultimately disappearing almost entirely, after which purpurin can no longer be discovered in the solution, whereas alizarin suffers no such decomposition (Schunck).—2. Its optical properties. Stokes has shown that when a solution of purpurin is examined by a prism, the spectrum which it exhibits is totally different from that which is produced in like manner by alizarin. (See LIGHT, p. 638; also PURPURIN.)

Considerable difference of opinion likewise exists as to the relative value of alizarin and purpurin as dyeing materials. According to Robiquet and Schunck, the finest and most permanent madder-colours are produced by alizarin; whereas Runge and Strecker are of opinion that the liveliest tints are produced by purpurin, and that this substance likewise plays the principal part in the manufacture of Turkey-red. According to E. Kopp, on the other hand, the real basis of Turkey-red is alizarin; and he further states that purpurin, though it dyes mordanted fabrics perfectly, does not yield colours of so great a degree of stability, and has not so great an affinity for oiled cloth, as alizarin.

From Schunck's experiments, it appears that all the usual madder-colours may be obtained by means of alizarin, and that the colours so produced are as pure and brilliant as ordinary madder-colours are after a long course of treatment with soap, acids, &c. They are likewise equally fast, and quite equal to ordinary madder-colours in their power of resisting decomposition by soap, alkalis, &c.

In short, the final result of dyeing with madder and its preparations appears to be simply the combination of alizarin with the various mordants employed. It can easily be shown, indeed, that the finer madder-colours contain little besides alizarin in combination with the mordant. If, for instance, a few yards of 'madder-pink calico' be treated with hydrochloric acid to remove the alumina of the mordant, then well washed and treated with caustic alkali, a violet solution is obtained from which acids precipitate yellow flocks consisting of almost pure alizarin. Purpurin, on the other hand, is found to have almost entirely disappeared from all madder-colours which have been subjected to a long course of after-treatment; a result quite in accordance with the fact above mentioned of the decomposition of purpurin in alkaline solution on exposure to the air. (Schunck.)

Madder likewise contains certain yellow colouring matters: but they are useless, if not positively injurious, in the process of dyeing. Rubiacin is a yellow crystallised colouring matter, coinciding in most of its properties with the *madder-orange* of Runge. It is only slightly soluble in boiling water, but dissolves more freely in boiling alcohol,

and crystallises therefrom, on cooling, in greenish yellow lustrous scales and needles. It dissolves without decomposition in strong sulphuric and in boiling nitric acid, and with purple colour in alkalis. Its compounds with metallic oxides are mostly red. When treated with a boiling solution of ferric chloride or nitrate, it dissolves entirely, yielding a brownish-red solution, which gives with hydrochloric acid a flocculent precipitate of rubiacic acid.

Of the two resinous colouring matters already mentioned (p. 742), one is a dark-brown, brittle, resin-like body, very soluble in alcohol, and melting at a little above 100° ; the other is a reddish-brown powder, less soluble in alcohol than the preceding. These two colouring matters, together with rubiacin, constitute probably the tawny or dun colouring matter of madder mentioned by the older chemists. They do not contribute to the intensity of the colours dyed with madder, and exert a very prejudicial effect on the beauty of the dyes. If printed calico be dyed with a mixture of alizarin and any one of these three colouring matters, the colours are found to be both weaker and less beautiful than when alizarin is used alone. The red acquires an orange tinge, and the purple a reddish hue, whilst the black is less intense, and the parts which should remain white have acquired a yellowish colour. The effect of these colouring matters must, therefore, be counteracted as much as possible by preventing them either from dissolving in the dye-bath, or from attaching themselves to the fabric.

The other organic constituents of madder are also for the most part injurious in dyeing. The pectin, in the state in which it exists in the root, is probably an indifferent substance; but, in consequence of the ease and rapidity with which it passes into pectic acid, it may act very prejudicially in dyeing, by combining with the mordants and preventing them from taking up the colouring matter.

The extractive matter of madder, when in an unaltered state, produces no injurious effects directly; but by the action of oxygen, especially at elevated temperatures, it acquires a brown colour, and then contributes, together with the rubiacin and resinous colouring matters, to deteriorate the colours, and sully the white parts of the fabric. Hence the uniform dirty reddish-brown tint which a piece of calico exhibits, both on the printed and unprinted portions, after having been dyed with madder; the removal of this tinge is one of the objects of the after-treatment with soap and other materials. In the process of manufacturing garancin, this substance is partly decomposed, partly removed by the subsequent washing; and this explains, in a great measure, the greater purity and brilliancy of garancin colours, as compared with madder colours. The extractive matter, when pure, has the appearance of a yellow syrup, like honey, is easily soluble in water and in alcohol, and is not precipitated from its aqueous solution by any earthy or metallic salt; but the solution, if evaporated in contact with the air, gradually turns brown, and then gives an abundant brown precipitate with acetate of lead. Its aqueous solution mixed with hydrochloric or sulphuric acid, and boiled, becomes green and deposits a dark-green powder. Hence this extractive matter has been called chlorogenin by Schunck, rubichloric acid by Rochleder. The xanthin of Kuhlmann and the madder-yellow of Runge appear to be mixtures of the extractive matter with a bitter principle.

The sugar contained in madder is probably glucose: it has not hitherto been obtained in the crystallised state; but it yields alcohol and carbonic acid by fermentation, like ordinary sugar. The woody fibre which remains after madder has been thoroughly exhausted by the action of various solvents (p. 742), always retains a slight reddish or brownish tinge, from the presence of some colouring matter which cannot be completely removed, and seems to adhere to it in the same way as it does to the fibre of unmordanted cotton.

The inorganic constituents of madder-root have been analysed by H. Köchlin (Ann. Ch. Pharm. lix. 344) and K. Moy (*ibid.* liv. 346); those of the seed by Schiel (Handw. d. Chem. iv. 609).

	Ash of root.			
	From Alsace.	From Zealand.	Ash of Seed	
Potash	29.35	26.64	3.42	20.08
Soda	15.89	11.67	25.76	6.20
Lime	34.54	29.25	16.29	29.89
Magnesia	3.72	3.68	3.17	2.48
Ferric oxide	1.18	3.36	2.67	3.74
Phosphoric anhydride	5.26	4.62	16.84	5.10
Sulphuric "	3.68	2.14	2.86	3.00
Silicic "	1.64	5.36	16.41	19.22
Chloride of sodium	4.71	13.26	12.58	10.29
	99.97	99.97	100.00	100.00

The *Alsace madder* (*a*) grown on a highly calcareous soil yielded 8.25 per cent. ash; *b* yielded 8.4 per cent. The seed of *Avignon madder* gave 8.14 per cent. ash.

Formation of the Red Colouring Matters.—The extraction of alizarin and purpurin from madder by the action of solvents shows that these colouring matters exist ready-formed in madder in its ordinary state, as used by the dyer. But it still remains a question whether they exist in the root while growing or when newly dug up, or whether they are formed by any subsequent process of chemical change. Now, it has long been known that when ground madder is kept tightly packed in casks, it constantly improves in quality for several years, after which it again deteriorates; and it was always supposed that this effect was due to some process of slow fermentation. The real nature of the change, however, remained for a long time unknown. Strecker supposes that the change which goes on consists in the conversion of alizarin into purpurin; but this would constitute anything but an improvement in quality, since the colours produced by purpurin are in most respects inferior to those of alizarin. Besides this, alizarin is a body not easily decomposed, unless exposed to the action of very potent agents; and any portion of it once formed in the root, would probably resist the action of air and moisture for a very long period of time, if not entirely. Mr. Higgin of Manchester states, as the results of his experiments on this subject, that there exists in madder a peculiar albuminous ferment, which, by acting on the xanthin, gives rise to the formation of colouring matter; and that this process takes place to some extent even during the short period of time occupied in dyeing. This view has been confirmed in its main features by the experiments of Schunck.

That the whole of the colouring matter of madder does not exist ready-formed in the article as used by the dyer, may be rendered evident by a simple experiment. If madder be exhausted with cold water, the clear watery extract does not contain any alizarin or other colouring matter, since these are almost insoluble in cold water. Nevertheless, the extract when gradually heated is found capable of dyeing in the same way as madder itself. If made tolerably strong, it possesses a deep yellow colour and a very bitter taste; but if it be allowed to stand in a warm place for a few hours, it gelatinises, and the insoluble jelly which is formed is found to possess the whole of the tinctorial power of the liquid, while the latter has lost its yellow colour and bitter taste. Hence it may be inferred that the substance which imparts to the extract its bitter taste and yellow colour, is capable of giving rise to the formation of a certain portion of colouring matter. By extracting madder with boiling water, the subsequent gelatinisation or coagulation is prevented, and the extract retains its yellow colour and bitter taste; a proof that the coagulation observed in the extract with cold water is a result of some process of chemical change which is arrested when the temperature is sufficiently raised. When the extract is agitated with a little animal charcoal, the latter absorbs the bitter principle, and gives it up again to boiling spirits of wine, which on evaporation leaves it in an almost perfect state of purity. In this manner Schunck obtained a substance to which he has given the name of Rubian, and of which the principal characteristics are these:—It is amorphous and shining like gum, has a deep yellow colour and an intensely bitter taste, is easily soluble in water and alcohol. It is not a colouring matter in the practical sense of the word, for it gives to mordants in dyeing only the faintest shades of colour. But if its watery solution be mixed with sulphuric acid and boiled, it gradually deposits a quantity of insoluble yellow flocks and becomes almost colourless. These flocks, after being well washed, are found to dye exactly the same colours as alizarin. In fact they contain alizarin. The liquid gives the reactions of sugar. Taking this fact into consideration, it becomes possible to give an account of the principal change which takes place in the process of manufacturing garancin. It is evident that during this process, the easily soluble rubian becomes converted into the difficultly soluble alizarin, that there is in this case, in fact, an actual formation of colouring matter which is added to that already existing in the root. A similar change takes place when caustic alkali is used in place of the acid. A solution of rubian on being mixed with caustic potash or soda, simply turns red, but on being boiled, it becomes dark purple and deposits a purple powder which consists chiefly of a compound of alizarin with alkali, insoluble in caustic lye. Fermentation also decomposes rubian with great facility; but in order to effect its decomposition it is not indifferent what ferment is taken: a peculiar ferment is essential to the purpose. A solution of rubian may be left for several days in contact with yeast, decomposing albumin, casein, emulsin, &c., without showing any sign of change. But if an extract of madder with cold water be mixed with a large excess of alcohol, flocks of a dirty red colour are precipitated, which, after being well washed with alcohol, are found to consist chiefly of an azotised principle called Erythrozym, which exerts a peculiar and powerful decomposing effect on rubian. If some of this substance be mixed with a watery solution of rubian, and the mixture be left to stand at the ordinary temperature, the rubian is found after a few hours to be as completely decomposed as

if it had been treated with a strong acid or caustic alkali, though no evolution of gas or any of the usual signs of fermentation have been manifested. The solution, if tolerably strong, gelatinises just as an extract of madder with cold water does, under the same circumstances. The jelly, when mixed with cold water, is found to be almost insoluble. The water acquires only a slight colour, but contains sugar in solution, while the insoluble portion contains alizarin mixed with the ferment. This process of decomposition affords an explanation of the fact, well known to madder dyers, that if the dye-bath be heated up rapidly to the boiling point, instead of gradually, as is the usual practice, prejudicial effects ensue. In fact, the sudden heating puts a stop to the action of the ferment, as would be the case in any other process of fermentation, whereas the gradual heating allows it to exert its full decomposing power on the rubian. Hence, too, the advantage of mixing together several sorts of madder, one containing perhaps an excess of rubian in proportion to ferment, the other a superabundance of ferment to counterbalance it. The improvement which takes place in the quality of madder after long keeping is probably also an effect of the same cause. Indeed, it seems highly probable that the alizarin, which undoubtedly exists ready formed in ordinary madder, owes its formation to the action of fermentation on rubian; and an experiment made with fresh madder roots goes far to prove that this is in fact the case, and that the fresh root contains no trace of ready formed colouring matter. Some madder roots having been taken out of the ground and cut small, without being dried, produced the ordinary colours when used for dyeing in the common manner. But on treating the roots, after being cut into pieces as quickly as possible, with boiling alcohol, a yellow extract was obtained, which contained rubian, but which, even after all the alcohol had been driven away, was found incapable of imparting to mordants any but the slightest shades of colour; while the portion of the root left undissolved by the alcohol, on being subjected to the same test as the extract, imparted to mordants no more colour than the latter. It was evident, therefore, that the alcohol in this case had effected a separation between the colour-producing body and the agent which, under ordinary circumstances, is destined to effect its transformation into colouring matter. The same relation, it is apparent, subsists between rubian and erythrozym, as between amygdalin and emulsin.

Erythrozym differs in composition from all other known ferments, containing but a small proportion of nitrogen not exceeding 4 per cent. It acts on an aqueous solution of sugar nearly in the same manner as yeast, giving rise to the formation of alcohol, carbonic acid, hydrogen and succinic acid, but it is distinguished from all other ferments by its power of acting on rubian.

As rubian, when subjected to the action of acids, alkalis, or erythrozym yields alizarin and glucose, the decomposition might at first sight be supposed to consist simply in the resolution of the rubian into these compounds, according to the usual mode of decomposition of glucosides. The real decomposition is however much more complex, the products never consisting of alizarin and glucose only. The part insoluble in cold water contains in all cases, besides alizarin, two resinous colouring matters, namely, Rubiretin, $C^{12}H^{10}O^4$, easily soluble in alcohol, and Verantin, $C^{14}H^{10}O^8$, less soluble in that liquid. But in addition to these, there is uniformly found accompanying the alizarin, a third body, belonging, as far as general appearance and properties are concerned, to the same class of substances as rubiacin. The third body is, however, in each case quite distinct. When acids have been employed for the decomposition of rubian, then this third body is found to have the following properties:—It is tolerably soluble in boiling water, and crystallises in lemon-yellow silky needles; it is decomposed on being heated, but resists the action of nitric and concentrated sulphuric acids; this substance, Rubianin, contains, according to Schunck, $C^{22}H^{14}O^{12}$. When alkalis are used instead of acids, the rubianin is replaced by Rubiadin, $C^{16}H^{10}O^8$,* which is a body crystallising in beautiful golden-yellow scales, insoluble in water, but soluble in alcohol, and completely volatilised when heated. But when rubian is decomposed by fermentation, it yields neither of these two, but in their place Rubiagin, a substance agreeing in composition with rubiadin, and resembling it in most of its properties, but essentially distinguished from it by passing into rubiacic acid when treated with ferric chloride. This substance is usually accompanied by another of similar properties, called Rubiagin, of which it is difficult to say whether it must be considered as distinct from the others, since it has not been obtained in a state of perfect purity. All these bodies which accompany alizarin make their appearance so invariably under the circumstances above mentioned, that their occurrence cannot be considered as accidental.

Assuming for rubian the formula $C^{22}H^{14}O^{14}$, Schunck's view of the formation of these compounds may be represented in equations as follows:—

* Schunck gives for rubiadin the formula, $C^{22}H^{12}O^9$; but this is improbable on account of the uneven numbers of hydrogen and oxygen atoms ($O = 8$).

a. Formation of alizarin ($C^{14}H^{10}O^4$ according to Schunck):

β. Of verantin and rubiretin:

c. Of rubianin and glucose:

d. Of rubiadin and rubiafin:

Or rubiadin and rubiafin may be considered as products of the further metamorphosis of rubianin:—

It appears, then, that rubian undergoes, not one, but three different processes of decomposition when acted on by acids, alkalis, or ferments; that the formation of sugar is connected not with that of alizarin, but with that of rubianin and its allies, and that in fact there is no reason why only one of these processes should not take place to the exclusion of the others; why, for instance, rubian should not be so decomposed as to yield alizarin alone, without any of the accompanying bodies, which are from this point of view, not only a source of loss, but also prejudicial in practice.

The formation of alizarin and of the other products of rubian above mentioned, does not depend upon oxidation. Nevertheless, according to Schunck, rubian does suffer a partial oxidation when its aqueous solution, mixed with an alkali or alkaline earth, is exposed to the air, the product formed being rubianic acid, $C^{22}H^{22}O^{10}$, (or perhaps $C^{22}H^{30}O^{12} = C^{22}H^{30}O^{14}$). Its formation may perhaps be represented by the equation:

Rubian.

Rubianic acid.

It is a true glucoside, and is resolved by the same agents which effect the decomposition of rubian into alizarin and glucose, no secondary products making their appearance; perhaps thus:

Rubianic acid.

Alizarin.

Glucose.

For further details respecting all these products, see RUBIAN.

Use of Madder in Dyeing. The chief use of madder is in cotton-dyeing and calico-printing. In woollen-dyeing it is not so much employed, especially in this country, only the ordinary woollen goods being dyed red with it; the colour is not so bright as that obtained with cochineal or lac, although more permanent and cheaper. Silk is seldom dyed with madder, because cochineal affords brighter tints.

The series of operations usually adopted for printed calicoes is as follows:—

1. The calico having been singed and bleached, the mordant is printed on; namely, '*red liquor*' (acetate of aluminium containing a small quantity of sulphate) for red or pink; '*iron liquor*' (ferrous acetate) for violet, purple, or black; and a mixture of this with *red-liquor* for chocolate.

2. The printed cloth is hung up with free access of air for about two days. During this process of "ageing," the mordant undergoes important changes, and becomes to a great extent insoluble, and therefore fixed in the cotton: *red-liquor* parts with a great part of its acetic acid, and its alumina remains as a highly basic sulphate; *iron-liquor* absorbs oxygen and loses acetic acid, and is thus converted into a basic ferric acetate. Of late years, a "rapid ageing process" has come into extensive use; it consists in passing the printed calico through a heated chamber, the atmosphere of which is kept exactly saturated with water-vapour. This process is frequently completed in about half an hour, but the time required for it, as well as for the ordinary ageing process, varies with the amount of mordant upon the cloth.

3. The next operation is called "dunting," and consists in passing the cloth through a hot mixture of cow-dung and water. During this process, superfluous portions of the mordant, which would otherwise get detached from the cloth during the dyeing and would be precipitated in combination with colouring matter upon the unprinted parts, are removed (perhaps in combination with organic constituents of the bath), and the remainder is converted more or less completely into phosphate. For a good many years past, the use of cow-dung in this process has been to a great extent superseded by that of an artificial preparation known as "dung substitute," first introduced by Mercer, the essential constituents of which are alkaline phosphates and arsenates. (See Dyeing, ii. 353.)

4. Steeping in the madder-bath, which is kept lukewarm at first, and gradually raised to the boiling heat.

3. "Clearing," by passing the fabric through a boiling mixture of bran and water, or soap and water, or through a weak solution of chloride of lime, or by "crofting," that is, exposing it for some time on the grass to the action of air and light, or by several of these processes in succession.

To obtain greater variety of colours, other dye-stuffs are sometimes added to the madder-bath, *e.g.* quercitron or fustic for orange, logwood for blacks, &c.

For further details relating to the operations of madder-dyeing, see *Ure's Dictionary of Arts, &c.*, articles MADDER and TURKEY-RED.

The chemical changes which take place during the process, may be shortly described as follows: In the first place, the water of the dye-bath extracts the more soluble constituents of the madder, such as the sugar, extractive madder, and bitter principle (rubicin). The latter is decomposed by the ferment, and the colouring matter thereby formed is added to that already existing in the root. As the temperature rises, the less soluble constituents, such as the alizarin, purpurin, rubiadin, resinous colouring matters, pectin and pectic acid, begin to dissolve, and at the same time combine partly with the mordants of the fabric, partly with the lime and other bases contained in the root, or added to the dye-bath, and thus permit the liquid to take up fresh quantities from the madder. The extractive matter acquires at the same time a brown colour by the combined action of heat and oxygen, and covers the white portions of a piece of printed calico with a uniform brown tinge. At the same time the alumina mordant has acquired a dirty brownish-red colour, and the iron mordant a black or brownish-purple, so that the fabric, after removal from the dye-bath, presents a very unsightly appearance. To clear the whites, and at the same time brighten the colours by removing the rubiadin, resinous matters, extractive matter, &c., and leave nothing but the alizarin combined with the mordants, is the object of the fifth operation or series of operations above-mentioned. But even this treatment, though sufficient for the more ordinary descriptions of goods, does not completely remove the foreign substances; for which reason the finer descriptions of printed calicoes are subjected to an after-treatment, which is as follows: "The goods, after being very fully dyed, generally with addition of chalk, and then washed, are passed for some time through a solution of soap, which is heated to a moderate temperature. By this means, a great deal of colour is removed, as may be seen by the red tinge of the soap-liquor, and the purity of the white portions is almost entirely restored. During this process, the brown and yellow colouring matters are probably removed by double decomposition, the alkali of the soap combining with and dissolving them, while the fat acid takes their place in the fabric. After being washed, the goods are passed through a weak solution of acid, mostly sulphuric or oxalic, or an acid tin-salt, which causes the colours to assume an orange tinge. The point at which the action of the acid liquid is to be arrested, can only be ascertained by practice. The next step in the process is, after washing the goods, to treat them again with soap-liquor in a close vessel under pressure. By exposing the goods on the grass for some time after the first soaping, the use of acid may be obviated; but the process then becomes much more tedious. In this way are produced those beautiful pinks and lilacs, which, for delicacy of hue, combined with great permanence, are not surpassed by any dyed colours known in the arts. Whether the fat acid of the soap employed forms an essential constituent of these colours, is not certainly known; but it is probable that it contributes to their beauty and durability. It is certain, however, that they always contain fat acid. If a piece of calico which has gone through the processes just described be treated with muriatic acid, the colour is destroyed, and a yellow stain is left in its place. This yellow stain disappears on treating the calico, after washing with water, with alkali, yielding a solution of a beautiful purple colour. This solution gives again, with an excess of acid, a yellow flocculent precipitate, which, after filtration, dissolves almost entirely in boiling alcohol, and the solution, on evaporation, affords needle-shaped crystals of pure alizarin, mixed with white masses of fat acid. The latter, therefore, seems to occupy the place taken up by the impurities before treatment with soap." (Schunck.)

An essential condition for the production of permanent madder-colours is the presence of a certain quantity of lime in the bath. This was first pointed out by Hausmann, who, after having produced very fine reds at Rouen, where the water is calcareous, encountered the greatest obstacles in dyeing the same reds at Logelbach near Colmar, where the water is nearly pure; but on adding chalk to his dye-bath, he obtained reds as beautiful and as permanent as those which he had formerly produced at Rouen. It has also long been known that Avignon madder, which is grown on a highly calcareous soil, and contains so much calcic carbonate as to effervesce with acids, affords the most permanent colours, whereas Alsace madder requires the addition of chalk in order to produce the same effect. The lime appears to act by uniting with those constituents of the madder (the rubiadin, pectic acid, &c.), which when taken up by the mordants in large quantity, act injuriously on the colour: for Schunck and

Robiquet have shown by experiment that, in dyeing with pure alizarin, the less addition of lime is rather injurious than otherwise, as it weakens the colours without adding to their durability. On the other hand, the addition of rubiacin, of the resinous colouring matters, or of pectic acid to alizarin was found to be very prejudicial, the red then acquiring an orange, and the purple a reddish hue, while the black became brownish, and the white parts of the fabric assumed a yellowish tinge: but these effects disappeared completely as soon as the foreign colouring matter was completely saturated with lime, the tinctorial power of the alizarin then reappearing with all its original intensity. Too great a quantity of lime must however be avoided, as it would take hold of the alizarin itself, and prevent it from uniting with the mordants.

Preparations of Madder. Since madder contains a variety of substances which impair the brightness and permanency of the colours produced by alizarin and purpurin, it follows that the process of dyeing with it must be greatly facilitated by the previous removal of these substances. This object is attained by treating madder with sulphuric acid, which destroys the rubiacin, resinous colouring matters, gum, pectin, extractive matter, &c., and at the same time, by its action on the rubian still existing in the madder, increases the quantity of alizarin and purpurin. Madder thus treated produces dyes which require less clearing than ordinary madder-colours; and there is this further advantage in its use, that nearly all the colouring matter contained in it is available for dyeing, whereas when crude madder is employed, nearly a third of the colouring matter remains in the residue unutilised. These considerations have led to the use of the following preparations of madder:

1. **Sulphuric Charcoal** (*Charbon sulfurique*).—This name was given by Robiquet to a product which he obtained by treating pulverised madder with a considerable quantity of rather strong sulphuric acid for several hours, then diluting with water, filtering, washing, and drying the residue. It dyes strongly and produces very fine colours; but being difficult and costly to prepare on the large scale, its manufacture has been abandoned, excepting for the preparation of colorin, a product introduced into commerce by MM. Lagier and Thomas, and obtained by exhausting the sulphuric charcoal with alcohol and distilling the solution to the consistence of an extract.

2. **Garancin**, first prepared by Lagier, Robiquet, and Colin, is obtained in a similar manner to sulphuric charcoal, excepting that a smaller quantity of acid is added (less than a third of the weight of the madder), and the mixture is more largely diluted with water and boiled for a longer time. The product is washed, dried, and ground with a small quantity of chalk or sodic carbonate to neutralise any acid that may be retained by the woody fibre. Madder yields from 33 to 36 per cent. of garancin. Garancin colours are regarded as somewhat less stable than those obtained directly from madder; but, if the garancin be well prepared, the colours are generally fine and brilliant, and the white ground remains intact. The violets which it produces are however not quite satisfactory, and to obtain a rose colour with it is very difficult.

3. **Pinc Coffin**, or *Alizarine commerciale*, introduced by Messrs. Pincoff and Co. of Manchester, is a garancin prepared and washed with the greatest care, then made as neutral as possible, and heated above 100° by high pressure steam, whereby a certain quantity of brown colouring matter is destroyed or rendered inert. This product yields very pure and bright violet tints without requiring clearing, and the other colours obtained with it are equally satisfactory.

4. **Garanceux**.—This is a product obtained by treating the waste madder of the dye-houses, which, as already observed, still retains a considerable quantity of colouring matter, with sulphuric acid, then filtering, washing, drying, and grinding. The substance thus obtained still dyes tolerably well, and may be used for a certain class of patterns not containing rose or violet tints.

5. **Flowers of Madder** (*Fleur de Garance*) is the name given to a kind of washed madder first prepared at Avignon by MM. Julien and Rocquer. The madder is suspended in water containing a small proportion of acid, partly to saturate earthy carbonates, partly to render the colouring principles less soluble. It is left in contact with the water for some hours, during which time alizarin and purpurin are formed, and become insoluble, and sometimes a true fermentation is set up. The product is then carefully washed, so as to remove only the more soluble matters. The first liquors, being strongly charged with sugar, are subjected to vinous fermentation, and on subsequently distilling them, a considerable quantity of alcohol is obtained. Madder yields about 50 per cent. of this product, which, being free from gummy and saccharine bodies, and especially from the brown colouring principle which soils the mordants, yield much finer colours than madder itself. More than half the quantity of madder cultivated at the present day is converted into flowers of madder and garancin.

6. **Madder Extracts**.—All the products above mentioned contain nearly the whole of the woody fibre of the root, an impurity which prevents their use in calico-

printing. To get rid of this, garancin or sulphuric charcoal, or flowers of madder, is treated with certain solvents, as in the preparation of colorin already mentioned, whereby the colouring matters are dissolved out and the woody fibre and other impurities are left behind. The solvents used for this purpose are:—

a. *Aluminium-salts*, alum being almost always the salt employed. The garancin, &c., is repeatedly boiled with an aqueous solution of alum, the colouring matter precipitated from the filtrate by sulphuric acid, and the precipitate collected and washed. The extract thus obtained almost always contains alumina, but is otherwise very pure, and yields very brilliant colours in dyeing and calico-printing; but the process is costly, because it requires large quantities of alum and sulphuric acid, and to recover the alum in the crystalline form, and separate it from the acid, the mother-liquors must be strongly concentrated in leaden vessels. Moreover, the residue of the madder, being impregnated with alum, which prevents its further use in dyeing, is totally lost.

b. *Alkalis and Alkaline-salts*.—The alkaline extracts are obtained by repeatedly treating madder or its derivatives with solution of caustic soda, carbonate or phosphate of sodium, or aqueous ammonia, filtering, precipitating the colouring matter by a mineral acid, filtering again, then washing and drying. This process is more economical than that with alum, but the extracts are much contaminated with resinous and pectous substances, very dark coloured, and when used for dyeing, yield colours which require very careful soaping and clearing, whereby the depth of the colour is greatly diminished. The extracts may however be improved in quality by boiling them, while yet moist, with dilute sulphuric acid, then filtering and washing.

c. *Spirituuous solvents*.—The extracts prepared by treating good garancin or flowers of madder with alcohol or wood-spirit, have a fine yellow or yellow-brown colour, and dye very well, especially if they are preserved in the pasty condition. If they are thoroughly dried, the colouring matters become so completely enveloped by the resin, that they are very difficult to moisten, and nearly insoluble in water, even at the boiling heat.

d. *Direct preparation of Rubian from Madder*; E. Kopp's process (Bull. Soc. industr. de Mulhouse (1861) xxxi. 9; Rép. Chim. app. 1861, pp. 166, 223, 276; Jahresber. 1861, p. 938).—This process consists in the treatment of madder with *sulphurous acid*. It differs essentially from all the preceding both in principle and in practice, requiring the use, not of flowers of madder or garancin, but of madder in the natural state and as little altered as possible, in which, in fact, the colorific principle (rubian) has not yet been transformed into alizarin or purpurin, these compounds, when once formed, being no longer soluble in water containing sulphurous acid.

The process, as carried out on the large scale by MM. Schnaaff and Lauth of Strasbourg, is as follows:—The ground madder is macerated for eight or ten hours with 10 or 12 times its weight of water containing 2 or 3 per cent. of sulphurous acid; the resulting solution is filtered, and the residue is pressed. On mixing the filtrate, which contains the colorific matter, with 3 per cent. of its weight of sulphuric acid, of specific gravity 1.52, and heating to 30° or 40° C., purpurin is deposited in large red or orange-coloured flakes, which are separated by decantation and filtration, and then washed.

The mother-liquor of the purpurin, heated to the boiling point, gives off carbonic acid, and yields a precipitate of alizarin coloured greenish-black by a foreign substance, which is likewise produced by the action of acids on the xanthin of MM. Kuhlmann and Higgin. This green alizarin is collected, filtered, and washed. It may be further purified by sublimation, or by solution in alcohol or wood-spirit.

The mother-liquor of the green alizarin contains the whole of the sulphuric acid used, together with the saccharine, gummy, and other matters extracted by the water from the madder. This acid liquor is used for converting into weak garancin, the madder-residue which has been exhausted by aqueous sulphurous acid and pressed. The mode of operating is exactly the same as for transforming fresh madder into garancin.

The mother-liquor of the garancin, which is still acid, but likewise saccharine, is neutralised with lime or chalk, and fermented so as to obtain alcohol.

This process is very simple and economical, the quantity of sulphuric acid consumed being about the same as employed in the preparation of ordinary garancin, and the only other material used being the small quantity of sulphur (or pyrites) required to produce the sulphurous acid.

By a careful experiment on the small scale, Kopp obtained from 100 pts. of *Alsatian madder*:

1.85	grms.	purpurin.	
3.15	"	green alizarin	} dried at 40° C.
0.30	"	yellow "	
42.0	"	madder-residue	dried at 40°.
35.0	"	"	converted into garancin and dried at 100°;
82.30			

and he estimates the united colouring powers of these materials as equal to $1\frac{1}{2}$ times that of the madder if employed in the crude state.

It does not appear likely that any other antiseptic substance can be advantageously substituted for the sulphurous acid. Kopp has unsuccessfully tried phenol, creosote, arsenious acid, and volatile oils; while the use of antiseptic salts, such as those of aluminium, mercury, copper, lead, &c. is inadmissible, because the residues, which always contain a portion of the colouring matter, would be contaminated with metallic oxides, and could not then be rendered available for dyeing, in the form of garancin or garanceux. (See Hofmann's *Report on Chemical Products and Processes in the International Exhibition of 1862*.)

7. Madder Lakes.—These lakes, which are obtained by precipitating aqueous extracts of madder or its derivatives with salts of aluminium, iron, tin, &c., but especially with aluminium-salts, possess a degree of fastness which withstands the strongest agents. They are, however, but little used in dyeing and calico-printing, on account of their high price, but are extensively employed as artists' pigments. For the preparation of an aluminous madder-lake, see *Lake* (p. 466); also *Ure's Dictionary of Arts, &c.*, iii. 15.

The residue of madder treated with sulphurous acid by E. Kopp's process, but not yet exhausted, yields, when washed with boiling water, a yellow liquor still retaining a considerable quantity of colouring matter or of rubian. This liquor, mixed with a salt of aluminium more or less neutralised, furnishes, on boiling, fine red or rose-coloured lakes, according as the proportion of aluminium-salt is greater or smaller.

The same liquid mixed with milk of lime, produces, on boiling, a violet lime lake (a compound of alizarin and purpurin with lime), which may serve for producing, by double decomposition, other compounds of the colouring matter with metallic oxides; or, if decomposed with heated hydrochloric acid, it will yield the colouring matter in the form of a yellow or brownish-yellow extract resembling colorin (p. 748).

Valuation of Madder. The method usually adopted for ascertaining the value of any sample of madder, is to dye a certain quantity of mordanted calico with a weighed quantity of the sample, and compare the depth and solidity of the colours with those produced by the same weight of another sample of known quality.

Thibierge (*Rép. Chim. app.* 1803, p. 157) proposes to estimate the value of a sample of madder by precipitating the alcoholic tincture obtained by treating madder with 100 times its weight of alcohol, with a standard solution of neutral acetate of lead. A similar method was proposed some time ago by Basset, who, however, weighed the precipitate. Thibierge states that the colour of the precipitate obtained, especially if controlled by that of the precipitate produced by stannous chloride, is sufficiently characteristic to detect the presence of any adulteration. The method of precipitation with a standard solution of acetate of lead is certainly expeditious, but it remains to be proved that the precipitation is regular and complete, and that the result is not affected by the presence of any foreign body extracted from the madder by alcohol.

Madder is sometimes adulterated with sand, clay, brick-dust, ochre, saw-dust, bran, bark, logwood, and other dye-woods, sumach, and quercitron-bark. Some of these adulterations are difficult to detect. Those which contain tannin may be discovered by the usual tests for that substance, since madder contains no tannin. If the adulteration is of a mineral nature, its presence may be detected by incinerating a weighed quantity of the sample. If the quantity of ash which is left exceeds 10 per cent., adulteration may be suspected.

MADDER, EAST INDIAN. See *MUNJEET*.

MADREPORES. Calcareous concretions produced by *polypi*, placed at the ends of calcareous ramifications which are fixed at their base, and perforated by numerous pores.

MAGISTERY. A term formerly applied to certain white precipitates; thus the basic nitrate of bismuth thrown down on adding water to a solution of the metal in nitric acid, was called *magistery of bismuth*.

MAGMA. A precipitate or mass of crystals, or mixture of substances in a pulpy or pasty state.

MAGNESIA. The oxide of magnesium (p. 754).

MAGNESIA ALBA. A pharmaceutical preparation consisting of a mixture of several hydrocarbonates of magnesium obtained by precipitating a soluble magnesium-salt with an alkaline carbonate. (See *CARBONATES*, i. 788.)

MAGNESIA NIGRA. An old name for black oxide of manganese (*q. v.*)

MAGNESITE. Native carbonate of magnesium. (See *CARBONATES*, i. p. 787.)

MAGNESIUM.

MAGNESIUM. Syn. *Magnium*. Symbol Mg; Atomic weight Mg = 12.

This metal is usually classed with those whose oxides constitute the alkaline earths; but it is much more closely analogous to zinc than to any other element. It occurs in the mineral kingdom, as hydrate, carbonate, borate, phosphate, sulphate, chloride, and nitrate, sometimes in the solid state, sometimes dissolved in various mineral waters (including salt springs), and in sea-water; in a variety of minerals, consisting of silicate of magnesium combined with other silicates, as in soap-stone, meerschaum, steatite, ophite, tolite, anorthite, hornblende, asbestos, talc, augite, chrysolite,—and combined with aluminium, in spinel and zeilanite. It also occurs in the bodies of plants and animals, chiefly as carbonate and phosphate, and in combination with organic acids.

Our acquaintance with the compounds of this metal does not date from early times. The knowledge of carbonate of magnesium or *magnesia alba*, as a medicine, was first promulgated from Rome in the beginning of the eighteenth century. Valentin in 1707 and Slovogt in 1709, subsequently found the same earth in the mother-liquor of salt-petre and in Epsom salts. Hoffmann, Black, Margraf, and Bergman pointed out the characters which distinguish it from lime, with which it was at first confounded. Davy first obtained from it the metal magnesium, which Bussy succeeded in preparing in a state of greater purity. It has since been obtained in much larger quantities by Bunsen, Matthiessen, and Deville and Caron.

Preparation of the metal.—1. By heating the anhydrous chloride with potassium in a porcelain or platinum crucible. When cold, the contents of the vessel are digested in cold water, by which the soluble chlorides are dissolved out, and the metal is left as a grey powder, which can be melted into globules. (Bussy, *Pogg. Ann.* xviii. 140.)

2. *By the electrolysis of the fused chloride.* A porcelain crucible is divided in its upper part into two halves by a vertical diaphragm (made out of a thin porcelain crucible cover), and fitted with a cover (filled from a tile), through which the extremities of the carbon-poles of a galvanic battery are introduced into the two halves of the crucible. The crucible is then heated to redness, together with the cover and the poles, and filled with fused chloride of magnesium; and the salt is subjected to the action of a battery of 10 zinc carbon elements. The negative pole is cut like a saw (*fig.* 427, vol. ii. p. 438) so that the magnesium, as it separates, may lodge in the cavities, and not float on the surface of the specifically heavier liquid (Bunsen, *Ann. Ch. Pharm.* lxxxii. 137). According to Matthiessen (*Chem. Soc. J.* viii. 107), the metal may be much more easily obtained from a fused mixture of 4 at. chloride of magnesium and 3 at. chloride of potassium, which is prepared with greater facility than the pure anhydrous chloride of magnesium. The two salts mixed in the proper proportion * with a little chloride of ammonium, may be fused and electrolysed in Bunsen's apparatus just described, the cutting of the negative pole being, however, dispensed with, as the metal is heavier than the fused mixture. A very simple and convenient way of reducing the metal, especially for the lecture table, is to fuse the mixture in a common clay tobacco pipe *rest in* argand spirit-lamp or gas-burner, the negative pole being an iron wire passed up the pipe stem, and the positive pole a piece of gas-coke, just touching the surface of the fused chlorides. (Matthiessen.)

Magnesium may, however, be obtained in much larger quantity, by heating a mixture of 600 grms. of chloride of magnesium, 100 grms. fused chloride of sodium, and 100 grms. of pulverised fluoride of calcium, with 100 grms. of sodium, to bright redness, in a covered earthen crucible. The magnesium is thereby obtained in globules, which are afterwards heated nearly to whiteness in a boat of compact charcoal placed within an inclined tube of the same material, through which a stream of dry hydrogen is passed. The magnesium then volatilises and condenses in the upper part of the tube. Lastly, it is remelted with a flux composed of chloride of magnesium, chloride of sodium, and fluoride of calcium, and is thus obtained in large globules. It *is* however, usually retains portions of carbon, silicium, and nitrogen, from which it may be purified by careful distillation in a current of hydrogen (Deville and Caron, *Ann. Ch. Pharm.* ci. 359). Sonstadt has recently prepared magnesium by this process on a considerable scale for commercial purposes.

Properties.—Magnesium on the recently fractured surface is sometimes slightly crystalline and coarsely laminated; sometimes fine-grained. In the former case, it is silvery-white and shining; in the latter, bluish-grey and dull. Its specific gravity is 1.7420 at + 5° C. (Bunsen); 1.75, according to Deville and Caron. It is about as hard as calcspar, and may be easily filed, bored, sawn, and flattened to a certain extent, but is scarcely more ductile than zinc at ordinary temperatures; it may, however, be drawn out into wire. It melts at a moderate red heat (Bunsen); melts, and volatilises at about the same temperature as zinc (Deville and Caron). It does not

* The solution of the chloride of magnesium may be evaporated almost to dryness and analysed, and the proportion of anhydrous salt present.

alter in a dry atmosphere, but in damp air soon becomes covered with a film of hydrate of magnesium. Heated to redness in the air, or in oxygen gas, it burns with a dazzling bluish-white light, and forms magnesia. The light of burning magnesium is remarkably rich in chemical rays, and may be used for taking photographs. It decomposes pure cold water but slowly, acidulated water very quickly; when thrown on aqueous hydrochloric acid, it takes fire momentarily; strong sulphuric acid dissolves it but slowly; a mixture of sulphuric acid and fuming nitric acid does not act upon it at ordinary temperatures. It burns when heated in chlorine gas; also in bromine-vapour, though with less facility; in sulphur and iodine-vapour very brilliantly (Bunsen). It unites directly with nitrogen, forming a transparent crystallised nitride, Mg^3N^2 . (Deville.)

Magnesium forms but one series of compounds, in which it is diatomic, e.g.:

MAGNESIUM, BROMIDE OF, $MgBr^2$, is found in sea-water and in numerous salt springs. It is produced by heating magnesium in bromine-vapour, or by passing the vapour over an ignited mixture of magnesia and charcoal. In the anhydrous state, it is a white mass of crystalline aspect, which is not fusible below a red heat, and not volatile. It deliquesces rapidly in the air, and dissolves in water with a hissing noise and evolution of heat. The solution, which may also be produced by dissolving magnesia in hydrobromic acid, yields, by evaporation over oil of vitriol, crystals containing 3 at. water. When evaporated by heat, it gives off part of its hydrobromic acid, and leaves a mixture of magnesia and bromide of magnesium.

MAGNESIUM, CHLORIDE OF, $MgCl^2$, is an ingredient of sea-water and of many salt-springs and other mineral waters. It is produced when magnesium burns in chlorine gas, also by passing a stream of chlorine over an ignited mixture of magnesia and charcoal. This, however, is not a good mode of preparation, because the chloride of magnesium has but little volatility, and does not separate easily from the charcoal. Neither can the anhydrous chloride be obtained by dissolving magnesia in hydrochloric acid and evaporating to dryness, because it is then partly decomposed by the water, giving off hydrochloric acid and leaving magnesia. The best mode of preparing it is to evaporate to dryness a solution of magnesia in hydrochloric acid mixed with sal-ammoniac, and ignite the residue in a platinum crucible. A double chloride of magnesium and ammonium is thus formed, from which the water is expelled before it can decompose the chloride of magnesium; and at a higher temperature the anhydrous double chloride is likewise decomposed, giving off sal-ammoniac, and leaving pure chloride of magnesium.

Anhydrous chloride of magnesium is a white translucent mass consisting of large, flexible crystalline plates, having a pearly lustre, and sharp bitter taste. It melts to a clear liquid at a low red heat. It dissolves readily in water, with considerable rise of temperature. The hydrated chloride is deposited from a hot concentrated solution on cooling, in needles and prisms containing $MgCl^2 \cdot 6H^2O$. The crystals are highly deliquescent, dissolve in 0.6 pts. of cold water, in 0.273 pts. of hot water, and in 2 pts. of alcohol of specific gravity 0.817.

Chloride of magnesium unites with the alkaline chlorides. The potassium-salt, $KCl \cdot MgCl^2 \cdot 6H^2O$, crystallises, by careful evaporation from the last mother-liquor of sea-water in rhombohedral crystals.—The sodium-salt contains, according to Poggiale (Compt. rend. xx. 1130), $NaCl \cdot MgCl^2 \cdot H^2O$.

MAGNESIUM, DETECTION AND ESTIMATION OF. Magnesium-salts are colourless, unless they contain a coloured acid. The carbonate, borate, phosphate, arsenate, arsenite, and many of the organic salts, are insoluble in water; but most of these salts are soluble in a solution of chloride of ammonium; most of the others are soluble. The aqueous solutions have a bitter taste. All magnesium-salts, excepting the ignited metaphosphate, dissolve in hydrochloric acid.

1. *Reactions in the dry way.*—All magnesium-salts containing volatile acids are decomposed by ignition, leaving a residue of magnesia. Magnesium-salts heated before the blowpipe with a small quantity of nitrate of cobalt, leave a rose-coloured residue.

2. *Reactions in Solution.*—Solutions of magnesium-salts are not precipitated by sulphuric acid or sulphide of ammonium. The fixed alkalis and their carbonates produce a white precipitate of hydrate or carbonate of magnesium, insoluble in excess of the reagent, but soluble in ammoniacal salts, especially of chloride of ammonium. If the solution contains ammoniacal salts, no precipitate is formed. Ammonia added to a neutral solution of magnesia, not containing any ammoniacal salt, throws down a

white precipitate, insoluble in excess of ammonia; but if the solution previously contained an excess of acid, no precipitate is formed, the magnesium being kept in solution by the ammoniacal salt produced, and even when the original solution is neutral, only a part of the magnesia is precipitated, the rest being held in solution in the same manner. Magnesium-salts are not precipitated by carbonate of ammonium, ferrocyanide of potassium, or alkaline sulphates. Baryta or lime-water added to the solution of a magnesium-salt forms a precipitate of hydrate of magnesium. This reaction affords an easy method of separating magnesia from the alkalis.

Ordinary phosphate of sodium added to a neutral solution of a magnesium-salt produces a gelatinous precipitate of phosphate of magnesium, soluble in nitric or hydrochloric acid; but if ammonia be then added in excess to the acid solution, a precipitate of phosphate of magnesium and ammonium, $Mg^{++}(NH_4^+)PO_4$, is formed, which is flocculent or gelatinous at first, but soon becomes crystalline, especially on agitation. The same precipitate is likewise produced on adding a soluble phosphate to the solution of a magnesium-salt already containing ammonia. It is an extremely delicate test of the presence of magnesia. If the solution is very dilute, the precipitate attaches itself in crystalline grains to the sides of the vessel. According to Harting (J. pr. Chem. xxii. 50), a solution containing only $\frac{1}{200,000}$ of magnesia, gives a precipitate, after 24 hours with phosphate of ammonium mixed with free ammonia, provided the latter solution is highly concentrated and added in equal quantity. Oxalic acid or acid oxalate of potassium precipitates neutral magnesium-solutions, provided no ammoniacal salts are present.

3. *Quantitative Estimation and Separation.*—When magnesia occurs in a solution not containing any other fixed substance, its quantity may be determined by evaporating to dryness, igniting the residue, then moistening it with sulphuric acid slightly diluted with water, and expelling the excess of that acid at a low red heat: sulphate of magnesium then remains, containing 33.7 per cent. of magnesia, or 19.22 per cent. of magnesium.

If the solution contains other fixed substances, the magnesia must be precipitated by the addition of ammonia in excess and phosphate of sodium. The precipitated ammonio-magnesian phosphate does not settle down at once, but its deposition may be accelerated by leaving the vessel in a warm place. Care must be taken, however, not to allow the liquid to get very hot, as in that case, hydrate of magnesium will be precipitated, and will be very difficult to redissolve. The precipitate, after standing for about two hours, is collected on a filter and washed with water containing ammonia, as pure water decomposes it. It is then dried and ignited, whereby it is converted into pyrophosphate of magnesium, $2Mg^{++}O.P_2O_5$ or $Mg^{++}P_2O_7$, containing 36.33 per cent. magnesia, or 21.62 per cent. magnesium.

From the heavy metals, magnesium may be separated, either by sulphuric acid or by sulphide of ammonium; from aluminium and the other metals of the earths proper, also by sulphide of ammonium. In precipitating by sulphide of ammonium, however, it is necessary to guard against the simultaneous precipitation of small quantities of magnesia, for which purpose the ammoniacal liquid should be boiled, before filtering, till the excess of ammonia is expelled; any magnesia that may have been precipitated will then be redissolved (H. Rose, Pogg. Ann. ex. 411). For the separation of magnesium from manganese, see MANGANESE.

From aluminium, magnesium may be separated by precipitating the former with hyposulphite of sodium (i. 155).

From barium and strontium, magnesium is separated by sulphuric acid; from calcium by oxalate of ammonium, with addition of chloride of ammonium, to prevent the precipitation of the magnesia. When, however, the quantity of calcium present is very small in proportion to the magnesium, this mode of precipitation does not give exact results; and it is better, according to Scheerer (Ann. Ch. Pharm. ex. 36), to convert the two metals into sulphates; dissolve the sulphates in water; carefully add alcohol with stirring, till permanent turbidity is produced; leave the liquid to itself for a few hours, by which time the sulphate of calcium will be completely precipitated, together with a small quantity of sulphate of magnesium; wash the precipitate on a filter with alcohol diluted with an equal volume of water; then redissolve it in water, add hydrochloric acid in excess, and precipitate the lime with oxalic acid and ammonia.

From the alkali-metals, magnesium may be separated by converting the bases into sulphates, and adding baryta-water. The magnesia is then precipitated in the form of hydrate, together with sulphate of barium. The precipitate, after washing, is digested with dilute sulphuric acid, which extracts the magnesia in the form of sulphate; and the filtrate, containing the alkalis together with the excess of baryta, is also treated with sulphuric acid, which precipitates the baryta, and converts the alkalis into sulphates.

Magnesium may also be separated from the alkali-metals by means of mercuric iodide.

The solution, from which all metals except those of the alkalis and magnesium have been removed, and which must contain no fixed acid, is digested with excess of finely divided mercuric oxide; the whole evaporated to dryness, and the residue heated to drive off the mercury. The magnesium then remains as magnesia, and the alkalis can be washed out with water.

Chancel (*Compt. rend.* 194) recommends the following method. The magnesia is precipitated from the solution containing sal-ammoniac and free ammonia, by *phosphate of ammonium*; the filtrate is evaporated to dryness; the residue carefully ignited to expel ammoniacal salts; then redissolved in water; and the solution is mixed with nitrate of silver and a slight excess of carbonate of silver. After filtering off the phosphate of silver (and chloride, if the alkalis existed in the solution as chlorides), the excess of silver is removed from the filtrate by hydrochloric acid, and the alkalis are estimated as chlorides.

4. *Atomic Weight of Magnesium.*—Berzelius found that 100 pts. of magnesium, dissolved in pure sulphuric acid and ignited, gave 293.85 of sulphate of magnesium, $Mg^{+}SO_4$, whence the atomic weight of magnesium would be 25.24, a result too high according to later experiments.

Scheerer (*Pogg. Ann.* lxi. 135), by determining the quantity of sulphate of barium produced from a given quantity of sulphate of magnesium, found for magnesium the number 24.2. The results of Svanberg and Nordenfeldt (*J. pr. Chem.* xlv. 473), obtained by the decomposition of oxalate of magnesium ($Mg^{++}C_2O_4 \cdot 2H_2O$), made it 24.7; those obtained by converting a known weight of magnesia into sulphate gave it as 24.74; whilst those of Marchand and Scheerer (*Ann. Ch. Pharm.* lxxvi. 219), obtained by igniting the native carbonate (magnesite), gave the number 24.04. Dumas (*Ann. Ch. Phys.* [3] lv. 129) attempted to determine the atomic weight of magnesium by precipitating the chloride with nitrate of silver, but he found the greatest difficulty in obtaining the chloride free from magnesia. The mean of eleven experiments gave $Mg^{+} = 24.6$.

The mean of all these results is 24.32, but those of Marchand and Scheerer are generally regarded as the most trustworthy. Moreover Scheerer has lately shown, by his method of separating calcium and magnesium above given (p. 753), that the specimens of magnesite used by himself and Marchand in their determinations, contained small quantities of calcium not previously detected. He therefore considers that the number 24.04 found in those experiments was rather above than below the truth. On the whole, then, the atomic weight of magnesium may be regarded as 24.

MAGNESIUM, FLUORIDE OF. Obtained as a white tasteless powder by treating the carbonate with hydrofluoric acid, or mixing the sulphate with fluoride of potassium. It is insoluble in water and nearly insoluble in acids.

MAGNESIUM, FLUOBORIDE OF. See BOROFLUORIDES (i. 634).

MAGNESIUM, FLUOSILICIDE OF. See SILICOFLUORIDES.

MAGNESIUM, IODIDE OF. Obtained by evaporation of its solution, as a difficultly crystallisable hydrate, which deliquesces in the air, and when heated gives off hydriodic acid and leaves pure magnesia.

MAGNESIUM, NITRIDE OF. $Mg^{+}N^3$.—Deville and Caron (*Compt. rend.* xlv. 394), by distilling impure magnesium, obtained a black residue, and a distillate of magnesium covered with small transparent needles, which easily decomposed, with formation of magnesia and ammonia, and therefore contained a nitride of magnesium. Briegleb and Geuther (*Ann. Ch. Pharm.* cxxiii. 228) have obtained the same compound, in the amorphous state, by igniting metallic magnesium in ammonia or in nitrogen gas; the latter method giving the purest product. Nitride of magnesium thus prepared is a greenish-yellow amorphous mass, becoming brownish-yellow when hot. Heated in dry oxygen gas, it oxidises to magnesia, with vivid incandescence. It is decomposed by air and water, the reaction in the latter case being violent enough to make the water boil. Acids both dilute and concentrated, with the exception of strong sulphuric acid, form ammonium- and magnesium-salts, even in the cold; strong sulphuric acid, only when heated, and with evolution of sulphurous anhydride. The nitride heated in hydrochloric acid gas, yields chloride of ammonium and chloride of magnesium; in sulphuric acid, the corresponding sulphides. Carbonic anhydride and dry carbonic oxide decompose it, at the heat of a strong air-furnace, with separation of carbon and formation of cyanogen. When vapour of pentachloride of phosphorus is passed over nitride of magnesium heated in a stream of nitrogen, the nitride is converted into a greyish-white substance, probably P^3N^3 , according to the equation

When nitride of magnesium is heated to 160° – 180° in a sealed tube with oxychloride

of phosphorus, and the excess of oxychloride is distilled off, there remains a residuë which melts at 220°, and dissolves completely in water, with great evolution of heat, forming a solution which gives, with acetate of barium, a precipitate of metaphosphate of barium. Absolute alcohol and iodide of ethyl do not act on oxide of magnesium, even at 160°.

MAGNESIUM, OXIDE OF. *Magnesia.* MgO .—This earth, which is the only known oxide of magnesium, is produced in the form of a white amorphous powder, when magnesium burns in the air or in oxygen-gas, and remains in the same state when the carbonate, nitrate, or any other salt of magnesium containing a volatile acid, is ignited in the air. It may be obtained crystallised in cubes and regular octahedrons, by strongly igniting amorphous magnesia in a stream of hydrochloric acid gas (H. Deville, *Ann. Ch. Pharm.* cxx. 280; *Jahresb.* 1861, p. 7); also, according to Debray and Kuhlmann (*Ann. Ch. Pharm.* cxx. 283), by strongly igniting a mixture of sulphate of magnesium and an alkaline sulphate in a platinum crucible, so that the magnesia separated by the heat may crystallise from the fused alkaline sulphate. A mixture of magnesia and ferric oxide, strongly ignited in hydrochloric acid gas, yields a mixture of shining black octahedrons of magneto-ferrite, $MgO.Fe_2O_3$ or $\left. \begin{matrix} Mg \\ (Fe) \end{matrix} \right\} O_4$, and slightly coloured regular octahedrons of magnesia containing a small quantity of iron, exactly resembling periclase, a mineral consisting of magnesia with 1 part in 25 of ferrous oxide, which occurs disseminated through ejected masses of white lime-stone, and in spots of clustered crystals, on Monte Somma.

Ordinary calcined magnesia is prepared by gentle but prolonged ignition of the carbonate. It is a fine, white, very bulky powder, of specific gravity 3.07 to 3.200, increased by ignition in a pottery-furnace to 3.61 (H. Rose). It melts only at the very highest temperatures, as in the oxyhydrogen blowpipe flame, to which it imparts a pale red colour, and is then converted into a sort of enamel, which scratches glass like a diamond (Clarke). It is tasteless and inodorous; changes some of the more delicate vegetable colours, as that of moistened red litmus paper, like the alkalis; it is not caustic. It is partially decomposed by potassium at a white heat. It is very slightly soluble in water; in 55,368 pts., either cold or boiling, according to Fresenius (*Ann. Ch. Pharm.* lix. 117), the solution having a faint alkaline reaction.

A hydrate of magnesia, MgH_2O_2 , occurs native in rhombohedral forms, as brucite (i. 684), and is precipitated as a white powder on adding potash, soda, or baryta-water in excess to the solution of a magnesium-salt.

MAGNESIUM, SULPHIDE OF. A sulphide of magnesium is obtained, mixed, however, with magnesia, by heating a mixture of charcoal and sulphate of magnesium. A purer product is obtained by adding to the preceding mixture, an alkaline persulphide, or a mixture of carbonate of sodium with excess of sulphur. According to Frémy, sulphide of magnesium is easily produced by passing the vapour of sulphide of carbon over red-hot magnesia.

Solutions of magnesia are not precipitated by alkaline sulphides, but on mixing sulphate of magnesium with sulphide of barium, sulphate of barium is precipitated, and sulphide of magnesium remains in solution. Sulphide of magnesium is likewise obtained by passing sulphydric acid gas in excess into water containing magnesia in suspension. A solution of sulphide of hydrogen and magnesium is then formed, which is decomposed by boiling, into sulphydric acid, and a white gelatinous mass of sulphide of magnesium.

Sulphide of magnesium forms double salts with sulphide of carbon, and with the sulphides of arsenic.

Sulphide of magnesium is decomposed, by the continued action of water, into magnesia and sulphydric acid. The presence of that acid in mineral waters may, perhaps, be accounted for by the existence of sulphide of magnesium in the strata through which those waters percolate. (Pelouze and Frémy, *Traité*, ii. 286.)

MAGNESIUM-ETHYL. $Mg(C_2H_5)_2$.—When iodide of ethyl is added to magnesium-filings contained in a strong narrow glass tube, an action immediately takes place, attended with rise of temperature, and evolution of a considerable quantity of gas containing ethylene, and apparently also ethyl and hydride of ethyl. If the tube, after being cooled with cold water, be sealed and heated for some hours to 120°—130°, the contents solidify to a white mass, which, when subsequently distilled, yields a residuë of iodide of magnesium, and a distillate containing undecomposed iodide of ethyl, and magnesium-ethyl, which may be separated by fractional rectification.

Magnesium-ethyl is a colourless liquid, having a strong allineous odour, and boiling at a higher temperature than iodide of ethyl. It takes fire in the air, and decomposes water with violence. (Cahours, *Ann. Ch. Pharm.* cxiv. 227, 354; *Jahresb.* 1859,

p. 416. See also Hallwachs and Schafarik, *Ann. Ch. Pharm.* cix. 215; *Jahres* 1859, p. 407.)

Magnesium-methyl forms a doubly-crystallised double salt with iodide of magnesium. probable formula, MgO^2HPI (Wanklyn.)

MAGNESIUM-METHYL is produced by the action of magnesium on iodide of methyl in a manner similar to the above. It is likewise a mobile strong-smelling liquid, which instantly takes fire in the air, and quickly decomposes water, with evolution of marsh gas and separation of magnesia. (Cahours.)

MAGNETIC IRON ORE. Native ferroso-ferric oxide (iii. 337, 397).

MAGNETIC PYRITES. Ferroso-ferric sulphide (iii. 401).

MAGNETISM. It has been known from very early times, that the native black oxide of iron, or ferroso-ferric oxide (Fe^2O^2) possesses, at certain points of its surface, called poles, the power of attracting small pieces of iron. The Greeks gave to this mineral the name of *magnetes* ($\mu\gamma\eta\eta\iota\tau\iota\varsigma$), from the village of Magnesia in Lydia, near which it was found in considerable quantity: hence the name Magnetism, applied to the branch of science which treats of this peculiar kind of attraction, and of the various phenomena related to it.

The attractive power of the natural magnet may be communicated to iron and steel by contact, the attractive power thus developed continuing, in soft iron, only so long as the contact lasts, whereas, in hard iron, and more especially in steel, it continues after separation from the natural magnet. A bar of steel rubbed lengthwise, and in one constant direction, with the pole of a natural magnet, becomes itself a magnet, capable of attracting iron, and imparting its power in like manner to other bars of steel.

Another mode of imparting magnetism to iron or steel is by the action of an electric current or discharge, as already described in the article *ELECTRICITY* (ii. 448). A steel bar, placed within a helix of wire through which an electric current is passed, becomes a permanent magnet. Lastly, as we shall presently explain more particularly, a bar of iron or steel may be rendered magnetic by placing it in a certain position relatively to the earth.

The properties of magnets are the same in whatever manner their power may be developed.

There are only two other metals, viz. nickel and cobalt, in which the magnetic power can be conspicuously developed by the means above mentioned: in nickel it is considerable, but much less powerful than in iron; and in cobalt, still less. All other bodies are, indeed, more or less susceptible of magnetic influence, but they exhibit its effects only when subjected to very powerful electric or magnetic forces; and, in many cases, the mode of manifestation is very different from that which is exhibited by iron. See *DIAMAGNETISM* (p. 770).

Distribution of Magnetic Power.—In a magnetised steel bar, as in the natural magnet, the attractive power is not uniformly distributed, but is more or less concentrated in certain points called poles, situated at or near the ends of the bar, whence it diminishes with greater or less rapidity and regularity towards an intermediate point, or rather line, called the median line, generally in the middle of the bar. This may be shown by rolling the bar in iron filings, which then attach themselves in clusters round the ends, leaving the middle bare, as in *fig. 716*. If the two poles have equal attractive

Figs. 716.

Fig. 717.

Fig. 718.

power, and are situated at equal distances from the ends, and the power diminishes from each of them at the same rate towards the middle, the bar is said to be *regularly*

magnetised. This, however, is not always the case. Sometimes a magnet exhibits more than two poles, as shown in *fig. 717*.

Direction of a freely-suspended Magnetic Bar.—A regularly magnetised steel bar is suspended by its centre of gravity from a thread without torsion, or supported by an agate cap on a steel point, as in *fig. 718*; so that it can move freely in a horizontal plane, it takes up a particular position with respect to the poles of the earth, one end pointing more or less exactly towards the north, the other to the south. A bar-magnet thus suspended is called a magnetic needle, though the so-called needle is sometimes a stout bar weighing several pounds. Small needles are sometimes made of flat lozenge-shaped bars of steel, like that represented in *fig. 718*.

The particular angle which the bar in its position of equilibrium makes with the geographical meridian is different on different parts of the earth's surface, and varies at the same place at different times. In some parts, the suspended magnet points exactly north and south; in London, at the present time (1864), the direction is north-west and south-east, the position of equilibrium making an angle of $20^{\circ} 45'$ with the geographical meridian.

The vertical plane passing through the two poles of the needle is called the magnetic meridian of the place, and the angle which it makes with the geographical meridian is called the declination.

One particular end of the suspended bar always points towards the north, the other towards the south. If the bar be placed exactly in the opposite position, it may remain for a while in a condition of unstable equilibrium; but the slightest disturbance will cause it to swing back to its former position, in which, after a certain number of oscillations, it will come to rest. The two ends of the bar are accordingly designated as the north and south poles respectively.* Every regularly magnetised piece of iron or steel has two such poles, and two only, which are not interchangeable.

If the magnetic needle, instead of having its movements restricted to a horizontal plane, be suspended by its centre of gravity, in such a manner that it can move freely in all directions, it places itself, not only in the magnetic meridian, but likewise at a particular inclination to the horizon, which also differs according to the locality, and varies in the same place at different times. In London, at the present time, a freely suspended magnetic needle places itself at an angle of $68^{\circ} 15'$ to the horizon, with its north pole downwards. A magnet, suspended so as to exhibit this inclination, is called a dipping needle, and the angle of inclination is called the dip.

The north pole of the needle dips throughout the greater part of the northern hemisphere, and the south pole throughout the greater part of the opposite hemisphere, and between these two portions there is a line not deviating greatly from the earth's equator, on which the needle has no dip, but stands horizontally. In short, as will be seen from what follows, the movements of a freely-suspended needle in different parts of the world, are such as may be accounted for by regarding the earth as a great magnet, the northern hemisphere exhibiting southern, and the southern hemisphere northern magnetic polarity. (See MAGNETISM, TERRESTRIAL.)

MAGNETIC ATTRACTION AND REPULSION.

A piece of unmagnetised iron is attracted indifferently by either pole of a magnet, and, it need scarcely be observed, that the attraction is mutual, so that, whichever of the two is movable, will move towards the other; and if both are movable, they will approach one another with velocities which are inversely as their masses. Hence, if a piece of unmagnetised iron or steel be presented to either pole of a magnetic needle, the needle will move towards it. But, when a magnetised bar is presented to the needle, it is found that the north pole of the one attracts the south pole of the other, but repels the north, while a south pole attracts a north pole, but repels a south. The general law of magnetic attraction and repulsion is then exactly similar to that of electric attraction and repulsion (ii. 376), viz. *Similar magnetic poles repel, dissimilar poles attract one another*. Hence, to determine whether any piece of iron or steel is magnetised or not, it is sufficient to present the several parts of its surface to a delicately-suspended magnetic needle: if every part attracts the needle, the piece of iron is destitute of magnetic polarity; if, on the other hand, some parts attract, while others repel, the poles of the needle, the iron is shown to be magnetic, and the number and positions of its poles may be determined.

Magnetic attraction and repulsion are not prevented by the interposition of any substance not itself susceptible of magnetism. If a magnetic needle be deflected from its natural position, by placing a piece of iron, or another magnet, near it, and allowed to

* Sometimes by English writers, and commonly by French authors, the pole which points northwards is called the south pole (*pôle austral*), and that which points southwards the north pole (*pôle boreal*) of the magnet. In order to avoid this confusion, Faraday speaks of the pole which points northwards as the "marked pole."

settle itself in its position of equilibrium, that position will not be disturbed by the interposition of a screen of glass, paper, &c.; but, if a plate of iron be interposed, the needle will be attracted and take a new position, the distribution of the magnetic forces being altered by the interposition of the iron.

The force of magnetic attraction and repulsion varies inversely as the square of the distance between the poles or centres of action.—By the term *pole* we must here understand the point of application of all the forces exerted by one half of a magnet on any point of the other. It is evident, then, that the poles must vary in position according to the distance between the magnets; but unless the magnets are very close together, the distance between their poles will not differ sensibly from that which exists when the magnets are placed so far apart that all the acting forces may be regarded as parallel. The poles, understood in this sense, do not of course coincide with the points of strongest attraction, which are generally at the ends of the magnet, but they are nearer to those points in proportion as the magnetic power decreases more rapidly from the ends towards the middle.

This law of magnetic action may be demonstrated in three ways: 1. *By the Torsion-Balance.*—The construction of the magnetic torsion-balance is similar to that already described (ii. 380) for the measurement of the electric forces, the shellac needle being replaced by a magnetic needle, and the shellac stem by a bar-magnet. The mode of experimenting to determine the law of magnetic action with regard to distance, is exactly similar to that described at page 381, vol. ii., for measuring the force of electric attraction and repulsion.

2. *By the Method of Oscillations.*—Suppose a magnetic needle to be placed near a bar-magnet, with its centre on the prolongation of the axis of that magnet; it will then place itself in the direction of that axis, and if disturbed from that position will oscillate backwards and forwards, and ultimately settle in its original position of equilibrium. Now the oscillations of the needle thus vibrating under the influence of magnetic attraction, are regulated by the same laws as those of a pendulum oscillating under the influence of gravity, that is to say, *the squares of the times of oscillation are inversely as the attracting forces.* Supposing then the power of the magnet and needle to remain constant during the experiment, the diminution of the attractive force at different distances may be measured by counting the number of oscillations which the needle performs in a given time at different distances. It is necessary to observe, however, that, as the oscillations of the needle are determined by the magnetic force of the earth as well as by that of the magnet, the terrestrial force must be either compensated or allowed for.

To simplify the calculations as much as possible, the experiment may be performed with an *astatic needle*, that is to say, a system composed of two magnetic needles of equal power, joined together parallel to one another, but with their poles in contrary directions, by a small piece of straw or copper wire passing through their centres of gravity (ii. 443); such a combination will evidently place itself indifferently in all positions relatively to the magnetic meridian, because the magnetic force of the earth acts on the two needles composing it with equal force but in opposite directions. Now let one of the poles of such a needle be brought near the contrary pole of a bar-magnet, of such a length that the action of its farther pole may be left out of account. The distance between the poles of the magnet and needle is then to be measured, the needle made to vibrate, and the number of its oscillations performed in a given time, counted. The needle is then removed to a greater distance and the experiment is repeated. If then m and m' are the magnetic forces at the distances d , d' , and n , n' the corresponding numbers of oscillations in the same time; we have $n^2 : n'^2 = m : m'$. Now experiment shows that the quantities n , n' , d , d' are related by the equation $n : n' = d^2 : d'^2$, that is to say, the number of oscillations in a given time are inversely as the distances; consequently

$$m : m' = d'^2 : d^2.$$

The same result may be attained by the use of a needle not rendered astatic. Let N be the number of oscillations which it makes in a given time under the influence of the earth's magnetism alone; n the number performed in the same time under the joint influence of the terrestrial force and that of a magnet placed at a certain distance from the needle in the magnetic meridian; and n' the number performed in like manner when the magnet is removed to a greater distance. If then the magnetic forces of the earth, and of the magnet at the two distances mentioned, be denoted by F , m , m' respectively, we shall have

$$N^2 : n^2 = F : m + F$$

$$\text{and } N^2 : n'^2 = F : m' + F$$

$$\text{therefore } n^2 - N^2 : N^2 = m : F$$

$$\text{and } n'^2 - N^2 : N^2 = m' : F$$

$$\text{and finally } m : m' = n^2 - N^2 : n'^2 - N^2.$$

3. *By the Form of the Magnetic Curves.*—Place a bar-magnet under a sheet of stiff paper, and sprinkle some fine iron filings on it; pass a gauze sieve. These filings will arrange themselves round the magnet in *curvilinear curves* (fig. 719), radiating

FIG. 719.

as it were, from the two poles. Now these curves are clearly the graphic expression of the law of magnetic attraction and repulsion with regard to distance: for each of the filings under the influence of the magnet becomes itself a small magnet, the poles of which place themselves in a position determined by the resultant of the forces exerted upon them by the two poles of the magnet; and this position of equilibrium varies according to the distance of the filing from the two poles respectively. In fact, a small magnetic needle, placed on any part of the paper, will settle itself in the direction of a tangent to the curve passing through that point. If placed on any point of the prolongation of the axis of the magnet, it will take up a position parallel to that axis with its poles arranged consecutively with those of the bar-magnet; at any point on the line drawn through the centre of the magnet at right angles to its axis—every point of which line is equidistant from the two poles—the needle will place itself parallel to the bar-magnet, with its poles in the contrary direction; and in any intermediate position, the needle will place itself obliquely to the magnet, its inclination increasing with the difference of its distances from the two poles.

If then the mode of generation of the magnetic curves—or, what comes to the same thing, their general equation—can be determined, the law of force with regard to distance may be deduced from it. The curves may be obtained in a state convenient for measurement by forming them over a plate of glass in the manner above described, and laying upon it a sheet of paper covered with gum or starch paste. In this manner the filings will be fixed on the paper, and the curves may be measured.

By careful measurements of the curves formed by the joint action of two magnetic poles, either contrary or similar, on iron filings or infinitely small magnets, Roget has determined the following law: *The difference of the cosines of the angles formed with the magnetic axis (the line joining the two poles) by lines drawn from these two poles to any point of a magnetic curve, is a constant quantity, the two angles being taken on the same side of the axis.*

Roget has described an instrument for tracing the curves by continued motion, founded on this property, and has also given the following method for describing them by points.

From each pole as a centre, and with any radii whatever, describe two circles; produce the axis till it meets both these circles; divide the whole length into any number of equal parts, and project each point of division perpendicularly on the two circumferences. If radii indefinitely prolonged be then drawn through the centre of each circumference and the points thus determined upon it, these radii will intersect one another in points belonging to the curves.

If the two acting poles are of contrary name, the curves are said to be *converging* (fig. 719), and are the curvilinear diagonals in the direction of the magnetic axis of the

quadrilaterals formed by the intersection of the rays. If on the other hand the two poles are of the same name, the curves are said to be *divergent*, their direction being that of the curvilinear diagonals perpendicular to the former.

Now let A, B (fig. 720) be the two magnetic poles, M a point of the curve whose co-ordinates, referred to two rectangular axes, are x and y . Let AB be the axis of x , and its middle point, O, the origin. Also let $OA = OB = h$; $AM = r$; $BM = r'$; angle $MAB = i$; $MBA = i'$. Then $AP = h - x = r \cos i$; therefore $\cos i = \frac{h-x}{r}$; in like manner $\cos i' = \frac{h+x}{r'}$. Therefore, according to Roget's law,

$$\frac{h-x}{r} \pm \frac{h+x}{r'} = \text{constant};$$

$$\text{or } \frac{h-x}{\sqrt{(h-x)^2 + y^2}} \pm \frac{h+x}{\sqrt{(h+x)^2 + y^2}} = \text{constant}.$$

This is the equation of the magnetic curves, the upper or lower sign being taken according as the two poles are opposite or similar.

Fig. 720.

From this equation, by the processes of the differential calculus, the expression of the inclination of the tangent to the curve at any point may be found; and as this tangent is the direction assumed by a magnetic needle having its centre placed over the point of contact with the curve, which direction is determined by the resultant of the attractive and repulsive actions exerted upon it by the two poles A, B, it follows that the value of this inclination, properly expressed in terms of the distance of the point of contact from the two poles, will give the law of variation of

the intensity according to the distance. When these calculations are made, it is found, in accordance with the results of the other modes of measurement above described, that the intensity of the force of magnetic attraction and repulsion varies inversely as the square of the distance. (See De La Rive, *Traité de l'Electricité*, tome i. note D, p. 592.)

Comparison of the Power of different Magnets. Distribution of Magnetism.

The old method of comparing the power of magnets, or of different parts of the same magnet, consisted in ascertaining the weights which they were capable of supporting. This method, however, can give only a rough approximation to the truth, inasmuch as the weight which a magnet can support depends in great measure on the manner in which the weight is applied, and on the rate at which it is increased. When the weight with which a magnet is loaded is very gradually increased, it is found to be capable of supporting a much larger weight than could be supported by it if applied all at once.

Much more exact results are obtained with the torsion balance and by the method of oscillations, both of which methods have been applied to this purpose by Coulomb.

To compare the force of two or more magnets by the torsion balance, these magnets are introduced successively through the hole m (fig. 373; ii. 380) and the needle of the balance is kept at a constant angular distance by twisting the thread through different angles, which are to one another as the forces to be overcome. When the method of oscillations is employed, the magnets are placed successively at a constant distance from the needle, this distance being so great that they cannot alter the distribution of its magnetic power.

Magnetic Moments.—Another mode of comparing the power of magnets is to place each of them successively in a small stirrup suspended from the thread of the torsion-balance, so that the magnet may remain in the magnetic meridian when the thread is untwisted. The thread has then to be twisted through different degrees, so as to obtain for each magnet the same angle of deviation from the magnetic meridian. The angles of torsion thus found represent what Coulomb calls the magnetic moments of the several bars. It is evident that the magnetic moment depends both on the magnetic intensity of the bar, and on the distance of its poles from the axis of suspension.

Distribution of Magnetism.—To measure the relative attractive or repulsive forces exerted by the different parts of a bar-magnet, Coulomb introduced a vertical wooden rule into the glass case of the torsion-balance, in such a position that it touched the needle of the balance which rested in the magnetic meridian when the thread was

untwisted. At the back of this rule was a vertical groove in which the magnet to be tested was made to slide up and down, so as to bring the several parts of its length opposite to the pole of the needle of the same name as the half of the bar which was presented to it. The needle was thereby repelled; and to bring it back to its original position, the thread had to be twisted through a certain angle, which measured the repulsive force exerted. The bar was then shifted in the groove, so as to bring another part of it opposite to the pole of the needle, and a similar experiment was made. The magnetic bar being very close to the needle, it is only the points very nearly on a level with the needle that can exert any sensible influence over it, those which are even a few millimetres above or below, acting too obliquely.

In applying the method of oscillations to the same purpose, a small needle, magnetised to saturation, so that its magnetic state may not be altered by the action of the bar, is made to oscillate near different parts of the bar. Denoting by m, m' the magnetic intensities at two different points, and by N, n, n' the number of oscillations made in a given time, under the influence of the earth alone, and under this influence added to that of the two points of the bar under consideration, we find, as on page 758,

$$m : m' = n^2 - N^2 : n'^2 - N^2.$$

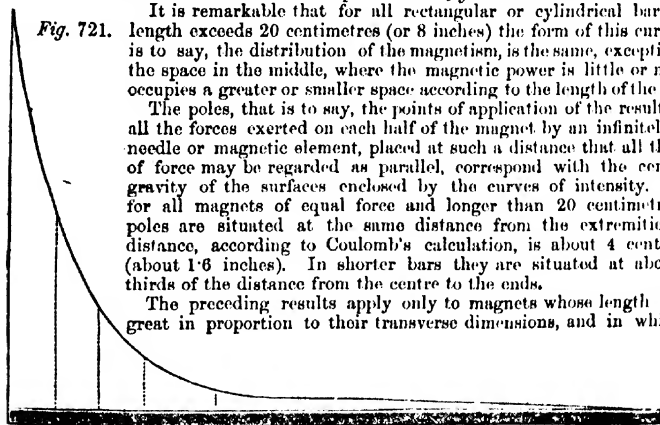

Either of these methods gives directly the relative magnetic intensity of any part of a bar, excepting at the extremities, for which the intensities found by direct experiment must be doubled, in order to give the true force at these points, as compared with the rest: for the power observed at these extreme points would evidently be double of what it actually appears to be, if the magnet were prolonged, so as to present, beyond these extremities, points of equal magnetic force with those which are within them, as is the case for every other part of the bar.

The results obtained by these methods may be represented graphically by erecting, at the several points of a horizontal line representing a magnetised bar, perpendiculars whose lengths are proportional to the intensities observed at these points. The ends of these ordinates form a curve like that represented in fig. 721.

It is remarkable that for all rectangular or cylindrical bars whose length exceeds 20 centimetres (or 8 inches) the form of this curve, that is to say, the distribution of the magnetism, is the same, excepting that the space in the middle, where the magnetic power is little or nothing, occupies a greater or smaller space according to the length of the bar.

The poles, that is to say, the points of application of the resultants of all the forces exerted on each half of the magnet by an infinitely small needle or magnetic element, placed at such a distance that all the lines of force may be regarded as parallel, correspond with the centres of gravity of the surfaces enclosed by the curves of intensity. Hence for all magnets of equal force and longer than 20 centimetres, the poles are situated at the same distance from the extremities: this distance, according to Coulomb's calculation, is about 4 centimetres (about 1·6 inches). In shorter bars they are situated at about two thirds of the distance from the centre to the ends.

The preceding results apply only to magnets whose length is very great in proportion to their transverse dimensions, and in which the

form is perfectly regular—that is, prismatic or cylindrical, and the magnetisation likewise regular: in lozenge-shaped needles, the poles are much farther from the extremities.

MAGNETIC INDUCTION.

It has already been mentioned that a piece of iron or steel placed in contact with a pole of a magnet, either natural or artificial, becomes itself a magnet. This action likewise takes place, though with diminished intensity, at a distance, and is not prevented by the interposition of non-magnetic bodies. This effect is called magnetic induction, and the law according to which it takes place is precisely analogous to that of electric induction (ii. 384), viz. that *The extremity of the iron or steel nearest to the inducing magnetic pole, becomes a pole of contrary name, and the farther extremity a pole of the same name as the inducing pole.* Thus, suppose a bar of soft iron to be placed in contact with the north pole of a magnet; on presenting a magnetic needle to its farther extremity, the needle will turn its south pole to the bar, showing that that

end has become a north pole. If the bar be detached and the inducing magnet removed, the polarity of the bar is immediately destroyed, and the needle returns to its normal position; and if the south pole of the magnet be now placed in contact with or near to the end of the bar, the needle will turn round and present its north pole to the farther extremity. The polarity of the end of the bar which is in contact with the inducing magnet, cannot easily be tested in a similar manner, on account of the contrary action of the inducing pole; but if a short steel bar be substituted for the soft iron, and left in contact with the magnet for a few seconds, it will, on being separated, exhibit two poles, that which has been in contact with the pole of the inducing magnet being a pole of contrary name.

Moreover, the iron or steel thus rendered magnetic by induction will act in a precisely similar manner on any other piece of iron or steel in its neighbourhood, developing polarity in it, if previously unmagnetised, and altering the distribution and intensity of its polarity if previously magnetised. Consequently, just as the electric polarity of a charged body is intensified by developing electricity in a neighbouring conductor (ii. 385) so likewise may the polarity of a magnetic bar be strengthened by inducing magnetism in a neighbouring piece of iron. Thus, suppose a bar of soft iron, B, to be placed in contact with the north pole of a steel magnet, A, in the manner represented in *fig. 722*, B will then become a magnet with its poles disposed similarly to those of

Fig. 722.

A, and will act upon A, just as if B were the original magnet, and A the unmagnetised iron. The original polarity of A will therefore be strengthened; and, in fact, it is found that a steel magnet is rendered more powerful and capable of supporting a greater weight, by leaving pieces of soft iron in contact with its poles.

It will be easily understood, from the preceding explanations, that the attraction of unmagnetised iron by the magnet is not an isolated phenomenon, but merely a particular case of the general law of the attraction between similar magnetic poles. This is also easily shown by experiment. Suspend a piece of iron, a key for example, from the north pole of a bar magnet; then bring the north pole of a second magnet in contact with the first; the key will be held with greater force than before, because the two magnets polarise it in the same way. Now turn the second magnet round, and bring its south pole in contact with the north pole of the first; the key will immediately drop off, because the second magnet induces in it a polarity contrary to that of the first, and reduces it to the condition of unmagnetised iron.

The case is, however, different if the two magnets act at opposite ends of the unmagnetised iron. Thus, let two magnetic poles P, P', (*fig. 723*) be brought in contact with the two ends of a bar of soft iron B, not more than two or three inches long. If the poles P, P', are similar, the iron will not be held up by them, because they tend to

Fig. 723.

Fig. 724.

polarise it in opposite ways; but if the poles P, P' are dissimilar, their polarising actions will conspire, and the piece of iron will be held up with greater force than it would be by either of them alone. Hence also a magnet bent in the form of a horse-shoe (*fig. 724*) will hold a piece of iron placed across its poles, with greater force than a bar magnet of the same size and intrinsic magnetic force; and by uniting a number of such horse-shoe magnets with their similar poles together, great power may be obtained.

Another fact tending to show that the attraction of iron by a magnet must be preceded by magnetisation of the iron is, that very hard steel, which acquires polarity but slowly is scarcely attracted by the magnet.

It is easy to see that the poles *s*, *n*, of a piece of iron laid across the poles of a horse-shoe magnet will strengthen its polarity; in fact it is the constant practice to keep horse-shoe magnets, when not in use, with a piece of soft iron—thence called a *keeper*—across their poles. In like manner the best way of preserving the power of bar

Fig. 725.

magnets is to lay two of them side by side in a box, with their poles pointing opposite ways and with keepers placed across them (*fig. 725*).

Molecular Constitution of Magnets.

All the magnetic phenomena hitherto considered are consistent with the supposition that the north polarity resides in one half of the magnet, and the south polarity in the other, each kind of polarity gradually increasing in intensity from the median line to the ends. But there are certain effects which show that magnetic, like electric power, resides in molecules, not in masses. Take a steel wire regularly magnetised, and break it in the middle. It will be found that each half is a complete magnet, having a north and a south pole, with a median line between them; and if each half be again divided in the middle, four complete magnets will be obtained, each having a north and a south pole, and so on, to whatever extent the division may be carried. This result is easily intelligible, if we suppose the original magnet to be a collection of molecules, each having a north and a south pole, and all the similar poles pointing the same way. It is easy to see that, in such a row of particles, as in *fig. 726*, the opposite polarities towards the middle of the series will

Fig. 726.

neutralise one another, and only those of the two extremities will be perceptible; but that, if the series be divided at any point, each half will exhibit polarity similar to that of the whole. That such a series of polarised particles really acts like an ordinary magnet, may be shown by partly filling a glass tube with steel filings, and passing the pole of a strong magnet five or six times along the outside of it in one constant direction, taking care not to shake the tube. The individual filings will thus be magnetised, and the whole column, if presented to a magnetic needle, will attract and repel its poles, just like an ordinary bar magnet, exhibiting a north pole at one end, a south pole at the other, and no polarity in the middle; but on shaking the tube, or turning out the filings and putting them in again, so as to destroy the regularity of the arrangement, every trace of polarity will disappear.

It is necessary, however, to observe that, in a single row of particles, such as that in *fig. 726*, each possessing equal magnetic polarity, the resultant polarity would be exhibited only at the very extremities. Now, this is not what is actually observed in magnets; and the difference must be attributed to the lateral actions of the particles in the several rows composing the magnet, one on the other.

Processes of Magnetisation.

From what has been said of the molecular constitution of magnets, it is clear that the process of magnetisation must consist in polarising each separate molecule of which the bar is composed. Now, when a bar of soft iron is placed in contact with a magnetic pole, the nearest particles become polarised by the direct influence of that pole, these polarise the next, and thus the polarisation is rapidly developed all along the bar. But hard iron and steel offer a certain resistance, called the *coercive force*, to the polarisation of their molecules, so that the development of magnetism in them, especially in steel, is slower in proportion to the hardness of the temper. Thus, when a bar of hard steel is placed in contact with the north pole of a magnet, the nearer extremity immediately becomes a south pole, but the farther end shows no polarity at first. A north pole is, however, formed at a short distance from the south, and near this another weak south pole, just as if the bar were divided at that point, and the portion of it first polarised acted like a separate magnet on the portion beyond. These

poles gradually advance along the bar, a feeble south pole appearing after a while at the farther end, succeeded, after a while—if the bar is not too long—by a north pole, the bar then appearing regularly magnetised. If, however, the bar is very long, and made of very hard steel, it never attains this regular magnetisation, but exhibits a series of alternate or *consecutive* poles, which never reach its farther extremity. The coercive force may, however, be more or less overcome, and regular magnetisation facilitated, by striking the bar with a piece of metal, so as to make it ring, and throw its particles into vibration.

It is obvious that the polarisation of the whole series of particles composing the bar will be accelerated by laying it between two bar magnets, with their opposite poles facing one another, or across the poles of a horse-shoe-magnet, the magnetisation then taking place in two directions at once, and both tending to the same result.

Another process more generally adopted, consists in passing the pole of a magnet from one end to the other of the piece of steel to be magnetised, repeating the friction several times and always in the same direction. Each particle of the steel is then brought successively under the influence of the magnet, and it is found that the magnetic power of the bar increases with the number of strokes up to a certain point, after which no further increase takes place. The polarity imparted to each particle as the magnetic pole approaches it, is reversed when the pole passes over it, so that the polarity finally imparted to the bar is that which corresponds to the last position of the inducing magnetic pole. If, for example, the steel bar be rubbed with the north pole of a magnet, the end first touched will be a north, and the other end, by which the magnet leaves the bar, will be a south pole. It is not very easy to understand what is gained by repeating the friction, inasmuch as the polarity imparted by each stroke is reversed at the commencement of the next. Possibly the coercive force of the steel is overcome by the disturbance consequent on the continued reversal of the polarity, much in the same manner as it is by vibration.

Greater power may be obtained by a combination of the two methods above described, namely, by laying the bar to be magnetised between the opposite poles of two magnets, or those of a horse-shoe-magnet, then, taking two other bar magnets, one in each hand, bring down their opposite poles on the middle of the bar to be magnetised, and keeping them at an inclination of 25° or 30° , draw them outwards, with a regular motion, towards the extremities of the bar. Ten or twelve strokes given in this manner, and always in the same direction, will give to the bar, if not very large, as much magnetic power as it is capable of retaining. It is of course necessary that the pole of each movable magnet which touches the bar, should be of the same name as that of the fixed magnetic pole towards which it is made to move. This method, invented by Duhamel, and called the *method of single touch*, is the best for magnetising compass needles, and bars of no great length and thickness, in which regular distribution of magnetism is desired rather than great attractive power; but for magnetising long, thick bars, especially when it is desired to give them their full power, the following method of *Æpinus*, called the *double touch*, is to be preferred. The bar is laid between two powerful magnets as in the preceding method, and likewise rubbed with the opposite poles of two magnets; but instead of drawing these poles from the middle towards the opposite ends of the bar, they are tied together, with a piece of cork or wood between them to keep them at a certain distance apart, and made to travel together along the bar, first one way and then the other, beginning and leaving off in the middle. A horse-shoe-magnet may be conveniently used instead of two bar-magnets tied together. By this method it is likewise easy to magnetise two steel bars together, namely, by placing them parallel to one another, with soft iron keepers across their extremities, as in *fig. 725*, and passing the two magnetic poles several times round the rectangle thus formed, beginning in the middle of one of the bars, and leaving off at the same place. In this, as indeed in all methods of magnetising, the bars, after having been rubbed a certain number of times on one side, should be turned round and rubbed in the same manner on the other.

In both these methods, when two movable magnets are employed, the polarity which any particle acquires while outside the magnetic poles, is reversed when by their motion it is brought between them. Now the advantage of the double touch method consists in this, that the two poles of the movable magnet or magnets are separated by only a small distance, so that the sum of their actions on a particle between them is made as great, and the difference of their actions on an outside particle as small, as possible. This very circumstance, however, by developing powerful magnetism at once in a particular part of the bar, creates a tendency to the formation of consecutive poles when the steel is very hard. Hence, as already observed, the single touch method is usually adopted where regularity of magnetisation is the main object in view.

Magnetisation by the Electric Current.—Very great magnetic power may be developed in soft iron by placing it within a long coil of wire through which an electric current

is passing (ii. 448). Steel bars may be magnetised in the same way, but the magnetism thus developed in them is but feeble, apparently because there is a want of vibratory movement to overcome the coercive force. The magnetisation may indeed be facilitated, as in other cases, by striking the bar so as to make it ring while it is under the influence of the current; but the best mode of magnetising steel bars by the electric current, is to pass the bar through a short movable coil of wire, then fix it between two soft iron electro-magnets, the coils of which are connected with the movable coil, so as to form one continuous circuit, and, having made the connection with the battery, pass the movable coil backwards and forwards along the whole length of the bar, rubbing it at the same time against its surface, so as to excite a vibratory motion in the particles. In this way very powerful and regular magnetisation may be obtained (Daguin, *Traité de Physique*, iii. 608). It is easy to see, however, that this mode of magnetisation requires rather complex apparatus, especially as, to develop powerful magnetism in soft iron requires a very long coil of wire passing several times round the bar, and consequently a powerful battery of several cells to overcome the resistance of the circuit. In most cases, therefore, the simpler methods of magnetisation by the single and double touch are found more convenient.

Magnetisation by Terrestrial Induction.—If a bar of soft iron, destitute of magnetism when placed horizontally, be held in the line of the magnetic dip, or in the vertical position, which in these latitudes does not differ greatly from it, its lower extremity will be found to have acquired north, and the upper, south polarity. On reversing the bar, the polarity will be also reversed, the lower extremity being still a north pole. This effect is due to the inductive action of the earth, the northern hemisphere of which acts, as already observed, like the south pole of an ordinary magnet.

A bar of hard iron or steel held in a similar position, does not immediately exhibit magnetic polarity, but on striking it several times with a key or a hammer, it becomes permanently magnetised with its north pole downwards. In this way, permanent magnets may be obtained without the use of other magnets or of the electric current. The effect on steel may be greatly augmented by resting it on a bar of iron held vertically, and striking both. Scoresby obtained powerful magnets by the following method: A large bar of iron was placed vertically and struck, and having thus acquired a certain amount of magnetic power, it was placed successively on each of two steel bars, 30 inches long, and one inch wide, these bars being also placed vertically and struck at the same time. Six smaller bars of steel 8 inches long and half an inch wide were then magnetised in a similar manner, by resting them vertically on one of the larger steel bars, and striking them, by which treatment they acquired in a few minutes considerable suspending power. Lastly, the six small bars were joined two and two by their opposite poles, by means of soft iron keepers, and rubbed with the others according to the double touch method. By this treatment they were found to be magnetised to saturation.

In consequence of the magnetic action of the earth, all bars of iron, such as railings, lightning conductors, &c., standing for a length of time in a vertical position, become permanently magnetised, their lower ends in the northern hemisphere acquiring north polarity. The magnetism of the native black oxide of iron has doubtless been produced by the same causes, the very different magnetic power exhibited by different specimens being partly attributable to the different positions of the veins of ore with regard to the line of the magnetic dip, that is to say, the line of the resultant of the terrestrial magnetic forces.

Circumstances which influence the Power of Magnets.

Whatever may be the process of magnetisation adopted, there exists, for each bar or needle, a limit of magnetic force which cannot be permanently exceeded; this limit, which is called the point of saturation, depends essentially on the coercive power of the iron or steel of which the bar is made.

Steel bars may, however, be magnetised beyond their point of saturation, and do not return to it immediately, the time occupied in returning to it depending upon various circumstances, such as changes of temperature, the neighbourhood of other magnets, position with regard to the earth, &c. To ascertain whether a bar has been magnetised to saturation, it is sufficient to remagnetise it, in the same direction, with magnets stronger than those which were used in magnetising it originally; if it thereby acquires but little increase of power, and this power disappears after a while, we may conclude that the point of saturation had previously been attained.

Influence of Size and Shape.—With regard to size, Coulomb found: 1. That the magnetic moments of saturated magnets of the same substance and of similar form are nearly proportional to the cubes of their like dimensions. 2. That, in cylindrical needles of the same length, the magnetic power is sensibly proportional to the

diameter. 3. The time of oscillation of a bar having a rectangular section, whose breadth is l , thickness e , and length $2L$, is given by the formula:

$$t = m\sqrt{l} + nL,$$

in which m and n are constants, depending on the nature and hardness of the steel.

With regard to form, Coulomb found that thin lozenge-shaped bars have a greater directive force than rectangular needles of the same weight, thickness, and hardness.

Influence of Hardening and Tempering.—Coulomb, having magnetised a steel bar to saturation, after hardening it to different degrees, and testing its power by the method of oscillations, obtained the following numbers:—

Temperature of hardening	875°	975°	1075°	1187°
Time of 10 oscillations	93"	78"	64"	63"

Steel does not undergo any sensible modification of structure when hardened at temperatures below 870°, and accordingly the magnetic results are the same at all degrees of hardening below this limit; but when hardened at about 1100°, the steel is capable of acquiring double the magnetic force which it retains when hardened at lower temperatures: for the time occupied by the ten oscillations being 63" instead of 93", the magnetic forces are inversely as the squares of these numbers, that is as 3969 to 8649.

A steel bar hardened at a cherry-red heat, and then magnetised after having been tempered at different degrees, gave the following results:

Tempering heat	15°	267°	512°	1122°
Time of 10 oscillations	63"	64.5"	70"	93"

Hence it appears that the magnetic force is less in proportion as the steel is more tempered, the coercive force in fact diminishing with the hardness.

Very different results were obtained with thin and very elongated laminæ or needles. By magnetising them at different degrees of hardness, Coulomb found that when hardened at a white heat, they did not retain a higher degree of magnetic power than after having been completely tempered. In proportion as the hardness was diminished by tempering, the magnetisation became stronger, down to the tempering produced by a dull red heat. On tempering them still more, the directive force which they were capable of receiving continually diminished. Biot explains this anomaly by the formation of two consecutive poles in very elongated and strongly hardened needles, each half of the needle thus possessing two poles of contrary name, whereby the directive force is greatly lessened. But as the hardness is diminished, the poles nearest to the centre approach continually nearer to it, and finally disappear altogether.

Compass needles are usually tempered at the blue, that is to say, at about 300° C. In this state, the coercive force, though not at its maximum, is still very great, and the steel is less fragile than when more hardened, and less liable to acquire consecutive poles.

Nobili (Bibl. Univ. vi. 82) has endeavoured to explain the influence of hardening on magnetisation by the inequality of density of the different parts of the hardened bar. He found that when a bundle of thin steel wires (about 50) was very strongly magnetised, and the wires separated a short time afterwards, each of them appeared strongly magnetised in the same direction; but when the bundle was made up again, and untied a few hours afterwards, several of the wires were found to be unmagnetised, and some had had their polarity reversed. Similar results had previously been obtained by Coulomb. It appears then that, in a system of parallel rows of magnetised particles, those which are most strongly polarised destroy or reverse the polarity of the weaker series, and determine the polarity of the whole, and if the original polarity of all the rows were equal, the magnetic power of the entire system would probably soon be extinct. Now a magnetised bar may be regarded as made up of concentric layers of polarised particles, and if the external shell is rendered denser than the interior by hardening, so that a larger number of magnetic elements are there included within a given space, this external shell will receive a higher degree of polarity than the external portions, and accordingly will neutralise their action and determine the polarity of the whole system. For the same reason soft iron which has been hammered or wire-drawn, acquires the power of retaining a certain portion of magnetism. According to this view, the coercive or retaining power does not depend upon any peculiarity in the physical or chemical constitution of steel, but is entirely due to the different densities of the superficial portions of its mass. This is in accordance with the fact that small bars are capable of retaining a proportionally greater power than large ones, their surface being greater in proportion to their volume. It is also supported by the following experiment made by Nobili. Two cylinders were constructed of the same kind of steel, and of equal length and diameter, but one solid, weighing 28 grms. the other hollow, weighing 16 grms. They were then hardened to the same degree, and both were magnetised to saturation. When placed at equal distances from a compass-needle, the solid cylinder deflected it 9½°, the hollow cylinder 19°. The great difference of power

thus shown in favour of the hollow cylinder, the mass of which was not much more than half that of the other, appears to be due to the circumstance that it was hardened both within and without, and was therefore covered on both surfaces with the dense crust which, according to the preceding view, preserves the magnetic power, whereas the solid cylinder was thus hardened only at its outer surface. On the other hand, however, it must be admitted that this mode of explaining the retaining power of steel does not account for the known fact, that iron containing a small quantity of sulphur is capable of retaining magnetism, although perfectly homogeneous, and that very hard steel is scarcely if at all attracted by the magnet.

Influence of Heat.—The power of magnets is diminished by rise of temperature, temporarily or permanently according to the degree of heat applied. The effect of heat is to diminish the coercive force; and at a red heat, as first observed by Gilbert, a steel magnet loses the whole of its power. When, on the other hand, a magnet is only slightly heated, its power suffers only a temporary diminution, the original intensity being regained on cooling. This circumstance must be attended to in estimating the relative intensities of the earth's magnetism at different localities, by observation of the oscillations of a magnetic needle, as, if the temperature is higher at one place than at the other, allowance must be made for the diminution of magnetic intensity in the needle thereby produced.

On the other hand, magnetism is more easily imparted to steel at high temperatures; so that a bar may be very powerfully magnetised by placing it while red hot between the opposite poles of two strong magnets and cooling it quickly in that position. A steel bar heated to redness and then hardened by sudden cooling in the vertical position retains the magnetism imparted to it by the inductive action of the earth.

Coulomb has measured the decrease of the magnetic force of a bar as its temperature is raised. He first tempered the bar so that its coercive force should not vary during the heating, then having magnetised it and heated it to various temperatures, he obtained the following results:

Temperatures	15°	50°	100°	264°	425°	637°	850°
Time of 10 oscillations	63"	97·5"	104"	147"	215"	290"	very great,

According to Kupffer, the effect of heat upon a magnet is not instantaneous, but requires a considerable time to produce the utmost diminution of power of which it is capable. For example, on plunging a magnet several times into boiling water, and leaving it each time for ten minutes, a diminution of the magnetic force took place at each immersion up to the sixth, after which the power remained constant. Kupffer has also shown that when one half of a magnet is heated, that half becomes weakened, and the median line approaches nearer to the opposite end. According to Christie, the greater part of the diminution of the force of a magnet by heat takes place instantaneously, a result which is in accordance with the accumulation of magnetic power near the surface (p. 767).

Influence of Mechanical Actions on the Magnetic Power of Iron.

We have already had occasion to notice the influence of friction, percussion, and other causes which agitate the particles of bodies, in diminishing the coercive power of iron and steel, thereby weakening the power of permanent magnets, and facilitating the development of magnetism by induction. Various other mechanical actions which produce a temporary alteration in the molecular condition of a mass of iron, likewise produce a temporary alteration in the magnetic power which may be induced in it by any cause, the iron regaining its original magnetic power as soon as the disturbing force ceases to act.

Torsion.—The easiest way of examining the effect produced by torsion on the magnetic state of iron is that devised by E. Becquerel, which consists in making use of the currents excited in a helix enveloping the magnet, by every increase or diminution of its magnetic power (ii. 451). For this purpose, a wire of well annealed iron, stretched by a weight, is passed through a vertical glass tube, round which is coiled a helix in connection with a delicate galvanometer. The wire in this position becomes magnetised by the inducing action of the earth, and it is found that, on twisting it either way, the galvanometer needle is deflected, in a direction which shows that the magnetic power of the wire is diminished by the torsion; and when the wire is untwisted, the needle moves in the contrary direction, indicating that the magnetic polarity of the wire is returning towards its primitive state. On allowing the wire to oscillate freely by torsion, and interposing in the electric circuit a commutator which changes the direction of the current through the galvanometer every time it is reversed in the helix, that is to say, at the moments when the wire passes through the position of equilibrium and of maximum torsion, a continuous current may be obtained.

Wertheim has made numerous experiments on the relations between magnetism and torsion, by a method similar to that of Becquerel, using however a horizontal bar of iron enveloped by two helices, one formed of thick wire to receive the current which magnetises the bar, the other of a long thin wire to receive the induced currents and convey them to a galvanometer. The helices are placed near the ends of the bar, and occupy but a small portion of its length. Having first shown that the softest iron always possesses a certain amount of coercive power, and therefore always retains a certain amount of the magnetic polarity once induced in it, Wertheim obtained the following results:—1. Torsion and detorsion do not by themselves develop any magnetism in iron: for on placing the bar at right angles to the magnetic meridian, and twisting it, no induced current is developed.—2. If the bar is placed in the magnetic meridian, or subjected to the action of a magnet placed on the continuation of its axis or to the action of the electric current, the magnetising action of either of these causes is accelerated both by torsion and by detorsion; but when once the magnetic equilibrium is established, torsion weakens the total magnetisation, and detorsion restores it to its former amount: hence the maximum of magnetisation takes place in the state of *mechanical equilibrium*.—3. If the bar is withdrawn from the action of the magnetising agent, repeated torsion and detorsion quickly destroys the excess of temporary magnetisation, but continues to act indefinitely on the permanent magnetisation, which is diminished by torsion and restored by detorsion.—4. When the bar is in any given condition of magnetic equilibrium, all the effects of torsion are proportional to the angles of torsion; but the magnitude of these effects appears to depend much more upon the permanent magnetisation, than on the temporary magnetisation produced by the external cause.—5. The form of the section of the bar does not appear to exert any influence, but the deflections increase with its area and with the intensity of the magnetisation.—6. The order of the effects produced is the same for all kinds of iron, the only difference being in the absolute intensities of those effects. The hardest iron requires the greatest number of torsions and detorsions, to bring it to its condition of magnetic equilibrium, indicated by the equality of the opposite induced currents.—7. Steel also, the more it is hardened, requires a greater number of torsions and detorsions to bring it to a state of magnetic equilibrium; but when once this equilibrium is established, it cannot, according to Wertheim, be modified by torsion and detorsion alone, as is the case with iron. Matteucci, on the other hand, always obtained feeble currents in this case, these currents being weaker as the steel was more hardened. Hard iron exhibits an anomaly which has not been explained, the modification produced in it by torsion being greater immediately after the interruption of the magnetising current than during its passage. In this case, the diminution does not take place till after some time.

When the bar is in a state of temporary or permanent torsion before magnetisation, similar results are obtained: that is to say, the magnetic maximum corresponds, not with the initial state of torsion, but with that which exists in the state of mechanical equilibrium; so that the magnetism increases when the bar is twisted in the direction which diminishes the primitive torsion, and diminishes when the original torsion is re-established. But if the initial permanent torsion is produced while the bar is under the action of the magnetising current, a *rotation of the maximum* is observed; that is to say, the maximum is displaced, and in the direction of the torsion, the angle of rotation being greater as the iron is harder, and the permanent torsion greater. This angle is always less than half the temporary torsion which necessarily takes place during the production of a permanent torsion.

For further details on this subject, and on the reciprocal influence of magnetism on torsion, see Wiedemann (*Galvanismus und Electro-magnetismus*, ii. 430-449).

Traction and Flexion.—According to Matteucci, a sudden elongation produced by tension in a wire of iron or steel, while subjected to the magnetising action of an electric current, produces an *increase* in the magnetic force, and a sudden shortening diminishes it. These results have been confirmed by Wertheim, who has also shown that *flexion* and *deflection* act in the same manner as torsion and detorsion. All these effects are due to the displacements of the molecules produced by these various forces, whereby they are enabled to arrange themselves, either in the position most favourable for magnetisation, or the contrary.

Wertheim finds, in the increase of the magnetic capacity of iron by traction, an explanation of the well-known fact, that a magnet while loaded becomes continually stronger, but returns to its primitive state as soon as the weight is removed. He also attributes the great irregularities of the compass in large iron ships to the inevitable flexions of the iron which take place during the voyage, these flexions producing changes in the magnetisation of the iron, of which the *compensators* (p. 780) are unable to take account. These phenomena are the converse of those observed by Loulé (Phil. Mag. xxx. 76 and 225), who found that an iron bar increases in length when

magnetised under ordinary circumstances, but contracts if already powerfully stretched by mechanical strain previous to magnetisation.

Magnetism compared with Electricity.

The phenomena of magnetic induction, above described, are analogous in almost every particular to those of static electric induction; but there is one essential difference between the two: *there is no such thing as magnetic discharge*. In the case of electrified bodies, we know that, when the opposite polarities of the neighbouring surfaces attain a certain degree of intensity, discharge takes place between them in the form of a spark; and the distribution of the electric forces, after this discharge, is no longer the same as before, the one body appearing to have lost a certain amount of power, and the other to have gained it (ii. 385). But in magnetic induction, nothing of the kind is observed. Whatever may be the power of a magnet, and however intensely a piece of soft iron may be polarised by contact with it, the iron can take nothing from the magnet; but as soon as the contact is broken, the soft iron loses its polarity, and the steel magnet is found to have lost nothing, but rather to have had its polarity intensified. Neither does hard iron or steel, though it remains magnetised after separation, take any power from the original magnet, its retention of polarity being in fact analogous, not to the condition of a body which has been electrified by discharge, but to a non-conducting body like sealing-wax, which has been electrified merely by induction, and then removed from the neighbourhood of the inducing body.

The phenomena of magnetism are not then precisely analogous to those of static electricity, notwithstanding the exact parallelism which exists between the two up to a certain point. But, as already explained under *ELECTRICITY* (ii. 447), the laws of magnetic attraction and repulsion are exactly similar to those of the mutual action of electric currents. Two helices of copper wire, through which electric currents are passing, attract and repel one another exactly like magnets, and, accordingly, all the phenomena of magnetic attraction and repulsion may be accounted for, if we assume that a magnet consists of an aggregate of particles having electric currents constantly circulating round them in one direction. This theory has been sufficiently developed in the article referred to, and we need not dwell upon it further.

But, as a bar of iron or steel is rendered magnetic by the action of an electric current passing near it at right angles to its length, we must suppose, if this theory be true, that an electric current has the power of inducing in magnetic bodies a system of electric currents in the same direction as itself; moreover, that these currents, once established, will continue, in soft iron, as long as the original current continues to act, and, in the case of steel, even after it has ceased. Now, this is not what is observed to take place in the action of electric currents on conducting bodies in general. We know that when a conducting wire forming a closed circuit is placed near another wire conveying an electric current, the latter, at the instant when it begins to flow, induces, in the first wire, a current opposite in direction to itself, this current, however, being merely instantaneous, and no induced current being perceptible so long as the inducing current continues to flow with uniform strength; and, finally, that when the original current ceases (or the battery circuit is broken), another momentary current passes through the second wire in the same direction as the inducing current. These effects of electrodynamic induction are evidently totally different from those which must be supposed to take place in magnets, according to Ampère's theory; and we must, therefore, suppose that magnetic bodies have a peculiar molecular constitution, which enables an electric current passing near them to excite continuous currents round their particles in the same direction as its own; or rather, perhaps, that these currents pre-exist in all magnetic bodies, even before the development of magnetic polarity, but are disposed without regularity, so that they neutralise one another; and that magnetisation, either by an electric current, or by another magnet, is the process by which these molecular currents are made to move in one direction (ii. 448).

The hypothesis that the molecules of magnetic bodies, such as iron and steel, are encircled by continuous closed currents of electricity, which, before the development of magnetic polarity, circulate indiscriminately in all planes, but, in a magnetised bar, circulate in such a manner that, on the whole, the prevailing direction of rotation is in the same direction as that of the hands of a watch conceived as situated at the centre of the bar, with its face towards the south pole and its back towards the north pole, and in a plane perpendicular to the line joining the two poles: this hypothesis accounts for all the most important facts connected with magnetisation, and receives from some of them a striking confirmation. According to this view, magnetisation consists in giving to the particles of a piece of iron such an arrangement that the prevailing direction of its molecular currents shall be that indicated above. Coercive force is, on the same view, a resistance to the motion of the particles, which requires to be overcome equally to produce magnetisation or demagnetisation; and the saturated state of a

magnet is when the greatest possible number of molecular currents circulate in the same direction, with their axes parallel to that of the magnet.

That magnetisation is really attended by molecular motion is proved by the emission of musical sounds by a piece of soft iron which is suddenly magnetised or demagnetised, when it is so supported that the greater part of its mass is free to vibrate. The magnetic effects developed by torsion likewise show the intimate connection between molecular motion and magnetisation. This view also enables us to see why the coercive force of steel is increased by hardening; for the hardness of steel is nothing more than the result of the great resistance which its molecules oppose to mutual motion. The difference between the molecules of soft iron and those of steel with respect to magnetisation, may be regarded as analogous to that presented by a very finely hung magnetic needle and one that is coarsely hung, when a magnet is brought near them. The finely hung needle is immediately and completely turned from its normal position on the approach of the magnet, and at once returns to it when the magnet is removed: the coarsely suspended needle, however, is at first much less affected by the magnet, and does not turn to the full extent until the friction of its point of support is overcome by a gentle tap or shake, and, similarly, when the disturbing magnet is taken away, it does not return completely to its first position without the same aid. This comparison may serve to explain the influence of a blow or vibration in facilitating the magnetisation of an unmagnetised steel bar, and in weakening the force of a saturated steel magnet.

Universality of Magnetic Action—Diamagnetism.

Magnetism was for a long time regarded as peculiar to a small number of bodies, namely, iron, nickel, cobalt, and certain of their compounds; but later researches have shown that all bodies are more or less susceptible of magnetic influence, though they are not all affected in the same way. The question of the universality of magnetism was raised as early as the beginning of the eighteenth century. Muschenbroek and Nollet found that a large number of bodies in the state of powder, the ashes of plants, and small fragments of organic substances, were attracted by the magnet; but they attributed the result to the presence of small quantities of iron in the substances examined. The subject was also investigated by Lehmann and Cavallo; and Brugmanns, in 1778, observed that bismuth is repelled by the poles of powerful magnets,—a remarkable discovery, which did not receive at the time the attention it deserved. Coulomb, in 1802, found that fine needles of gold, silver, and other metals, also of glass, and of various vegetable and animal substances, suspended by a thread of unspun silk between the opposite poles of two powerful magnets, oscillated till they came to rest in a line between the poles; but he also showed that a very minute quantity of iron, not exceeding $\frac{1}{135,140}$, intimately mixed with a needle of wax, was sufficient to produce this effect: hence he considered it uncertain whether the effects observed were due to the action of the magnets on the various substances themselves, or on minute quantities of iron contained in them. After the discovery of electro-magnetism, Becquerel observed that rods of shellac, wood, and other substances, suspended by threads of unspun silk within the coil of a galvanometer, placed themselves with their axes parallel to the plane of the coil, instead of at right angles to it, as an iron needle would: this effect was exhibited in a remarkable manner by a paper tube filled with ferric oxide. Lebaillif, in 1828, found that a delicately suspended magnetic needle was repelled by bismuth and antimony, thus confirming the important observation previously made by Brugmanns. The same kind of repulsive action was subsequently observed by Saigey in several other substances.

But these facts, however important they may now appear, excited but little attention at the time of their discovery, inasmuch as they could not be referred to any general law; and the question of the universality of magnetism remained undecided, until Faraday, in 1846, discovered that most transparent substances, when subjected to the influence of powerful magnets, acquire the power of circular polarisation (p. 676); and regarding this effect as resulting from the action of the magnet on the molecules of the transparent body, he was led to undertake a series of researches which resulted in the grand discovery, that all bodies whatever are subject to magnetic influence, but are not all affected by it in the same way, being divided, with respect to their magnetic susceptibilities, into two great classes—the *Magnetic* and the *Diamagnetic*. The former class includes those bodies which exhibit the well-known phenomena of ordinary magnetic attraction and repulsion—being attracted, when in their natural state, by either pole of a magnet, and, when shaped into bars or rods, and suspended joining two opposite magnetic poles, pointing axially—that is to say, in a straight line between them. The bodies belonging to this class are mostly metallic (including oxides and salts), viz. iron, nickel, cobalt, manganese, chromium, cerium, titanium, palladium, platinum, osmium. The magnetic properties of iron, nickel, and cobalt have long been known.

In the other metals of the series, magnetic susceptibility can only be detected by the use of magnets of great power. Manganese, chromium, cerium, titanium, and osmium are placed by Faraday in the magnetic class, because certain of their compounds exhibit the ordinary magnetic relations.

The second or *Diamagnetic* class includes all liquids and solids, both organic and inorganic, which do not belong to the *magnetic* class. The law which governs the action of magnets on these bodies is as follows:—*A particle of a diamagnetic body placed in the neighbourhood of either pole of a magnet is repelled by that pole.* Hence, a bar of any diamagnetic substance suspended by its centre midway between two magnetic poles will point *equatorially*, that is to say, at right angles to the straight line joining the two poles—that being the position in which every part of it is at the greatest possible distance from each of the poles; and if its centre be placed on either side of the axial line, the whole bar will recede from that line, placing itself at the same time equatorially. A globe or cube does not *point*, but exhibits the simple phenomenon of repulsion. If two small balls of any diamagnetic substance be suspended between the two magnetic poles, they will be driven towards one another, as if they were actuated by mutual attraction. The position which a bar of any substance takes up when suspended horizontally between two magnetic poles furnishes the best means of determining whether it belongs to the magnetic or the diamagnetic class: if it be magnetic, it will place itself axially; if diamagnetic, equatorially.

The diamagnetic force cannot be perceptibly developed without the use of exceedingly powerful magnets: electro-magnets answer the purpose best, but large permanent magnets may also be used. The great power required to develop this mode of action accounts for its having been previously overlooked by most observers.

Bismuth appears to be the most powerfully diamagnetic of all substances; then follows phosphorus, then antimony, then heavy glass (silico-borate of lead). Among the metals, the order of diamagnetic energy appears to be as follows: bismuth, antimony, zinc, tin, cadmium, sodium, mercury, lead, silver, copper, gold, arsenic, uranium, rhodium, iridium, tungsten. (Faraday, *Experimental Researches in Electricity*, series 20 and 21: Phil. Trans. 1846, 21.)

Thallium is strongly diamagnetic, being nearly equal in that respect to bismuth. (Crookes.)

Air and other gases exhibit decided magnetic and diamagnetic relations. In his first experiments on this subject, Faraday was led to the conclusion that gaseous bodies were indifferent to magnetic action, forming the zero, or middle point, between the two classes of magnetic and diamagnetic bodies. Bancalari has, however, since discovered that flame possesses diamagnetic properties; and Zantedeschi has shown that air and other gases likewise exhibit diamagnetic relations. The researches of these Italian philosophers have been confirmed and extended by Faraday: the following are the principal results.

An arrangement was made by which a stream of any gas could be delivered in a vertical direction, either upwards or downwards, near the middle point of the axial line, between two powerful magnetic poles of opposite names, but at a short distance on one side of that line. By this arrangement it was found that the following gases were driven away from the magnetic axis and passed off in the equatorial direction; that is to say, they exhibited diamagnetic relations with regard to atmospheric air: nitrogen, hydrogen, carbonic anhydride, carbonic oxide, coal-gas, olefiant gas, sulphurous anhydride, hydrochloric acid, hydriodic acid, fluoride of silicon, ammonia, chlorine, nitrous oxide, and the vapours of bromine and iodine. Nitric oxide and pernitric oxide were also slightly diamagnetic in air. Oxygen was strongly magnetic—that is to say, it was drawn towards the axis, and then along it in opposite directions towards the two poles, round which it accumulated.

The first-mentioned gases evidently differed from each other in diamagnetic energy; but it was found impossible by the means above described to form anything like a precise estimate of their relative powers. To determine this point, the magnetic poles were surrounded with an atmosphere of one gas, while the other gas was directed in a vertical stream, either upwards or downwards, near the axial line as before. By this method it was found that (1) *In carbonic anhydride*, air and oxygen passed axially; nitrogen, hydrogen, coal-gas, olefiant gas, hydrochloric acid, and ammonia, equatorially; so likewise did carbonic oxide and nitrous oxide, but the action was feeble. (2) *In coal-gas*, air appeared magnetic, though but slightly; oxygen was strongly magnetic; nitrogen was strongly diamagnetic; olefiant gas, carbonic oxide, and carbonic anhydride, feebly so. (3) *In hydrogen gas*, air, when free from smoke, passed axially; but when mixed with smoke, it was either indifferent or passed equatorially. Hydrogen gas and atmospheric air seem to be not far removed from one another in the scale. Oxygen was strongly magnetic; nitric oxide also magnetic, but in a less degree. Nitrogen was strongly diamagnetic; nitrous oxide, carbonic oxide, carbonic anhydride,

and olefant gas were also diamagnetic; hydrochloric acid and chlorine slightly. Oxygen appears to be the most magnetic of all gases.

When a spiral of platinum wire was placed just below the middle point of the line and ignited by a voltaic current, the stream of hot air which rose up again the axial line was deflected at right angles to the axis, and passed off in the equatorial direction. The same effect was obtained in oxygen, carbonic anhydride, and coal gas. Hence it appears that a heated gas is diamagnetic to the same when cold. A stream of cold air directed downwards near the axial line, was drawn towards that line.

The flame of a wax taper or of burning ether also takes an equatorial direction when placed in or near the middle of the axial line. When placed a little on one side of the axis, it is directed away from that line, just as if a gentle wind were blowing upon it in that direction. When made to rise exactly in the axial line, it divides itself into two long tongues, directed at right angles to the axis. This effect is particularly striking with the large flame produced by setting fire to a ball of cotton soaked in ether. These effects are evidently analogous to those just described with hot air; but they are doubtless partly due to the solid carbonaceous particles in the flame, which are diamagnetic. In corroboration of this supposition, it is found that the brightest flames are the most strongly diamagnetic. (Faraday, Phil. Mag. [3] xxxi. 401: see also Zantedeschi, xxxi. 421.)

Specific Magnetism. This term was introduced by E. Becquerel, to denote the action exerted by a magnet on the unit of volume of a body placed at the unit of distance, as compared with that which is exerted on a certain substance taken as the standard of comparison. Another mode of estimation is to compare the effects produced on a small magnetic needle, by a cube, equal to the unit of volume, placed at the unit of distance from the needle. The measurements are made either by the torsion balance, or by determining the weight required to keep the body in a certain position of equilibrium while under the influence of the magnet.

By these methods, Plücker, representing the specific magnetism of soft iron by 100,000, has found for native magnetic oxide the number 40,227, for specular iron ore 533, for brown hæmatite 71, which is the lowest number found for any of the compounds of iron, solid or liquid.

The following are the results obtained by Plücker for certain *diamagnetic* substances at ordinary temperatures, and for equal weights referred to water as unit.

Specific Diamagnetic Powers. (Plücker.)

Water	100	Flowers of sulphur	71 $\frac{1}{2}$
Phosphorus	100	Common salt	70 $\frac{1}{4}$
Sulphide of carbon	102	Nitric acid	48 $\frac{1}{2}$
Hydrochloric acid	102	Nitrate of bismuth	35 $\frac{1}{2}$
Ether	127 $\frac{1}{2}$	Sulphuric acid	34 $\frac{1}{4}$
Oil of turpentine	123 $\frac{1}{4}$	Mercury	23 $\frac{1}{4}$

This table shows that the diamagnetic powers of different groups of substances may be approximately expressed by simple numbers; but it is doubtful whether this result is accidental, or expresses an actual law.

The following table contains some of the results obtained by E. Becquerel, the magnetic power of water being taken as unity, and the results referred to equal volumes. Diamagnetic substances are denoted by the *minus* sign.

Specific Magnetic Powers. (E. Becquerel.)

Solids.	Specific magnetism in air.	Liquids.	Specific gravity.	Specific magnetism in air.
Water	-1.00	Water	1.0000	-1.00
Zinc	-0.25	Alcohol	0.8069	-0.97
White wax	-0.57	Ammonia	0.8059	-1.02
Melted sulphur	-1.14	Common salt	1.2084	-1.13
Copper (electrotype)	-1.41	Chloride of magnesium	1.3197	-1.21
Copper, pure	-1.68	Sulphide of carbon	1.3197	-1.33?
Lead, commercial	-1.53	Sulphate of copper	1.1265	+0.81
Phosphorus	-1.64	" of nickel	1.0827	+2.16
Selenium	-1.65	Ferrous sulphate	1.1728	+18.02
Silver, pure	-2.32	"	1.1923	+21.12
Gold (nugget)	-2.41	" chloride	1.0695	+9.19
Gold, pure	-3.47	"	1.2767	+36.07
Bismuth	-21.76	" (concentrated)	1.4334	+65.01
"	-22.67			

To compare the magnetic powers of iron with water, and thence with other bodies,—which is somewhat difficult, on account of the very great disproportion existing between the two,—Bequerel made use of the concentrated solution of ferrous chloride, as an intermediate term of comparison. This solution, which has a specific magnetic power of +658.13, that of water being -10, was introduced into a tube of thin glass, 4 centimetres long, suspended between the contrary poles of two bar magnets, and its oscillations were compared with that of a bar of wax of the same length mixed with a known weight of soft iron filings. The numbers of oscillations made by such bars in a given time are independent of their bulk, and proportional to the quantity of filings contained in them. In this manner it was found that ferrous chloride experiences, for equal volumes, the same amount of action as an inert substance containing 0.2 milligr. of iron per cubic centimetre. Now, the magnetic power of water, compared with ferrous chloride, being $\frac{-10}{+658.13} = -0.0152$, will also be equal to that of an

inert substance containing $0.0152 \times 0.2 = 0.003$ milligr. of iron per cubic centimetre, but of contrary sign. Hence, as a cubic centimetre of iron weighs 7.68 grms., the magnetic powers of iron, ferrous chloride, and water are, for equal volumes, as the numbers +1,000,000 : +25.7 : -0.4; and for equal weights, as +1,000,000 : +140 : -3.

Faraday has also compared the magnetic powers of a considerable number of substances by the method of torsion. The next table contains some of his results for equal volumes *in vacuo*, and referred to water as unity. They were all obtained at the temperature of 15.5° C. (60° F.), and for gases under the pressure of 0.76 metre.

Specific Magnetic Powers. (Faraday.)

Substances.	Magnetic powers.	Substances.	Magnetic powers.	Substances.	Magnetic powers.
Proto-ammoniu- ret of copper	+1.309	Cyanogen . .	-0.009	Ammonia (liquid)	-1.010
Per-ammoniu- ret of copper	+1.240	Glass . . .	-0.188	Sulphide of car- bon	-1.031
Oxygen . . .	+0.181	Zinc, pure . .	-0.772	Nitrate of potas- sium (sat.)	-1.036
Air	+0.035	Ether	-8.797	Sulphuric acid .	-1.081
Olefiant gas .	+0.006	Alcohol (abs.)	-0.815	Sulphur	-1.221

Hydrogen . . .	-0.001	Camphine . .	-0.859	Bismuth . . .	-20.369
Ammonia gas .	-0.005	Linseed oil . .	-0.886		
		Olive oil . . .	-0.886		
		Wax	-0.887		
		Nitric acid . .	-0.911		

A comparison of the specific magnetic powers of different elementary bodies shows that, in many instances, the most magnetic are those which have the smallest atomic volume (i. 442), or those whose atoms are the closest together; and that diamagnetic bodies, on the other hand, are those whose atoms have the largest spaces between them. Thus bismuth, the most diamagnetic of all bodies, has also a high atomic volume (21.2); whereas iron, nickel, and cobalt have very low atomic volumes, viz. about 3.6. But on the other hand, copper and zinc, which have also small atomic volumes, viz. 3.6 and 4.6 respectively, are slightly diamagnetic; and sodium and potassium, whose atomic volumes are larger than those of any other metals (sodium 23.7, potassium 45.6), are, according to Lamy, slightly magnetic. The relative distances between the atoms is, therefore, not the only, and perhaps not the principal, cause which determines the difference between magnetic and diamagnetic bodies.

No definite relation has yet been discovered between the magnetic or diamagnetic powers of compounds and those of their elements. It is known, however, that the compounds of iron are for the most part magnetic; but exceptions occur even among these, the ferrocyanide and ferricyanide of potassium, for example, being diamagnetic. The magnetic relations of atoms are, therefore, dependent to a certain extent on their state of combination.

The magnetic and diamagnetic powers of mixtures are, according to Matteucci, sensibly equal to the sum [? the mean] of those of their components.

Specific Magnetism of Oxygen and Air.—Matteucci has compared the magnetic power of oxygen with that of iron by the following method, which serves also to show, in a striking manner, that oxygen is magnetic:—A large bubble of oxygen is introduced into a tube filled with alcohol, and the tube is placed transversely between the hemispherical polar extremities of a very strong electro-magnet. If the bubble is placed tangentially to the polar line, it elongates towards this line; and if its centre is over the

polar line, it shortens. If the alcohol is saturated with protochloride of iron, the bubble in the latter position splits into two, which move away from one another. By ascertaining by trial the proportion of ferrous chloride, for which the bubble experiences no perceptible change of form, a solution will be obtained, having the same magnetic power as oxygen gas. By this method Matteucci found that oxygen has the same magnetic power as an alcoholic solution of ferrous chloride containing three milligrammes of iron in a cubic centimetre.

E. Becquerel has made numerous experiments for the purpose of measuring the magnetic power of oxygen as compared with water, and thence with iron. A small tube of glass filled with wax was suspended from a torsion apparatus, and the effects produced upon it by an electro-magnet in a vacuum, in oxygen and water, were compared. These actions, at the temperature of 12° , were, in oxygen under a pressure of 0.76 met., $V_o = -0.2676$; in a vacuum, $V_v = -0.1145$; and in water, $V_w = +0.7033$. Hence $V_o - V_v = +0.1530$; $V_w - V_v = -0.8178$; and the magnetism of oxygen, compared with water *in vacuo*, is $0.1530 : 0.8178 = 0.1871$. Hence, for equal volumes, the magnetic power of oxygen is nearly $\frac{1}{5}$ of that of water, but of contrary sign. For air the same method gives the number 0.03771: hence, as the magnetic power of oxygen multiplied by 0.21 is 0.392, it follows that the magnetic power of the air is due to the oxygen contained in it. These results are nearly the same as those obtained by Faraday (p. 773) and Matteucci; and Becquerel has further confirmed them by Plücker's method. Lastly, he has shown that the magnetic power of oxygen is proportional to its pressure—a result probably true also for other gases.

Taking the magnetic power of iron as the standard, and calling it 1,000,000, we find that, for equal weights, the magnetic power of oxygen is 377, and that of air 88. Oxygen, weight for weight, has three times the magnetic power of ferrous chloride, which is the most magnetic of all liquids. Hence a cubic metre of oxygen gas would act on a magnetic needle with the force of 54 centigrammes of iron, and a cubic metre of air with the force of 11 centigrammes of iron. The whole atmosphere is consequently equal in magnetic power to a shell of iron covering the whole earth to the thickness of 0.1 millimetre. It is easy to conceive that such a magnetic envelope, in a state of constant agitation, is capable of disturbing the magnetic needle; and as its magnetic power varies with its temperature (see below), the heating which it undergoes at different hours of the day may contribute to produce the diurnal variations (p. 782).

Influence of Temperature on Magnetism and Diamagnetism.—The effect of heat on the magnetic power of iron and steel has already been mentioned (p. 767). It was formerly supposed that iron at a white heat becomes totally unsusceptible of magnetic influence. Faraday has, however, shown that, though the susceptibility of magnetic bodies properly so called is rapidly diminished by heat, it is never completely destroyed, but is still perceptible at the highest temperatures, provided that electro-magnets of great power are employed to develop it. These results have been confirmed by Plücker, who has shown that the specific diamagnetism and magnetism of solids and liquids diminish, for the most part, as their temperature is raised, but that there are some exceptions to the rule. Mercury, for example, exhibits no change of diamagnetic power at 300° ; neither do sulphur and stearin, even when heated above their melting points. Brunner has shown that water in the state of ice and of vapour has the same specific magnetism as in the liquid state.

According to Matteucci (Bibl. Univ. de Genève [Arch. des Sc. xxiii.], 24), the magnetism of iron increases up to a certain temperature, then decreases rapidly. The diamagnetic power of bismuth diminishes between 0° and 212° C.—nearly in proportion to the increase of temperature, and vanishes altogether at the melting point. Non-metallic bodies, on the contrary, such as sulphur and phosphorus, scarcely suffer any diminution of diamagnetic power in consequence of change of state.

A globule of iron melted in a lime-spoon by the oxy-hydrogen blowpipe was still attracted by the magnet; but to exhibit the attraction, a very large electro-magnet was required, charged with 30 Grove's cells. Matteucci estimates the magnetic power of melted iron at only 0.000016 of its power at common temperatures: hence it is not surprising that iron at a white heat should have been found insensible to the attractive power of ordinary magnets. Copper, standard gold, zinc, porcelain, and certain kinds of charcoal, which according to Matteucci are magnetic at common temperatures, become diamagnetic when heated. Platinum remains magnetic in the state of fusion, its power appearing scarcely to have suffered any diminution.

Heat appears also to diminish the magnetic power of gases: thus Faraday found that heated air is repelled by the magnet when surrounded by cold air (p. 771). E. Becquerel, however, concludes from his experiments on oxygen, that heat does not act directly in diminishing the magnetic power of gases, the diminution observed being solely due to change of density.

Influence of Compression and Crystalline Structure on Magnetism and Diamagnetism.

—Faraday observed that the position assumed by a bar of bismuth under the influence of magnetic forces, is affected in a remarkable manner by its crystalline structure; and that when a cubic crystal of the metal is suspended between the poles of an electro-magnet, a certain line, perpendicular to the principal cleavage-plane of the crystal (called by Faraday the *magne-crystalline axis*), tends to place itself axially between the poles, and in other parts of the field, tangentially to the magnetic curve passing through the point where the crystal is situated. Plücker also remarked that a plate of tourmaline cut parallel to its axis, and suspended between the poles of an electro-magnet with that axis horizontal, places itself with the axis in the equatorial position, although the crystal is magnetic, in consequence of the iron which it contains, and if suspended with the axis vertical, is attracted by either pole of the magnet. Hence he concluded that the axis is repelled by the magnetic poles, and that the repulsion thus exerted is more powerful than the attraction due to the magnetic properties of the mass. Calc-spar, on the contrary, which is diamagnetic, places itself with its principal crystallographic axis in the line between the magnetic poles: similar results are obtained with heavy spar and diopase, which are magnetic.

These phenomena have been reduced to a general law by the researches of Tyndall and Knoblauch (Ann. Ch. Phys. [3] xxxv. 375; xxxvii. 76), who have shown that when the particles of a body are more closely packed in one direction than in others, this direction—other circumstances being the same—is the one on which the forces acting upon the body are exerted with the greatest energy, and consequently this line of direction places itself axially or equatorially between the poles of a magnet according as the body is magnetic or diamagnetic. Thus a cylinder of carbonate of iron made into a paste with gum, places itself axially, if of uniform density in all directions; but if the paste be strongly pressed between boards into a thin cake, a bar or needle formed out of it will place itself equatorially between the poles, even if its length be ten times as great as its breadth. Conversely, a bar formed of a paste of bismuth filings and gum, which places itself equatorially if of uniform density, will assume the axial position if the paste be compressed transversely to the length of the bar.

The effects observed in crystals of bismuth and other substances are of the same nature. That the molecular structure of crystals is not the same in all directions, is evident from their optical relations, their rates of expansion, and their heat-conducting powers; and the direction in which they place themselves under the influence of a magnet is determined by their relative densities in different directions, in the same manner as in the artificial structures above mentioned.

It is not, however, the direction of the axis of a crystal that ultimately determines the position which it assumes under the influence of a magnet, so much as that of the planes of cleavage, these planes taking the axial direction when the crystal is magnetic, and the equatorial if it is diamagnetic.

Thus, if two cubes be formed of the same dimensions, one from a crystal of beryl, the other from scapolite, both of which are magnetic, the former will place itself with its principal axis equatorially between the magnetic poles, the latter axially, because in beryl the cleavage-planes are perpendicular to the axis, whereas in scapolite they are parallel to it. Conversely, a cube of nitre, which is diamagnetic, places itself with the principal axis equatorial, whereas a cube of topaz, also diamagnetic, takes up the contrary position; because the cleavage-planes of nitre are parallel, and those of topaz are perpendicular, to the principal axis of the crystal. In all cases, the cleavage-planes place themselves axially or equatorially, according as the crystal is magnetic or diamagnetic. The manner in which this result is produced will be easily understood if we remember that a crystal may be regarded as an aggregate of very thin plates laid parallel to each other, but not in absolute contact. It is easy, indeed, to imitate the arrangement artificially. Thus, if a number of strips of emery-paper, an inch long and a quarter of an inch wide, be gummed together one upon the other, so as to form a rectangular bar, this bar will place itself axially between the poles of a magnet (the emery being magnetic); in fact, it represents a magnetic crystal having its cleavage planes parallel to the axis. But if another bar be formed, also an inch long, of square pieces of emery-paper, a quarter of an inch broad, having their surfaces transverse to its length, it will place itself equatorially, because, in that position, the layers of magnetic substance will take up the axial position. If the paper be covered with a paste of bismuth powder instead of emery, the effects will be exactly opposite.—*Traité d'Electricité*, par A. De la Rive (i. 516—529).

Diamagnetic Polarity. Soon after the discovery of diamagnetism, the question was raised, whether diamagnetic bodies possess opposite poles analogous to those of magnetic bodies. Faraday, from his earlier experiments, concluded that such was not the case, but that every part of a diamagnetic body was equally repelled by either pole of a magnet. On the other hand, Reich (Ann. Ch. Phys. [3] xxxvi. 127) found

that a very delicately suspended ball of bismuth, though repelled by either pole of a horse shoe magnet, when presented to them separately, remained at rest when suspended at equal distances from the two: hence he concluded that the resultant effect

Fig. 727.

of the two magnetic poles is due, not to the sum, but to the difference of their action, just as would be the case with the attractive actions exerted by the two poles on a ball of iron, and that the first effect of the magnet on the bismuth is to develop in it a certain polarity, whence results the repulsion. The question was likewise examined by Weber and Poggendorff, Plücker, H. C. Oersted, and Matteucci, but without decisive results, and the question as to the existence of diamagnetic polarity remained doubtful till it was taken up by Tyndall (Phil. Trans., 1855 and 1856), who, by means of an apparatus suggested by Weber, has completely established the existence of polarity in diamagnetic bodies.

This apparatus, represented in fig. 727, consists of two equal vertical helices, *A A'*, having an internal diameter of two centimetres, and coiled round copper tubes, which project above them at *t, t'*; these two helices convey the same electric current, but in contrary directions. They are fixed to a stout board suspended against a wall, and within them are suspended two small diamagnetic bars, *l, l'*, attached to an endless cord passing round the pulleys *P, P'*. An astatic needle, *sn*, represented in projection at *NS, N'S'*, is suspended on a level with the middle of the helices *A, A'*, by silk cords attached to the centre of a torsion-circle, *r*. This circle is capable of turning independently of the screw *v*, the nut of which is embedded in a copper cross-piece fixed to the extremities of the copper tubes *t, t'*. The magnets *NS, N'S'* are enclosed in a copper box, *a*, to diminish the amplitude of the oscillations; they are joined by a brass rod, on which they can be made to approach one another more or less.

The deflections of the astatic needle are observed by reflection in a mirror *m, M*, and measured by the reflection of a horizontal scale placed at a distance, as in Gauss's magnetometers. On transmitting a voltaic current from one or two Grove's cells through the two coils in opposite directions, the bismuth bars within them become diamagnetised; and by carefully raising or lowering the astatic bars *NS, S'N'*, a position may be found in which the magnets become indifferent to the action of the current. If, whilst the apparatus is thus arranged, the wheel *P* be turned to the right, the bismuth bars will be brought into the position represented in the figure, and the astatic needle will be deflected. This effect is clearly due to the development of polarity in the bismuth bars: for, in consequence of the opposite direction of the currents on the two helices, the lower end of one bismuth bar will, if polar, be in the same condition as the upper end of the other, and each will therefore attract one particular end, say the north, of each magnet composing the astatic combination, and repel the south end: both bars therefore tend to deflect both magnets in the same direction; on turning the wheel to the left, so as to bring the bismuth bars into the opposite position, the needles will be equally deflected in the contrary direction.

These effects are most marked with bodies like bismuth and antimony, which have the greatest diamagnetic energy; but they are also distinctly shown, even in non-conducting bodies—such as heavy glass, phosphorus, sulphur, sulphide of carbon, &c.

If the deviation produced by solid bismuth be represented by 75 divisions of the scale employed, the following table will represent the action, found by Tyndall, of the other bodies enumerated in it:

Bismuth, solid	75	Heavy glass	4
„ powdered	37	Phosphorus	4
Antimony	13.5	Distilled water	4
Sulphide of carbon	5.6	Calcspar	2
White marble	6	Nitre	1.7

When magnetic substances, such as iron in bars or in filings, sulphate, carbonate, or chloride of iron, slate, solutions of salts of iron, nickel, or cobalt, are substituted for the diamagnetic bars, the astatic needles are deflected in the contrary direction to that in which, under the same circumstances, they would be deflected by diamagnetic bodies.

Theory of Diamagnetism. The phenomena of diamagnetism naturally suggest the inquiry, whether the repulsion exerted by a magnetic pole on diamagnetic bodies

is a force distinct from that of magnetism, as exerted upon iron and other bodies of the magnetic class; or whether, on the other hand, the magnetic and diamagnetic conditions of matter are merely relative, so that all bodies are magnetic in different degrees, and the apparent repulsion of a diamagnetic body, such as bismuth, is merely the result of its being attracted by the magnet less than the particles of the surrounding medium, just as a balloon recedes from the earth, because its weight is less than that of an equal bulk of the surrounding air. It is easy to show that the same body may appear magnetic or diamagnetic, according to the medium in which it is placed. Protosulphate of iron is a magnetic substance, and water is diamagnetic: hence it is possible, by varying the strength of an aqueous solution of this salt, to make it either magnetic, indifferent, or diamagnetic, when suspended in air. Again, a tube containing a solution of protosulphate of iron suspended horizontally within a jar, also filled with a solution of the same salt, and placed between the poles of two powerful electro-magnets, will place itself axially or equatorially, according as the solution contained in it is stronger or weaker than that in the jar. In the same manner, then, we may conceive that bismuth places itself equatorially between two magnetic poles, because it is less magnetic than the surrounding air. But the diamagnetism of bismuth and other bodies of the same class shows itself in a vacuum as well as in air: hence, if diamagnetism is not to be regarded as a distinct force, we must suppose that the *ether* is also magnetic, and occupies in the magnetic scale the place intermediate between magnetic and diamagnetic bodies.

That a body suspended in a medium of greater magnetic susceptibility than itself, will recede from a magnetic pole in its neighbourhood, in consequence of the greater force with which the particles of the medium are impelled towards the magnet, is so obvious a consequence of mechanical laws, that we can scarcely avoid attributing the movements of diamagnetic bodies to the cause just mentioned, at least, when the body is suspended in air or other magnetic gas. There is, however, some difficulty in reconciling the phenomena exhibited by compressed and crystallised bodies (p. 774) with this view. Tyndall some time ago (*Phil. Mag.* [4] ix. 205) objected to it, that the intensity of diamagnetism as well as that of magnetism is increased by compression; whereas, if the repulsion of a diamagnetic body were merely the result of the greater attraction exerted upon the particles of the surrounding medium, it ought to be weakest in that direction in which the body is most compressed, inasmuch as the compression must increase the total amount of attraction exerted on the particles of the body in that direction, but cannot in any way affect that which is exerted on the surrounding medium. Williamson (*Proc. Roy. Soc.* vii. 306) has, however, pointed out that, in considering this question, it is necessary also to take account of the attraction exerted on the magnetic medium (or *ether*) interposed between the particles of the magnetic or diamagnetic body. When a cube of carbonate of iron is compressed, the ponderable particles being more magnetic than the medium which they displace, the force with which the body is attracted is increased proportionally to this excess. If it becomes more magnetic by compression, we must conclude that the loss of magnetic medium from its interstices is more than supplied by the magnetic matter which takes its place. Carbonate of calcium, on the other hand, is less magnetic than the quantity of medium which its particles displace; and when these particles are brought closer together by pressure, the mass becomes more diamagnetic, because a certain quantity of the magnetic medium is thus replaced by the less magnetic matter. In both bodies, so long as they retain their original crystalline forms, the optic axis is the direction in which the function of the ponderable particles predominates most strongly over that of the medium; so that in the iron-salt it is the strongest, and in the calcium-salt the feeblest magnetic direction of the crystal. On the other hand, Hirst (*Proc. Roy. Soc.* vii. 448) suggests that, in estimating the resultant action of a magnet on the particles of a body and the magnetic medium enclosed between them, account must be taken of the relative intensities of the action exerted on the medium in different directions: and he endeavours to show, by a process of reasoning for which we must refer to the paper above quoted, that, in two out of three possible cases, viz. (1), when the attraction of the magnet on the interposed medium is equal in all directions with regard to the line of compression, and (2) when it is greatest in that direction, the repulsion produced on a body whose specific magnetic susceptibility is less than that of the medium, will be a minimum in that direction; and, therefore, that in these two cases, the objection raised by Tyndall against the theory of diamagnetism under consideration is valid: but that, thirdly, in the somewhat improbable case in which the action of the magnet on the interposed medium is greatest in the direction at right angles to that of strongest attraction of the ponderable particles, the latter may be so far diminished, that the body may be most strongly repelled by a magnetic pole in the direction of greatest compression. If, therefore, this third case be also taken into account, Tynd-

dall's objection to the theory of a magnetic medium cannot be regarded as perfectly decisive.

On the whole, then, the phenomena exhibited by compressed and crystallised bodies do not quite decide the question whether diamagnetic repulsion is merely a differential phenomenon, or whether it is due to the action of a specific force. That it is partly differential, can, as already observed, scarcely be doubted; but, on the other hand, the existence of diamagnetic polarity shows decidedly that the effect is not wholly due to this cause: for if it were, every part of a diamagnetic body would be repelled by either pole of a magnet.

It becomes necessary, therefore, to seek some further explanation of the phenomena of diamagnetism; and the following theory has been proposed by Weber and De La Rive. We must suppose, in the first place, that each molecule of a body possesses a natural polarity, by virtue of which, negative electricity tends to accumulate at a certain point, *c*, of its surface (fig. 728), and positive electricity at the opposite point, *b*. If this molecule is isolated and a good conductor, the two electricities will recombine along its surface, forming currents contrary to those which are continually being produced in its

interior to re-establish the polar tension; and the actions which these currents would tend to produce on any external point, destroy one another. If now the molecule be supposed to make one of a group, all the atoms of this group will act upon each other so as to bring their contrary poles towards one another, as in fig. 729, and the opposite electricities, instead of recombining on the surface of each molecule, will form intermolecular discharges, and, consequently, a current in the direction of the external arrows. These currents, existing in all the molecular groups, are in fact those which are assumed to exist in Ampère's theory (p. 769): in unmagnetised iron, they run in all directions, and the effect of magnetisation is to reduce them to parallelism. Now, these currents cannot pass between the molecules composing the group unless these molecules are sufficiently close together; and, accordingly, it is found that magnetic bodies are, generally speaking, those whose atoms are most closely packed; in other words, those which have the smallest atomic volumes (p. 773). Moreover, heat, which increases the distance between the atoms, diminishes the magnetic power of a body, and may even destroy it altogether. Diamagnetic bodies, on the contrary, having, generally speaking, a large atomic volume,—that is to say, their atoms being very wide apart,—these atoms cannot discharge their opposite electricities one to another, but are in the state of the isolated atom (fig. 728). If, however, these independently polarised atoms are brought near an electric current, or the system of currents constituting a magnet, the atoms are brought, by the polarised molecules of the current, into such a position that the contrary poles of the two systems are brought face to face, as in the formation of induced currents (fig. 447, vol. ii. p. 454). Consequently, these atoms will place themselves, in their own group, in the same manner as those in fig. 729; and if the action is sufficiently powerful, the polarity of the atoms of the molecular group will be increased by their mutual influence, to such an extent, that discharges will take place between them, producing a current in the opposite direction to that of the magnet, in consequence of which the body will be repelled from the magnet. According to this theory, then, the chief difference between magnetic and diamagnetic bodies consists in this,—that in the former the currents pre-exist round the molecular groups, and merely require to be brought to parallelism by magnetisation; whereas in the latter, they are brought into

existence only under the influence of powerful currents, capable of bringing the atoms into the necessary arrangement.

There are, however, considerable difficulties in the reception of this theory. In the first place, the diamagnetic powers of bodies are by no means proportional to their atomic volumes. Potassium and sodium, which have much greater atomic volumes than bismuth, are slightly magnetic; whereas zinc and copper, whose atomic volumes are very small, are slightly diamagnetic. With regard to these two latter metals, De la Rive observes that they are very good conductors, and, therefore, that the recomposition of the opposite electricities may take place along the surface of each, in spite of their close proximity: and in support of this explanation he remarks, that on combining copper with chlorine and oxygen, which diminish its conductivity, it becomes magnetic. But this mode of explanation will not account for the magnetism of potassium and sodium, which are intermediate in conductivity between iron and copper. Moreover, it is difficult to see how, according to this theory, the diamagnetism of a body should be increased by compression. On the whole, it must be admitted that we are still very far from a satisfactory theory of diamagnetism.

MAGNETISM, TERRESTRIAL. The magnetic action of the earth has been spoken of in a general way in the preceding article: we shall here examine it more particularly. A magnetic needle suspended by its centre of gravity in such a manner that it can move freely in all directions, and placed beyond the influence of other magnets and masses of iron, places itself: 1. At a particular angle with the geographical meridian of the place: this is called the declination.—2. At a particular angle to the horizon, called the inclination or dip of the needle.

1. *Declination*.—also called the *Variation of the Compass*.—The angle which the magnetic needle makes with the north and south line, or with the geographical meridian, is most conveniently observed with a needle whose movements are restricted to a horizontal plane; as by supporting it on a steel point by an agate cup (*fig. 718*), or on a stirrup of paper or copper suspended by a thread of unspun silk. When a needle thus suspended is carried to different parts of the earth's surface, its direction is continually changing. In certain parts of the world, it points exactly north and south; in all others, its position of equilibrium is more or less inclined to the geographical meridian of the place. A vertical plane passing through its position of equilibrium is called the magnetic meridian of the place.

The declination varies in direction and in amount both with place and with time. It is always spoken of with reference to the position of the north pole of the needle. Thus, when we say that the declination at London is at present to the west, we mean that the north pole of the needle points west of the geographical north.

The points of the earth's surface at which the needle points due north and south are situated on certain lines, called *lines of no declination*. One of these lines, whose direction does not deviate much from that of a great circle of the globe, may be traced from a certain point north-west of Hudson's Bay, across Canada, into the Atlantic Ocean, cutting the extreme east point of South America, near Cape St. Roche, whence it passes across the South Atlantic Ocean, and meets the meridian of London near the 60th degree of south latitude. Another line of no declination passes across the Southern Ocean at about 120° east longitude, traverses the west of Australia in a nearly northerly direction, then passes westwards, forming a large loop enclosing the islands of the Indian Archipelago and the two peninsulas of India, whence it passes northwards along the west of Japan, and enters Siberia, where it has not been further traced. Another branch, which is perhaps a continuation of that which traverses the Indian Ocean, passes northwards across the White Sea. There are, therefore, two systems of lines of no declination, which probably join one another in the polar regions, so as to form a single curve passing round the globe.

Between the American line on the west and the Asiatic lines on the east—that is to say, over nearly the whole of the Atlantic Ocean and the Old World—the declination is to the west; over the rest of the earth's surface it is to the east; and it diminishes on both sides as we approach these lines. In London, at the present time (1864), the declination is 20° 46' W.

Inclination or Dip.—Suppose a bar of unmagnetised steel to be suspended at its centre of gravity by a thread of unspun silk: it will come to rest in the horizontal position. But if it be magnetised, it will not only place itself in the magnetic meridian, but will take up an inclined position, the north pole in these latitudes pointing downwards. The amount of the inclination or dip of the needle is best observed by means of a long needle supported by its centre of gravity on a horizontal axis (*fig. 730*), so that its movements are confined to a vertical plane. A *dipping-needle* thus mounted is represented in *fig. 730*. The horizontal circle serves to place the plane of the needle's motion in the magnetic meridian, and the vertical circle to measure the dip.

As the needle always tends to place itself in the magnetic meridian, it is clear that if the vertical plane to which its movements are confined is placed at right angles to the magnetic meridian, the needle will stand vertically, this being the only position in which it can place itself in the magnetic meridian. If this position be determined and marked on the horizontal circle, the vertical circle may be placed in the magnetic meridian by moving it round 90° therefrom. The angle of inclination may then be directly observed.

Fig. 730.

The dip, like the declination, is of different amount in different localities. There are two points, one in each hemisphere, at which the dipping-needle stands exactly vertical; these are called the magnetic poles of the earth; and about midway between them is a line called the magnetic equator, or line of no dip, at which it stands horizontally. The magnetic equator is a somewhat sinuous line, not differing much from a great circle inclined to the geographical equator at an angle of 12° , and cutting it in two points near the longitudes 10° E. and 170° W., reckoned from the meridian of Paris. At all points between this line and the north magnetic pole, the north pole of the needle is directed downwards, the contrary being the case in the other magnetic hemisphere. The dip goes on increasing from the magnetic

equator towards each pole: in London at the present time it is $68^\circ 15'$, reckoning from the horizontal plane.

On comparing the positions assumed by the needle at different parts of the earth's surface, it is easily seen that they may be accounted for by regarding the earth as a great magnet, having its poles at the points where the dipping needle stands vertically, and its median line coinciding with the magnetic equator. The northern terrestrial magnetic pole, which corresponds with the south pole of an ordinary magnet, is situated on the continent of North America, to the north-west of Hudson's Bay, and, according to the observations of Capt. J. C. Ross, made in 1830, in latitude $70^\circ 5' 17''$ N. and longitude $96^\circ 43'$ W. from Greenwich (*Arago's Meteorological Essays, translated by Sabine*, p. 366). The position of the southern magnetic pole has been approximately fixed by the observations of the same navigator, in latitude 73° S. and longitude 130° E. The line of no declination passes through these two points, and the lines of equal declination converge towards them. From observations made at different points in England and the south of Scotland, between March 1858, and October 1860, Sabine deduces $68^\circ 59' 2''$ as the dip at the mean epoch, 1st January, 1860, at a point whose latitude and longitude were the means of those of the stations included in the survey, namely latitude $52^\circ 20'$, longitude $1^\circ 41'$ W. from Greenwich. The minimum dip was observed at St. Leonard's (latitude $50^\circ 51'$, longitude $0^\circ 33'$ E.), where it was $67^\circ 44' 5''$; and the maximum $71^\circ 29' 5''$, at Jordan Hill, near Glasgow (latitude $55^\circ 52'$, longitude $4^\circ 19'$ W.), the direction of the *isoclinical lines*, or lines of equal dip, being from N. $71^\circ 22'$ E. to S. $71^\circ 22'$ W. (Rep. Brit. Assoc., 1861, p. 250).

That the earth really acts like a magnet, is further shown by the magnetisation of masses of iron placed in or near the line of the dip. In our latitude, where the line of dip does not differ greatly from the vertical, bars of iron standing constantly in the vertical directions, such as railings, lightning-conductors, &c., become magnetised with their north poles downwards, just as they would be if placed above the south pole of a steel magnet.

The magnetisation of the masses of iron in a ship by the earth's action, causes a considerable deviation of the compass-needle from its normal position; and as the direction of the magnetisation thus induced is constantly changing as the ship changes its latitude, it is evident that serious irregularities in the indications of the compass may thence result: in short, there are several instances of shipwreck on record which have been clearly traced to this cause. This source of irregularity may, however, be corrected by fixing a disc of iron, called a *compensator*, in such a position with regard to the compass, that its action shall be equal and opposite to that of the whole mass of iron in the ship: the needle will then be free to take up its normal position under the influence of the earth's magnetism. It is, however, found better in practice to place the compensator in such a position that it shall produce an action equal to that of the iron in the ship, and in the same direction, so that, when placed in position, it will double the deviation produced by the iron in the ship: the amount of this deviation will thus be ascertained, and may be allowed for. This great service to navigation is the invention of Mr. Barlow, of Woolwich.

The magnetic power of the native black oxide of iron is, doubtless, also due to the inductive action of the earth, and the very different powers exhibited by different specimens of the ore may, in part at least, be attributed to the different position of the veins with regard to the line of the magnetic dip.

3. *Intensity of the Earth's Magnetic force.*—The magnetic force of the earth, like that of an ordinary magnet, is of different intensity in different parts. The relative intensities at different places are measured by counting the number of oscillations made in a given time by a magnetic needle: for these vibrations are subject to the same laws as those of a pendulum, being isochronous when small, and the squares of the numbers of oscillations in a given time being proportional to the force which tends to bring the needle back to its position of equilibrium.

The observations may be made either with the dipping or the horizontal needle. When a dipping-needle is disturbed from its normal position of equilibrium, it is urged back to that position by the whole force of the earth's magnetism: so that, if the intensities of the terrestrial magnetic forces at any two places are denoted by F, F' , and the corresponding number of oscillations made in a given time by n, n' , we have, for the relation between the two forces,

$$F : F' = n^2 : n'^2.$$

The horizontal needle, on the other hand, is urged back to its normal position by only a portion of the terrestrial force, which becomes less as the magnetic latitude is greater. For the total force F acting on the needle in the line of the dip, may be resolved into two others, one vertical, which is destroyed by the suspension, the other, f , horizontal, which is that which is effective in moving the needle; and if i be the dip at the place of observation, this horizontal force f is equal to $F \cos i$. Hence, for any two places at which the total intensities are F, F' , the angles of dip i, i' , and the numbers of oscillations n, n' , we have the relation,

$$\frac{n^2}{n'^2} = \frac{f}{f'} = \frac{F \cos i}{F' \cos i'}.$$

Therefore,

$$\frac{F}{F'} = \frac{n^2 \cos i'}{n'^2 \cos i}.$$

At the magnetic equator, $i = 0$, $\cos i = 1$, and therefore $f = F$; at the magnetic poles, $i = 90^\circ$, and therefore $f = 0$: in fact, at these points, the horizontal needle takes up all positions indifferently; and near the poles, the force which directs it is very small, so that its indications cannot be depended upon. But, excepting in these high magnetic latitudes, the results obtained with the horizontal needle are more trustworthy than those obtained with the dipping-needle, on account of errors affecting the latter, from want of perfect horizontality in the axis, the friction on the supports, &c.; whereas the horizontal needle is easily suspended by a thread of unspun silk, which gives it almost perfect freedom of motion. [For full details on the construction of instruments for observations on terrestrial magnetism, see Becquerel, *Traité de l'Electricité et du Magnétisme*, Paris, 1840, tome vii. The atlas to that work contains large diagrams of these instruments, and maps representing the directions of the magnetic meridians and parallels on the surface of the globe. See also Daguin, *Traité de Physique*, tome iii. pp. 27, 55.]

The magnetic intensity increases with the latitude. Humboldt found a point of minimum intensity on the magnetic equator in Northern Peru. This value is generally taken as the unit to which the magnetic intensities at other parts of the globe are referred, as in the following table.

Locality.	Date.	Latitude.	Magnetic intensity	Locality.	Date.	Latitude.	Magnetic intensity.
St. Anthony .	1802	0° 0'	1.087	Brussels .	1829	50° 52' N	1.374
Carthagena .	1801	10 25 N	1.294	Berlin .	1829	52 51	1.366
New York .	1822	40 43	1.803?	Christiania .	1820	59 55	1.419
Naples .	1805	40 50	1.274	Petersburg .	1828	59 66	1.410
Lyons .	1805	45 46	1.333	Baffin's Bay .	1818	62 43	1.590
Paris .	1800	48 52	1.348	Spitzbergen .	1823	79 40	1.567

Referred to the same unit, the magnetic intensity was 1.372 in London in 1827 (Sabine)

According to Sabine, the intensity at the north magnetic pole is 1.624; at the south magnetic pole, according to Sir James Ross, it is 2.052. The smallest intensity, 0.706, observed by A. Erman, is at $19^\circ 59' S.$ and $10.2^\circ E.$ (from Paris).

In later observations made by British observers, an absolute unit of intensity has been adopted, corresponding with a second of time, a foot of space, and a grain of mass.

The magnetic intensity on this scale at London is at present 10.29; that is to say, it is a force capable of generating in one second, in a mass of one grain, a velocity of 10.29 feet per second. The total force, expressed in absolute units, has been observed to vary at different parts of the earth's surface from about 6.4 to 15.8. (Sabine, *Admiralty Manual of Scientific Inquiry*; ed. 1859, p. 89.)

The mean amount of the total force in England, deduced by Sabine from the magnetic survey already referred to (p. 780), for 1st January 1860, is 10.332, the minimum, 10.225, having been observed at St. Leonard's, and the maximum, 10.626, at Fern Tower (lat. $56^{\circ} 22'$; long. $3^{\circ} 50' W.$). The direction of the *isodynamic lines*, or lines of equal intensity, in England, at the above date, was from N. $57^{\circ} 35' 7'' E.$ to S. $57^{\circ} 35' 7'' W.$

The isodynamic lines differ considerably from the isoclinical lines, or lines of equal dip, but bear considerable resemblance to the isothermal lines; whence it appears probable that the magnetic intensity of the earth (like that of an ordinary magnet) is affected by heat. (For a chart of these lines, see Becquerel, *loc. cit.*) According to Gauss, there are in each hemisphere two points of maximum magnetic intensity coinciding with the points of greatest cold, but not with the magnetic poles determined by the dip and declination of the needle.

Variations of the Magnetic Elements.

The declination, dip, and intensity at any point of the earth's surface are subject to continual variations, both regular and irregular; and the regular variations are of two kinds: secular variations, of considerable amount, and extending over long periods of time; and periodic variations, of small amount, and running through their phases at short intervals.

Variations of the Declination.—1. *Secular.* The earliest exact observations of the magnetic declination were made at London in 1576, and at Paris in 1580. At London, in 1576, it was $11^{\circ} 15'$ to the east; from that time it diminished till 1657–1662, when it was nothing, the needle then pointing due north and south; it then became westerly, attaining its maximum of $24^{\circ} 36'$ in 1800. In 1831 it had diminished to $24^{\circ} 0'$, and it is now (in 1864) $20^{\circ} 45' W.$ At Paris it was $11^{\circ} 30' E.$ in 1580, 0 in 1663, attained its maximum of $22^{\circ} 34' W.$ in 1814, and had diminished to $20^{\circ} 25' W.$ in 1851. At the Cape of Good Hope, the declination in 1605 was $0^{\circ} 30' E.$, became nothing between 1605 and 1609, then westerly, attaining its maximum of $25^{\circ} 40' W.$ about 1791. In all cases the declination given for each year is the mean of those obtained for each day and for each month, so as to eliminate the diurnal and annual variations.

2. *Annual.*—The declination of the needle is subject to small annual variations, which were discovered by Cassini in 1780. At Paris and London, it is greatest about the vernal equinox, diminishes from that time to the summer solstice, and increases again during the nine following months. The annual variation does not exceed from $15'$ to $18'$. It is also different in amount at different epochs. At London, from 1818 to 1820, it was reduced almost to nothing; at which time, also, the secular variation was extremely slow, being near its maximum.

3. *Diurnal.*—The diurnal variations of the declination were discovered by Graham in 1722. In Europe, the north pole of the needle begins to move westward at sunrise, and continues moving in the same direction till an hour or two after noon; after which it returns and regains its original position at about 10 p.m., at which it remains all night. It appears, then, that the westerly declination is greatest during the warmest part of the day. The amplitude of these movements is very small, and differs at different times of the year, being sometimes from $20'$ to $25'$, at other times not exceeding $5'$ or $6'$. It also becomes less as we approach the magnetic equator: thus, in the island of Rawak it never exceeds $3'$ or $4'$.

The periodic variations of the declination are the result of the superposition of two distinct variations,—one depending on the horary position of the sun, the other on his distance from the equator, the latter constituting the annual variation.

Variations of the Dip.—The secular variations of the magnetic dip are of smaller amount than those of the declination. At Paris, in 1671, when the dip was first observed, it was $73^{\circ} 0'$, and has since been continually diminishing; in 1851 it was $66^{\circ} 35'$. In London also the dip has continually diminished since 1720 by about $2.6'$ per annum. In August, 1821, it was $70^{\circ} 2' 81''$; in May, 1838, it was $69^{\circ} 17' 30''$; in August and September, 1854, it was $68^{\circ} 31' 13''$; it is now $68^{\circ} 15'$.

The dip likewise exhibits annual and diurnal variations, being, according to Hansteen, about $15'$ greater in summer than in winter, and $4'$ or $5'$ greater before noon than after.

Variations of the Intensity.—It is not yet distinctly ascertained whether the magnetic intensity of the earth exhibits secular variations: indeed, the settlement of the question is attended with very great difficulty, inasmuch as it requires that the needles used should preserve their magnetic power unaltered throughout the whole

course of the observations—a condition scarcely possible to fulfil for any great length of time. Gauss has found, indeed, by a peculiar method of observation which is independent of the force of the needles used, that the magnetic intensity at Göttingen has not varied sensibly during several years; but the time over which these observations have extended is as yet too short to warrant any general conclusion on the subject. It is, however, scarcely possible that the declination and dip should change at any place without some corresponding variation in the intensity. By absolute measurements made monthly at Kew since April, 1857, it appears that the total force had increased at that place, up to March 1862, at the average rate of 0.00125 annually.

Periodic variations of intensity are more easily observed. In studying these, it is usual to observe separately the variations of the horizontal and vertical components of the magnetic force. The horizontal component exhibits an hourly variation, which is the resultant of two elementary variations—one diurnal, the other semi-diurnal. The amplitude of the semi-diurnal variation increases with the latitude, and is nothing at the equator. The phases through which it passes depend on the angular distance of the sun from the magnetic meridian. In mean latitudes, the curve which represents the variation of the horizontal component is similar to that of the diurnal variation of the declination, but six hours behind it. The semi-diurnal period is scarcely perceptible at St. Helena, but increases in distinctness at higher latitudes.

The variations of the vertical component of the intensity follow the same periods as those of the horizontal components.

Irregular Variations or Perturbations of the Magnetic Elements.—The magnetic needle, especially the declination-needle, frequently experiences accidental deviations, which deflect it more or less from its normal position for various intervals of time, sometimes for several hours. Some of these disturbances may be traced to known causes,—namely, the *aurora borealis*, earthquakes, and volcanic eruptions. But few observations have been made on the perturbations arising from the two latter causes, which, moreover, produce sensible effects at small distances only. The deviations arising from these irregular disturbances rarely exceed a fraction of a degree, and the needle returns to its primitive position as soon as the disturbing cause has ceased to act.

The coincidence of the *aurora borealis* with certain perturbations of the magnetic needle was discovered in 1710 by Celsius and Hiorter. During the occurrence of an *aurora*, the declination-needle is seen to deviate from its normal position, even in localities where the meteor itself is not visible; so that the inspection of the needle often serves to announce the presence of an *aurora*, no trace of which can be directly seen. In our latitude, the deviation does not exceed 20'; but it is greater in the Arctic regions, where, indeed, the phenomenon has been principally studied. The culminating point of the auroral arch is always situated in the magnetic meridian of the place, and the centre of the crown to which the streams of light converge is situated on the prolongation of the line of the dip. So long as the auroral arch is stationary, the needle remains nearly at rest; but as soon as the arch begins to throw out streamers, the needle oscillates, sometimes through several degrees. The effects are more decided in proportion to the brightness of the *aurora*. The dip and the intensity are likewise affected by the *aurora* as well as the declination.

The establishment of magnetic observatories, in which the motions of the needle are observed continuously, has led to the discovery of perturbations which cannot be attributed to any of the preceding causes. One of the most remarkable facts brought to light, by observing the movements of the powerful magnets with which these establishments are furnished, is that the magnetism of the earth is in a state of constant fluctuation, like the waves of the sea. Hence, in studying the diurnal, annual, and secular variations of the declination, &c., it is necessary to take the mean of a large number of observations, in order to eliminate the irregular disturbances and bring out the general laws.

Another very remarkable phenomenon is the simultaneous occurrence of magnetic perturbations in very distant countries. Thus, Sabine mentions a magnetic disturbance which was felt simultaneously at Toronto, the Cape, Prague, and Van Diemen's Land. This coincidence of magnetic perturbations is so exact, that it has been proposed to make use of them in determining the longitude of the place of observation. Humboldt and Oltmann, in 1806, observed some remarkable perturbations recurring at the same hours for several successive nights. These simultaneous perturbations have received the name of *magnetic storms*.

There are also local perturbations extending to small distances only. Humboldt mentions one which was observed in the Saxon mines, but was imperceptible at Berlin. Magnetic storms observed simultaneously from Sicily to Upsala, were imperceptible between Upsala and Altona.

MAGNETO-ELECTRICITY. The development of electricity by magnetic action. (See ELECTRICITY, ii. 451.)

MAGNETOMETER. This name is specially applied to certain instruments devised by Gauss for measuring the intensity of the earth's magnetic force. (See Becquerel, *Traité de l'Electricité et du Magnetisme*, tome vii., and Daguin, *Traité de Physique*, iii. 78.)

MAGNIUM. Davy's name for Magnesium: it is also adopted by Gmelin in his *Handbuch*.

MAGNOFERRITE. A compound of ferric oxide and magnesia, $2\text{MgO} \cdot 3\text{Fe}_2\text{O}_3$ or $3\text{MgO} \cdot 4\text{Fe}_2\text{O}_3$, occurring in octahedral crystals among the products of the eruption of Vesuvius in 1855. Specific gravity about 4.6. (Rammelsberg, *Pogg. Ann.* cvii. 457; *Jahresber.* 1859, p. 776.)

MAHOGANY. See *Ure's Dictionary of Arts, &c.* iii. 16.

MAIZE. *Zea Mâis*.—The composition of the grain of this plant and of its ash is given in the article *CEREALS* (i. 825, 827). See also *ZRIN*. On the germination of maize, see v. *Planta* (*Jahresber.* 1860, p. 523). On the growth of maize in aqueous solutions of its constituents, see Stohmann (*ibid.* 1861, p. 734).

MAJORANA. See MARJORAM.

MAKWAH BUTTER. Syn. with GALAM BUTTER (ii. 758).

MALACHITE. Native carbonate of copper. (See CARBONATES, i. 783.)

MALACOLITE, also called *Sahlite*, *Pyrgom*, *Fassaite*.—A variety of augite, consisting of silicate of calcium and magnesium, with more or less iron (ferrosium), a small portion of the bases being frequently also replaced by water.

MALACONE. A mineral having the form of zircon, and nearly related to it in composition. Hardness = 6.5. Specific gravity = 3.9 to 4.05. Brown and vitreous to subresinous; powder reddish brown or uncoloured.

Analyses.—a. From Hitterø, Norway, by Scherer (*Pogg. Ann.* lxi. 436).—b. From the Ilmengebirg, by Hermann (*J. pr. Chem.* liii. 323).—c. From Chanteloube, Haute Vienne, by Damour (*Rammelsberg's Mineralchemie*, p. 891):

	SiO_2	ZrO_2	Fe_2O_3	Mn_2O_3	VO	CaO	MgO	H_2O
a.	31.31	63.40	0.41	..	0.34	0.39	0.11	3.03 = 98.99
b.	31.87	59.32	3.11	1.20	4.00 = 99.50
c.	31.05	61.44	3.29	0.14	..	0.08	..	3.09 = 99.09

These analyses lead to the formula $3(\text{ZrO}_2 \cdot \text{SiO}_2) \cdot \text{H}_2\text{O}$ or $3\text{ZrSiO}_4 \cdot \text{H}_2\text{O}$, which requires 32.60 per cent. SiO_2 , 64.22 ZrO_2 , and 3.18 water.

MALACIC ACID. } See MALIC ACID, AMIDES OF.

MALAMIDE. }

MALAMYLIC ACID. Syn. with AMYL-MALIC ACID. (See MALIC ETHERS.)

MALANIL. Syn. with PHENYL-MALIMIDE.

MALANILIC ACID. Syn. with PHENYL-MALAMIC ACID.

MALANILIDE. Syn. with PHENYL-MALAMIDE.

MALEIC ACID. $\text{C}_4\text{H}_2\text{O}_4 = \text{C}_4\text{H}_2\text{O}_2 \left. \begin{matrix} \text{O} \\ \text{H} \end{matrix} \right\} \text{O}_2$. *Pyromalic acid*. *Pyrosorbic acid*.

(Lassaigne, *Ann. Ch. Phys.* [2] xi. 93.—Pelouze, *ibid.* lvi. 72.—Liebig, *Ann. Ch. Pharm.* xi. 276.—Büchner, *ibid.* xlix. 57.—Kekulé, *Ann. Ch. Pharm. Suppl.* i. 129; ii. 85; *Jahresber.* 1861, p. 364; 1862, pp. 308, 319.—Gm. viii. 151.)—An acid isomeric with fumaric acid, and differing from malic acid ($\text{C}_4\text{H}_5\text{O}_4$) by 1 at. water. It is produced, together with fumaric acid, by the dry distillation of maleic acid. It has not yet been found ready formed in any plant. Equisetic acid, obtained from *Equisetum fluviatile*, was for some time regarded, on the authority of Regnault, as identical with maleic acid; but Baup has shown that it is really identical with aconitic acid ($\text{C}_6\text{H}_4\text{O}_6$).

To prepare maleic acid, malic acid is heated in a capacious retort, of which it fills about a fourth, the distillation being pushed on rapidly. Water then passes over first; afterwards, white vapours of maleic acid, which condense in the water. As soon as the residue in the retort thickens, the fire must be withdrawn; the distillation then goes on of itself for some time, till a solid residue is left in the retort, consisting of fumaric acid. An additional quantity of maleic acid may be obtained by distilling this residue at a higher temperature; but the product is then coloured and difficult to purify. By evaporating the distillate at a gentle heat, the maleic acid is obtained in crystals.

Maleic acid crystallises in oblique, rhomboidal prisms, generally having their summits modified with octahedral faces. It is colourless and inodorous; its taste, sour at first, soon excites a very unpleasant sensation of nausea. It is very soluble in water and in alcohol; dissolves also in ether. The aqueous solution reddens litmus strongly; when

left to itself in an open vessel, it creeps up the sides and effloresces in forms like cauliflower heads.

The crystals melt at about 130° , and the liquid acid begins to boil at about 160° , being then resolved into water and maleic anhydride, $C^4H^2O^3$. If the acid, instead of being rapidly heated to 160° , be boiled in a very long and narrow tube, so that the water which escapes is obliged to fall back upon it, the maleic acid is converted into the isomeric body fumaric acid. The same transformation takes place on heating the acid in a tube sealed at both ends.

Maleic acid is also converted into fumaric acid by heating it with concentrated *hydriodic* or *hydrobromic acid*, or by boiling for some time with dilute *nitric acid*. When hydriodic acid is used, the fumaric acid is subsequently converted into succinic acid.

Maleic acid in contact with water and *sodium-amalgam* takes up hydrogen, and is converted into succinic acid:

The same transformation takes place when maleate of calcium is fermented in contact with cheese. (Desaignes.)

In contact with water and *bromine*, maleic acid is converted into dibromosuccinic acid, $C^4H^2Br^2O^4$, and another more soluble acid of the same composition, called *isodibromosuccinic acid*. (Kekulé.)

MALEATES.—Maleic acid is dibasic, forming *acid salts*, $C^4H^3MO^4$, and *neutral salts*, $C^4H^2M^2O^4$. The maleates bear considerable resemblance to the fumarates, with which they are isomeric; but they may be distinguished by the difference of solubility between fumaric and maleic acid: solutions of the maleates are not precipitated by other acids, whereas on adding a mineral acid to the solution of a fumarate (sufficiently concentrated and not warm) a precipitate of fumaric acid is formed.

Maleates of Ammonium.—*a.* The *neutral salt* is obtained as a crystalline jelly by saturating the aqueous solution of the acid with ammonia, and evaporating over lime *in vacuo*. Absolute alcohol added to the concentrated aqueous solution throws down the salt in the form of a white crystalline powder, which may be dried by repeated washing with alcohol, and pressing between paper, but, when exposed to the air, quickly becomes glutinous and deliquescent (Büchner). This salt does not precipitate a solution of sesquichloride of iron, a character which distinguishes it from the corresponding salt of aconitic acid.

β. The *acid salt* is obtained by exactly neutralising a known quantity of the aqueous acid with ammonia, then adding an equal quantity of the acid, and evaporating to the crystallising point at a gentle heat. It forms crystalline laminae, which are permanent in the air, reddens litmus, and give off nothing at 100° : their solution evolves ammonia when boiled; it is very easily soluble in water, but not in alcohol.

Maleates of Barium. *a.* *Neutral salt.* $C^4H^2Ba^2O^4 \cdot 2H^2O$.—1. Maleic acid forms with baryta-water a pulverulent precipitate, which disappears on the addition of a small quantity of cold water, but reappears after a while in shining scales (Lassaigne). According to Pelouze, the precipitate is converted into the crystalline scales, even without addition of water. On adding a saturated solution of baryta-water to the concentrated aqueous acid, the precipitate redissolves at first in the *excess* of acid; even when sufficient baryta-water has been added to neutralise the acid, the precipitate is but small: but, after a few minutes, the whole solidifies to a tremulous gelatinous mass, resembling hydrate of aluminium, which, after being pressed, dries up to small crystalline laminae. These crystals are obtained still more distinct on evaporating the aqueous solution (Regnault).—2. The salt is also obtained by adding carbonate of barium to the hot aqueous acid, as long as effervescence continues, then filtering hot, and leaving the solution to crystallise (Büchner).—3. The concentrated acid added to acetate of barium throws down a white crystallo-granular, neutral salt. Part of the salt, however, remains dissolved in the acetic acid which is set free, and may be precipitated by ammonia: this portion is also crystallo-granular, and has the same composition (Büchner). The salt crystallises from its aqueous solution on cooling, in small shining needles united in stellate groups; and the solution, when evaporated at a temperature below its boiling point, becomes covered with a crystalline crust (Büchner). The crystals, after drying in the air, lose 5.62 per cent. (1 at.) water at 100° (Büchner), and 7.3 per cent. at 150° (Regnault). They dissolve sparingly in cold water (in 9 pts. water at 20° , according to Regnault), with tolerable facility in boiling water, easily in aqueous maleic or acetic acid, easily also in excess of baryta-water.

b. *Acid salt.* $C^4H^3Ba^2O^4 \cdot 5H^2O$.—Obtained by saturating the aqueous acid with the neutral salt; or by saturating a known quantity of the boiling aqueous acid with carbonate of barium, and adding another equal quantity of acid to the hot filtrate. The resulting solution yields, after rather strong concentration, indistinct crystals, which

red den litmus, give off the whole of their water of crystallisation (19·67 per cent.) at 100°, and dissolve in water, but not in alcohol. (Büchner.)

Maleates of Calcium.—*a.* The neutral salt, $C^4H^2Ca^2O^4$, is obtained, according to Büchner, in small needles, very soluble in water, and insoluble in alcohol, by saturating the boiling aqueous acid with carbonate of calcium, and concentrating the filtrate at a gentle heat. According to Pelouze, a solution of maleate of potassium mixed with concentrated aqueous chloride of calcium remains clear, but after a few days deposits needles which are but sparingly soluble in water. By saturating the boiling acid with carbonate of calcium and evaporating the filtrate at a gentle heat, small needles are obtained united in saline crusts; they do not give off any water at 100°; dissolve readily in water, but not in alcohol (Büchner). This salt, when fermented with casein, is converted into succinate of calcium. (Dessaignes.)

β. The acid salt, $C^4H^2Ca^2O^4 \cdot 5H^2O$, is formed by dissolving the neutral salt in a quantity of the aqueous acid equal to that which it already contains, and concentrating the solution somewhat strongly. It forms long rhombic prisms, which are permanent in the air, red den litmus, give off 24·1 per cent. (5 at.) of water at 100°, and dissolve readily in water, but not in alcohol. Oxalic acid added to the solution, throws down the lime. (Büchner.)

Maleate of Copper, $C^4H^2Cu^2O^4$.—1. On boiling carbonate of copper in the aqueous acid, the filtrate is found to contain in solution but a small quantity of salt, which crystallises out on evaporation; if the residue on the filter be freed from the carbonate of copper still adhering to it, by means of dilute acetic acid, which dissolves but a small quantity of the maleate, the latter remains in the form of crystals, which may be washed with cold water.—2. When a concentrated solution of acetate of copper is mixed with an equivalent quantity of maleic acid, and evaporated at a gentle heat, acetic acid goes off, and maleate of copper crystallises out; the crystals must be washed with cold water. The light blue crystals are but sparingly soluble in water, even at a boiling heat, but dissolve readily in aqueous ammonia. (Büchner.)

Maleate of Cuprammonium.—The dark blue solution of maleate of copper in ammonia may be evaporated, even near its boiling point, without loss of ammonia, and alcohol added to the concentrated solution precipitates the compound in the form of a neutral, azure-blue, crystalline powder, which gives off ammonia when heated with potash, and dissolves readily in water, but not in alcohol. (Büchner.)

Maleate of Iron (ferricum).—Neither maleic acid nor maleate of potassium precipitates ferric acetate; neither is ferric chloride precipitated by maleate of ammonium. A boiling solution of maleic acid dissolves a small quantity of ferric hydrate, forming a brownish solution which yields a red-brown syrup on evaporation.

Maleate of Lead, $C^4H^2Pb^2O^4 \cdot 3H^2O$.—1. Free maleic acid forms a precipitate with neutral acetate of lead (Lassaigne), but not with the nitrate (Braconnot); if the solution is dilute, the white precipitate changes in a few minutes into shining micaceous laminae; but if the solution is concentrated, and the acetate of lead in excess, the mixture solidifies to a tremulous mass, which changes slowly—or quickly on the addition of water—into crystalline laminae, which with difficulty give off their 16·5 per cent. (3 at.) water (Pelouze).—2. Maleate of potassium added to nitrate of lead, throws down white flakes; these soon change to a translucent pasty mass, and then, when washed upon a filter, diminish considerably in volume, and are converted into small pearly needles (Lassaigne). The salt dissolves in nitric, but not in acetic acid. (Braconnot.)

Maleates of Magnesium. a. Neutral salt, $C^4H^2Mg^2O^4$ (at 100°).—The aqueous acid saturated at the boiling heat with carbonate of magnesium, yields a liquor which leaves on evaporation a tumefied spongy mass perfectly soluble in water. The concentrated solution of the salt yields with alcohol a bulky precipitate, which is not hygrometric, but gives off 27·36 per cent. water at 100°; it is very soluble in water and in dilute alcohol.

β. Acid salt, $C^4H^2Mg^2O^4 \cdot 6H^2O$.—By cooling a solution of 1 at. of the neutral salt and 1 at. maleic acid in hot water, small transparent and colourless rhombic crystals are obtained, which red den litmus strongly, grate between the teeth, taste like Epsom salts, and dissolve readily in water, but are insoluble in alcohol. At 100° they give off 34·95 per cent. water.

Maleate of Nickel, $C^4H^2Ni^2O^4 \cdot H^2O$.—By boiling the aqueous acid with carbonate of nickel, and evaporating the dark green, slightly acid filtrate, a gummy liquid is obtained, and ultimately apple-green crystals and crystalline crusts, insoluble in alcohol, but readily soluble in water. (Büchner.)

Maleates of Potassium. a. The neutral salt, $C^4H^2K^2O^4$ (at 100°), is obtained by saturating the acid with carbonate of potassium, and evaporating, in radiate crystals

which are soft like wax, very soluble in water, but insoluble in alcohol. On adding alcohol to the concentrated aqueous solution, this salt is precipitated as a granulo-crystalline powder.

β. Acid salt, $2C^4H^3O^4 \cdot H^2O$.—On saturating the acid with carbonate of potassium, adding an equal quantity of maleic acid, and cooling the solution, after sufficient concentration, this salt is obtained in small crystals very soluble in water; the solution reddens litmus. The salt is insoluble in alcohol. It does not give off any water at 100° .

On adding maleic acid to a concentrated solution of the neutral potassic salt, no precipitate is formed immediately, but the acid salt is deposited after some time. (Büchner.)

Maleates of Silver. α. Neutral, $C^4H^2Ag^2O^4$.—The acid gives no precipitate with nitrate of silver, but maleate of potassium or ammonium throws down a white precipitate (Lassaigne, Braconnot). The white precipitate obtained with an alkaline maleate changes in a few hours to tolerably large, transparent and colourless crystals, having an adamantine lustre; after drying, it detonates slightly on the application of a gentle heat. (Liebig.)

β. Acid salt, $C^4H^3AgO^4$ (at 100°).—Obtained in fine colourless needles by mixing a solution of maleic acid with nitrate of silver, and evaporating at a gentle heat.

Maleates of Sodium. α. Neutral, $C^4H^2Na^2O^4$.—The aqueous acid saturated with carbonate of sodium and evaporated, yields a magma of needles on cooling. The salt is precipitated from its aqueous solution by alcohol, as a crystalline powder. It is not deliquescent.

β. The acid salt, $C^4H^3NaO^4 \cdot 3H^2O$, obtained like the acid potassium-salt, forms rhomboidal prisms, sparingly soluble in cold, more soluble in boiling water, insoluble in alcohol. The solution has an acid reaction. The crystals contain 28.3 per cent. crystallisation-water, which they give off at 100° .

Sodio-potassic maleate, $C^4H^2KNaO^4 \cdot H^2O$.—On neutralising an aqueous solution of maleate of sodium with carbonate of potassium, then evaporating and cooling the syrup, a few small crystals are obtained, floating in a gelatinous mother-liquid. On precipitating the concentrated aqueous solution with absolute alcohol, and setting the crystalline magma aside in contact with absolute alcohol, there is finally obtained a white, easily deliquescent, crystalline powder, which gives off 9.13 per cent. (2 at.) water at 100° , and contains 25.55 per cent. potash, and 17.64 per cent. soda. (Büchner.)

Neither the ammonio-potassic nor the ammonio-sodic salt has yet been obtained.

Maleates of Strontium.—α. The neutral salt, $C^4H^2Sr^2O^4 \cdot 5H^2O$, forms silky needles.—*β. The acid salt, $C^4H^3SrO^4 \cdot 8H^2O$,* obtained like the corresponding barium-salt, crystallises in rectangular prisms, which are limpid, and acid to litmus-paper. The salt is soluble in water, but insoluble in alcohol. It gives off the whole of its water (31.4 per cent.) at 100° . (Büchner.)

Maleate of Zinc, $C^4H^2ZnO^4 \cdot 2H^2O$.—On boiling the aqueous acid with carbonate of zinc, and evaporating the filtrate at a gentle heat, gelatinous flocks are deposited, which become completely crystalline on standing. The solution when heated, deposits the salt in crystalline crusts. The crystals do not lose anything at 100° ; they are very soluble in water, but insoluble in alcohol. (Büchner.)

Substitution-derivatives of Maleic Acid.

Maleic acid does not yield substitution-products by the direct action of chlorine or bromine; but compounds have been obtained by indirect processes, having the composition of these substitution-products, and analogous to maleic acid in their properties.

Bromomaleic acids. These compounds are produced by the decomposition of the brominated derivatives of succinic acid.

Monobromomaleic acid, $C^4H^3BrO^4$.—Of this acid there are four modifications. One of them, usually called bromomaleic acid, is obtained, as an acid barium-salt, by boiling an aqueous solution of dibromosuccinate of barium:

Bromomaleic acid, obtained from this barium-salt in the usual way, crystallises readily in large nodules, formed of prismatic crystals. It melts between 125° and 126° , and is resolved, at about 150° , into water and bromomaleic anhydride, an oily liquid, which, after repeated rectification, boils at about 212° , and in contact with water is slowly reconverted into the acid.

Bromomaleic acid is converted by sodium-amalgam into succinic acid. It does not, like bromomaleic acid, yield tartaric acid when boiled with lime. When heated to 100°

with water and bromine, it yields a crystallisable, deliquescent acid, which appears to be dibromotartaric acid:

Bromomaleic acid is dibasic. Its salts usually form nodules of indistinct crystals. The silver-salt, $C^4HBrAg^2O^4$, separates, on mixing bromomaleate of ammonium with nitrate of silver, as a white amorphous precipitate, which may be crystallised without decomposition from boiling water. (Kekulé.)

Isobromomaleic acid. This acid, isomeric with the preceding, is produced by heating isodibromosuccinic acid to 180° , or by boiling and evaporating its aqueous solution:

also by boiling isodibromosuccinic anhydride with water.

Isobromomaleic acid, is very much like bromomaleic acid, but melts at a higher temperature, viz. 160° . Its silver-salt is easily decomposed by boiling with water.

Isobromomaleic anhydride, C^4HBrO^2 , is obtained, with evolution of hydrobromic acid, on heating isodibromosuccinic anhydride to 180° . It is crystallisable.

Two other acids having the composition of bromomaleic acid, viz. meta- and para-bromomaleic acid, are found, together with dibromosuccinic acid, in the most soluble portion of the secondary products resulting from the action of bromine on succinic acid. Both are crystallisable and very soluble in water. The former melts at 126° — 127° ; the latter at 172° . Their silver-salts are more stable than that of isobromomaleic acid.

Dibromomaleic acid, $C^4H^2Br^2O^4$.—This acid is produced, in small quantity, together with dibromosuccinic acid, and the two last-mentioned modifications of monobromomaleic acid, by the action of bromine on succinic acid. It is found in the last mother-liquors, and may be obtained therefrom by distillation and slow evaporation of the distillate. It is probably a product of the decomposition of previously formed tribromosuccinic acid.

Dibromomaleic acid crystallises in nodular groups of large needles. It is extremely soluble, and volatilises with the aqueous vapours. Melts at 112° . Its lead- and silver-salts are crystalline precipitates, which detonate when heated; the silver-salt, also, by percussion. (Kekulé, *Lehrbuch d. org. Chemie*, ii. 315.—Ann. Ch. Pharm. cxxxi. 1.)

Chloromaleic acid, C^4HClO^2 .—Obtained by the action of pentachloride of phosphorus on tartaric acid. When 1 pt. of tartaric acid is heated with 5 or 6 pts. of the pentachloride, large quantities of hydrochloric acid are evolved, together with oxychloride of phosphorus, which must be removed by prolonged heating to 120° in a current of air. The residue consists of oily chloride of chloromaleyl, $C^4HClO^2.Cl^2$, which is resolved by water into hydrochloric and chloromaleic acids.

The reaction may be explained as follows:—The first product of the action of pentachloride of phosphorus on tartaric acid is the tetrachloride of the radicle of that acid:

Tartaric acid.

Tetrachloride
of tartryl.

and this tetrachloride, which is identical with dichloride of dichlorosuccinyl, is resolved by heat (in a manner analogous to the decomposition of isodibromosuccinic acid, already mentioned) into hydrochloric acid and dichloride of monochloromaleyl:

Dichloride of dichloro-
succinyl.

Dichloride of
chloromaleyl.

Chloromaleic acid forms white microscopic needles, soluble in water and fusible by heat. It is dibasic. The lead- and silver-salts are crystalline precipitates. (Perkin and Duppa, Ann. Ch. Pharm. cxv. 105.)

Isomaleic acid, $C^4H^2O^4$.

Isomaleic acid (p. 794), treated with pentachloride of phosphorus, yields a chloride, which, when in contact with water, is converted into this acid, isomeric with maleic acid.

Isomaleic acid is crystallisable, less soluble in water than maleic acid, more soluble than fumaric acid. The neutral potassium-salt forms deliquescent crystals. The lead-salt is an amorphous precipitate. The silver-salt is very soluble in water, and its solution, when boiled, deposits metallic silver. (Kämmerer, J. pr. Chem. lxxxviii. 321; Jahresber. 1863, p. 379.)

MALEIC ANHYDRIDE. $C^4H^2O^2 = C^4H^2O^2.O$. (Pelouze, Ann. Ch. Pharm.

MALIC ACID.

i. 263.—Kekulé, *Ann. Suppl.* ii. 87.)—This compound is obtained by rapidly distilling maleic acid, and rectifying the product several times, the first portion of the distillate being each time rejected. It is a white crystalline mass, which melts at 87°, and boils at 196°. In contact with water it is converted into maleic acid.

Maleic anhydride unites directly with bromine, producing a substance which has the composition of dibromosuccinic anhydride, $C^4H^2Br^2O^3$, is converted by water into isodibromosuccinic acid, and is resolved at 180° into hydrobromic acid and isobromomaleic anhydride. (Kekulé.)

MALIC ACID. $C^4H^4O^5 = \left\{ \begin{smallmatrix} (C^4H^3O^3) \\ H^1 \end{smallmatrix} \right\} O^2$. (Gm. x. 205.—Gerh. i. 787.)—This acid was discovered by Scheele in 1785, but its composition was first correctly determined by Liebig (*Ann. Ch. Pharm.* xxvi. 166). It is very widely diffused in the vegetable kingdom, and is contained in plants, sometimes in the free state, sometimes in the form of a potassium-, calcium-, or magnesium-salt. It is found in abundance, together with citric acid, in unripe apples, in the fruits of the barberry, sloe, elder, and mountain-ash, and in gooseberries, cherries, bilberries, strawberries, raspberries, and many other acid fruits. It is likewise found in the roots of marsh-mallow, angelica, aristolochia, bryony, liquorice, primrose, and madder; in carrots and potatoes; in the leaves and stems of aconite, belladonna, hemp, celandine, holy thistle, lettuce, tobacco, poppy, rue, sage, house-leek, tansy, thyme, valerian and niellot; in the flowers of chamomile, elder, and mullein; in pine-apples and grapes; in the seeds of caraway, cumin, parsley, anise, flax, and pepper; in asafetida, opopanax, myrrh, &c.

Malic acid, as it exists in plants, exerts a rotatory action on polarised light. An acid having exactly the same composition and properties, including the rotatory power, is produced, according to Piria (*Ann. Ch. Phys.* [3] xxii. 160), by the action of nitrous acid on asparagin or on active aspartic acid; but, by acting with nitrous acid upon inactive aspartic acid (produced by the metamorphosis of fumarimide), Pasteur has obtained a modification of malic acid destitute of rotatory power (*Ann. Ch. Phys.* [3] xxxiv. 46).

Malic acid is found, according to Berzelius, among the residues of the preparation of nitrous ether. Debus (*Ann. Ch. Pharm.* c. 1) could not detect malic acid in these residues, but found instead, glyoxylic acid.

Preparation.—From the berries of the Mountain-ash. These likewise contain small quantities of tartaric and citric acid, especially while very unripe. (Liebig.)

The juice of mountain-ash berries, not quite ripe, after being pressed, boiled up and filtered, is partly neutralised with carbonate of potassium, leaving, however, a sufficient excess of acid to redden litmus pretty strongly; then precipitated by nitrate of lead (or with neutral acetate of lead, if carbonate of potassium is not used); set aside for a few days, till the curdy precipitate is completely converted into small needles; these crystals freed from the admixed mucous or flocculent compound of lead-oxide and colouring matter (which is particularly abundant when acetate of lead is used) by careful elutriation with cold water; and, lastly, well washed with water.—a. The needles are boiled with a quantity of dilute sulphuric acid not sufficient to decompose the whole of them, as long as any granular deposit continues to subside; the uniform pulpy mass mixed with aqueous sulphide of barium, till a filtered sample is found to contain baryta; the liquid filtered (the sulphide of lead then acting as a decolorising agent); the colourless filtrate boiled with excess of carbonate of barium; the liquid again filtered (tartrate and citrate of barium remaining on the filter); the baryta precipitated from the filtrate by careful addition of dilute sulphuric acid; and the filtrate, which should show no turbidity, either with sulphuric acid or with chloride of barium, evaporated to the crystallising point. If the filtrate should become turbid on addition of sulphuric acid, it must be evaporated down, the residue exhausted with alcohol; the liquid filtered from the remaining malate of barium; and again evaporated.—b. Or the needles of impure malate of lead are boiled with a slight excess of dilute sulphuric acid; the filtrate divided into two equal portions; one portion exactly neutralised with ammonia; the other portion then added; and the reddish liquid evaporated and cooled; it then yields nearly colourless crystals of acid malate of ammonia, which may be rendered quite colourless by recrystallisation. These crystals are then precipitated by acetate of lead, and the precipitate, after thorough washing, is decomposed by sulphydric or sulphuric acid. (Liebig.)

By similar processes, malic acid may be obtained from house-leek, from cherries or barberries, from the berries of *Rhus coriaria*, from the stems of rhubarb, from apples, and from tobacco.

Properties.—The aqueous solution of malic acid concentrated to a syrup, and then left to evaporate in a warm place, yields groups of colourless shining needles or prisms of 4 or 6 faces. They melt at 83° C. (Pelouze), at 100° (Pasteur), and do not

suffer any loss of weight at 120°. They are odourless, have a sour taste, and deliquesce in the air. Malic acid is soluble in alcohol.

The aqueous solution of active malic acid rotates the plane of polarisation of a luminous ray to the left: $[\alpha] = -5^\circ$. Some of its salts possess dextro-rotatory, others levo-rotatory power. The presence of acids, whether mineral or organic, increases the tendency to levo-rotation. (Pasteur.)

Decompositions.—1. The acid heated for some hours to between 175° and 180° in a retort placed in the oil-bath, is resolved, without any evolution of gas or carbonisation, into water, maleic acid, which passes over in the liquid form with the water, and crystallises soon afterwards, and about an equal quantity of fumaric acid (ii. 741), part of which distils over, while the rest remains in the retort in the form of a crystalline mass. If the malic acid be suddenly heated to 200°, and kept for some time at that temperature, a comparatively large quantity of maleic acid is obtained; but at 150°, the malic acid is very slowly, but almost completely, resolved into water and fumaric acid. The first product of the decomposition perhaps consists entirely of maleic acid, which, however, if the heat be not quickly raised to the point of volatilisation, is converted into fumaric acid. (Pelouze.)

If a strong fire be made to act immediately on the malic acid, it swells up, turns brown, and yields, together with maleic and fumaric acids, large quantities of carbonic oxide and carbonic anhydride, empyreumatic oil, and charcoal, which must be regarded as decomposition-products of the maleic and fumaric, not of the malic acid. (Lassaigne).—2. In the open fire, the acid burns with the odour of burnt sugar.—3. The acid in combination with potash is decomposed by bromine, with formation of bromoform (Cahours, Ann. Chim. Phys. [3] xix. 507).—4. Nitric acid easily converts it into oxalic acid, with evolution of carbonic anhydride.

5. By the action of *reducing agents* it is converted into succinic acid. The reduction takes place readily on heating it with concentrated *hydriodic acid* to 130° (Schmitt, Ann. Ch. Pharm. cxiv. 106); also when malate of calcium is fermented in contact with yeast. (Piria, *ibid.* lxx. 102; Liebig, *ibid.* 104, and 363.)

6. By slow oxidation in the cold with *acid chromate of potassium*, it is converted into malonic acid (Dessaignes, Ann. Ch. Pharm. cvii. 251):

When heated with chromate of potassium and sulphuric acid, it gives off all its carbon as carbonic anhydride (Döbereiner). Boiled in dilute aqueous solution with *peroxide of manganese*, it yields a distillate containing aldehyde (Liebig, Ann. Ch. Pharm. cxiii. 14).

7. Malic acid gently heated with excess of *potassic hydrate*, is resolved into oxalic and acetic acids:

When malate of calcium (1 pt.) is heated with *pentachloride of phosphorus* (4 pts.), chloride of fumaryl passes over (Perkin and Duppa *ibid.* cxii. 24). When malic acid (1 at.) is heated with the pentachloride (2 at.) till it begins to turn brown, and the product is decomposed with water, fumaric acid is obtained. (Liës-Bodart, *ibid.* c. 327.)

MALATES.—Malic acid, though most probably triatomic, as shown by the constitution of its amides (p. 796), contains only 2 at. hydrogen replaceable by metals. It

may therefore be conveniently represented by the formula $\left. \begin{array}{c} \text{H} \\ \text{C}^2\text{H}^3\text{O}^2 \end{array} \right\} \text{O}^2$ (similar to that

of glycollic acid, which is diatomic but monobasic), and the neutral and acid malates

by the formulæ $\left. \begin{array}{c} \text{H} \\ \text{C}^2\text{H}^3\text{O}^2 \end{array} \right\} \text{O}^2$, and $\left. \begin{array}{c} \text{H} \\ \text{C}^2\text{H}^3\text{O}^2 \end{array} \right\} \text{O}^2$. Malic acid has a great tendency to form

acid salts.

The active and inactive modifications of malic acid yield respectively active and inactive salts. The former sometimes exhibit hemihedral modifications; the latter are always holohedral.

The malates heated to 200° give off water, and are converted into fumarates:

Nearly all malates are soluble in water. A solution of the acid or of a malate is not precipitated by *lime-water* or *chloride of calcium*, either in the cold or on heating; but on the addition of alcohol, a white precipitate of calcic malate separates. Neutral malate of calcium is also precipitated by long boiling of a solution of malic acid, nearly

neutralised with milk of lime. With acetate of lead, malic acid forms a white precipitate soluble in excess of malic acid and in ammonia: this precipitate when heated in the mother-liquid, melts to a semifluid, transparent mass. Malates are not blackened by heating with fuming sulphuric acid; this reaction distinguishes malic from citric and tartaric acids.

Malates of Aluminium.—The neutral salt is a transparent gum, which reddens litmus slightly, is permanent in the air, and dissolves readily in water, forming a solution which is not precipitated by potash or ammonia. There is also a basic salt sparingly soluble in water.

Malates of Ammonium.—*a.* The neutral salt is very soluble and uncrystallisable.

β. The acid salt, $C^4H^3(NH^4)O^5$, is prepared by treating malate of lead with dilute sulphuric acid, taking care to avoid an excess of acid, filtering, dividing the liquid into two parts, saturating one with ammonia, then adding the other, and evaporating to a syrup. The salt prepared with optically active malic acid crystallises in fine transparent prisms, belonging to the trimetric system, with well-defined and strongly reflecting faces. Ordinary combination, $\infty P : \infty P \infty : \frac{1}{2} P \infty$, sometimes with hemihedral

faces $\frac{P}{2}$. Inclination of the faces, $\infty P : \infty P = 71^\circ 36'$; $\frac{1}{2} P \infty : \frac{1}{2} P \infty$, in the plane of the brachydiagonal and vertical axis = $137^\circ 35'$; $P \infty : P \infty$ in the same plane = $103^\circ 36'$. Cleavage easy, perpendicular to the faces ∞P . The salt, when crystallised from pure water, or from water acidulated with nitric acid, is never hemihedral; but the crystals acquire that character when melted till they begin to decompose, and then recrystallised. It would appear, therefore, that the action of heat gives rise to the formation of small quantities of products which induce the development of hemihedral faces. Specific gravity of the crystals = 1.55 (that of water at $12.5^\circ = 1$). The crystals dissolve in 3.11 pts. of water at 15.7° . The solution deflects the plane of polarisation to the left: rotatory power for 100 millimetres: $[\alpha] = -6^\circ$ or -7° . If the salt is dissolved in nitric acid, it becomes dextro-rotatory: $[\alpha] = +5.6^\circ$. By dry distillation, it gives off water, and leaves an insoluble residue of fumarimide (ii. 746). Ammonia escapes, however, together with the water, and the residue contains fumaric and malic acids, together with malic acid both active and inactive.

The acid ammonium-salt of inactive malic acid forms two kinds of crystals.—(*a*) The solution when evaporated first yields crystals having the same composition as the active ammonium-salt, and the same form, with exception of the hemihedral faces, which are absent.—(*b*) The mother-liquor separated from these crystals deposits, after a while, large, hard, transparent crystals containing 2 at. water more than the salt *a*, and belonging to the monoclinic system. Ordinary combination, $\infty P : [\infty Pn] : [P\infty]$. Inclination of faces, $\infty P : \infty P$ in the plane of the clinodiagonal and principal axis = $124^\circ 19'$; $[\infty Pn] : \infty P = 149^\circ 33'$; $[P\infty] : [P\infty]$ in the plane of the clinodiagonal and principal axis = $127^\circ 20'$; $[P\infty] : \infty P = 85^\circ 22'$ and $119^\circ 22'$. Angle of the inclined axes = $110^\circ 56'$. No hemihedral faces. Inactive acid malate of ammonium is decomposed by heat in the same manner as the active salt.

Active acid malate of ammonium unites in atomic proportion with acid dextro-tartrate of ammonium; the inactive salt does not.

Malates of Antimony.—The neutral salt has not been obtained.

Malate of Antimony and Ammonium is obtained, according to Pasteur, by boiling a solution of acid malate of ammonium with antimonious oxide. The liquid left to evaporate yields the double salt in large crystals, having the hemihedral faces very fully developed. The solution is dextro-rotatory; for 100 millimetres: $[\alpha] = +115.47^\circ$.

Malate of Antimony and Potassium is obtained in the crystalline state by saturating acid malate of potassium with antimonious oxide. Neither of these double salts has been analysed.

Malates of Barium. *a.* Neutral salt, $C^4H^2Ba^2O^5 \cdot 2H^2O$?—It is difficult to saturate malic acid with carbonate of barium, so completely that the liquid shall no longer reddens litmus-paper. The solution evaporated in a vacuum deposits transparent plates neutral to test paper, and giving off 10.6 per cent., water at 220° . The solution when boiled deposits white crusts of the anhydrous salt, having no appearance of crystallisation; they are absolutely insoluble in water whether cold or boiling, but dissolve rapidly on adding a trace of nitric acid; the solution thus formed is not precipitated by ammonia.

β. Acid-salt.—Uncrystallisable and more soluble than the preceding.

Malates of Calcium. *a.* Neutral salt, $C^4H^2Ca^2O^5$.—1. Malic acid does not become turbid on addition of excess of lime-water (Braconnot, Ann. Ch. Phys. [2] li. 321; Lassaigne); not even in concentrated solutions and on the application of heat,—*a*

character by which malic is distinguished from citric acid (H. Rose, Pogg. Ann. **xxi.** 210; Winckler). The acid neutralised with lime-water yields on evaporation in vacuo (an acid mother-liquid remaining) large, thin, shining laminae, which dissolve readily in water, and after drying in vacuo at ordinary temperatures, give off all their water = 17 per cent. (2 at.) at 180°, and about half of it at 100°. Their aqueous solution, when left to evaporate in the air, again yields laminae, but when heated to the boiling point, deposits a white, granular, nearly insoluble salt with 1 at. water. Hence the laminae, in parting with half their water, likewise lose their solubility. (Richardson and Menzendorf, Ann. Ch. Pharm. **xxvi.** 135.)

2. Dilute malic acid agitated in the cold with excess of carbonate of calcium, remains strongly acid; but the filtrate, when boiled, coagulates to a pulp composed of granules of the monohydrated neutral-salt, which is nearly insoluble in water and in aqueous malic acid (Richardson and Menzendorf). From the solution thus obtained, the neutral salt separates in four-sided prisms, which grate between the teeth, dissolve in 83 pts. of cold and a somewhat smaller quantity of hot water (Lassaigne); or as a granular powder of anhydrous salt, which is nearly insoluble both in hot and in cold water. (Hagen, Ann. Ch. Pharm. **xxviii.** 257.)

3. The same granular powder is thrown down from the aqueous solution of the acid salt by several hours' boiling. (Hagen.)

4. A mixture of aqueous chloride of calcium and neutral malate of sodium deposits, after a while, the neutral malate of calcium, in transparent crystalline grains. This salt scarcely froths up in the fire; it is completely decomposed by the soluble alkaline carbonates. It dissolves in 147 pts. of cold water, forming a solution which tastes somewhat like nitre, and in at most 65 pts. of boiling water, from which it does not separate on cooling. (Braconnot.)

5. The solution of acid malate of calcium neutralised with a soluble alkaline carbonate, yields, by evaporation at a gentle heat, hard shining crystals of the neutral salt, which contain 3 at. water, give off 1 at. water at 100°, assuming the appearance of porcelain, and are completely dehydrated at 150°. (Hagen.)

6. The granular salt, left to itself in the moist state for two days, takes up water, and is converted, under circumstances not yet determined, into rough, translucent, globular crystals, which, after drying in the air, whereby they are rendered opaque, give off 22.49 per cent. (3 at.) water at 200°. (Dessaignes and Cathaud, J. Pharm. [3] **xiii.** 243.)

Neutral malate of calcium is easily obtained in the crystalline state by dissolving the acid malate in ammonia, and leaving the solution to evaporate. If the solution is dilute, an abundant crop of crystals is obtained in 24 hours; but if the salt is dissolved in hydrochloric acid, and ammonia then added in excess, it takes a considerable time to crystallise.

The crystalline form of this salt is hemihedral, and it produces dextro-rotation, whether dissolved in water or in hydrochloric acid. (Pasteur.)

Neutral malate of calcium, kept for some months under a shallow layer of water in a vessel covered with paper, is converted into succinate (Dessaignes). During the winter, crystallised hydrated carbonate of calcium and a mucous organisation are likewise produced; but in the summer months, the sole product consists of needles of succinate of calcium, which gradually rise above the diminishing malate of calcium, while a small quantity of gas is given off. (Dessaignes, Compt. rend. **xxviii.** 16.)

When a mixture of 4 pts. of malate of calcium, 24 pts. of water, and 1 pt. of yeast (or a smaller quantity of putrefying cheese or fibrin) is set aside in a warm place, a tolerably brisk evolution of pure carbonic anhydride takes place, the muddy calcium-salt begins in the course of three days to become granular and heavy, and after the evolution of gas is terminated, appears under the microscope to consist of transparent needles united in stellate groups, and composed of succinate and carbonate of calcium. The supernatant liquid contains acetate of calcium.

If too much yeast or cheese is used, or if the mixture becomes too hot, hydrogen gas is evolved as well as carbonic anhydride, and possibly in equal volume; and in that case there is obtained but little succinic and acetic, but a large quantity of butyric acid, and a colourless, volatile oil, smelling of apples, which may be obtained by distilling the liquid; this oil dissolves readily in water, and may be separated therefrom by chloride of calcium or carbonate of potassium: it, however, dissolves a larger quantity of chloride of calcium in the dry state. For the fermentation in which succinic and acetic acid are produced, and pure carbonic anhydride is evolved, the equation is:

For the fermentation, when hydrogen is evolved:

or, if the evolution of hydrogen is consequent on the decomposition of succinic acid:

Part of the carbonic acid remains with the lime. (Liebig, Ann. Ch. Pharm. lxx. 104, and 363.)

According to E. J. Kohl (Ann. Ch. Pharm. lxxviii. 252), malate of calcium fermented with putrefying casein gives off nothing but carbonic anhydride, and yields principally lactate of calcium, with small quantities of succinate, acetate, and carbonate. W. Baer (Arch. Pharm. [2] lxi. 147) obtained a similar result with the juice of mountain-ash berries, neutralised with carbonate of calcium, mixed with beer-yeast, and left to stand at ordinary temperatures. Winckler (Jahrb. pr. Pharm. xxii. 300) found a large quantity of lactic acid in the acid residue of cider, and supposes it to have been formed by fermentation of the malate of calcium contained in the juice of the apples. Rebling (Arch. Pharm. [2] lxvii. 300) observed that, in the fermentation of malate of calcium, valerianic acid is formed as well as succinic and butyric acids.

When a solution of inactive malic acid is neutralised with lime-water, no turbidity is produced; but on addition of alcohol, the neutral calcium-salt is deposited in white amorphous flakes. On boiling the neutralised aqueous solution, a granulo-crystalline precipitate is formed, having the composition $\text{C}^4\text{H}^4\text{Ca}^1\text{O}^5$, and but sparingly soluble in water, either hot or cold. When a solution of acid malate of ammonium containing the inactive acid is mixed with a soluble calcium-salt and excess of ammonia, no precipitate is formed at first, but after 24 hours, transparent crystals united in nodules are formed, containing $2\text{C}^4\text{H}^4\text{Ca}^1\text{O}^5$. 5aq. (Pasteur.)

β. Acid salt, $\text{C}^4\text{H}^4\text{Ca}^1\text{O}^5 \cdot 8\text{H}^2\text{O}$.—This salt may be prepared from the stems of *Ceranium zonale* (Braconnot). Also from the berries of *Rhus glabra* or *copallinum*, by exhausting them with hot water, evaporating the infusion, decolorising it with animal charcoal previously purified with hydrochloric acid, evaporating the filtrate further, setting it aside to crystallise, and purifying the resulting crystals, if necessary, by recrystallisation (Rogers, Sill. Am. J. xxvii. 294). Tobacco also contains it in large quantity. The solution of the neutral salt in warm dilute nitric acid, deposits the acid salt in crystals on cooling. (Hagen.)

The crystals of the salt prepared with the active acid belong to the trimetric system. Ordinary combination, $\infty\text{P} : \infty\text{Pn} : \infty\text{P}\infty : \text{mP}\infty$. Inclination of the faces, $\infty\text{P} : \infty\text{P} = 93^\circ 26'$; $\infty\text{P} : \infty\text{Pn} = 162^\circ 14'$; $\infty\text{P}\infty : \infty\text{P} = 133^\circ 17'$; $\infty\text{P}\infty : \text{P}\infty = 136^\circ 33'$; $\text{P}\infty : \text{mP}\infty = 163^\circ 30'$. Cleavage easy parallel to $\infty\text{P}\infty$. When crystallised from pure water, it does not exhibit hemihedral faces; but when crystallised from

nitric acid, all the crystals have four faces $\frac{\text{mP}}{2}$, and for a certain concentration of the

acid, these facets become so much developed as nearly to obliterate the principal faces of the crystal. The crystals dissolve in 50 pts. of cold water, and in a much smaller quantity of boiling water: they are insoluble in absolute alcohol. They give off 22.37 per cent. (nearly 3 at.) water at 100° , and are completely dehydrated at 180° .

The inactive salt resembles the preceding in every respect, excepting that it has no hemihedral faces.

According to Braconnot, acid malate of calcium saturated with alkaline carbonates yields double salts, viz. *ammonio-, potassio-, and sodio-calcic malates*; but they have not been analysed.

Malates of Copper.—*a.* The neutral salt, $\text{C}^4\text{H}^4\text{Cu}^1\text{O}^5 \cdot \text{H}^2\text{O}$, is a gummy mass of a fine green colour, and very soluble in water.

B. The acid salt, $\text{C}^4\text{H}^4\text{Cu}^1\text{O}^5 \cdot 2\text{H}^2\text{O}$, is obtained in fine blue crystals, by saturating the cold aqueous acid with cupric hydrate and evaporating at 40° .

γ. A basic salt, $2\text{C}^4\text{H}^4\text{Cu}^1\text{O}^5 \cdot \text{Cu}^1\text{O} \cdot 4\text{H}^2\text{O}$, is obtained, as a green insoluble powder, by boiling malic acid in excess with cupric carbonate. The carbonate treated in the cold with excess of malic acid dissolves in considerable quantity, and the solution, when boiled, immediately deposits the salt just mentioned; but if evaporated in a vacuum between 40° and 50° , it deposits dark green crystals containing the same proportion of malate and oxide of copper with 6 at. water.

A mixture of cupric sulphate and malate of ammonium deposits by spontaneous evaporation, first crystals of cupric sulphate, then green acicular crystals unalterable in the air, of a double salt, consisting of cupric malate and sulphate of ammonium. (H. Schulze, Arch. Pharm. [2] lvii. 273.)

Malate of Iron (ferricum).—Both the neutral and acid salts are brown, gummy, permanent in the air, very soluble in water and in alcohol. A solution of a ferric salt containing malic acid is not precipitated by alkalis.

Malates of Lead.—*a.* The neutral salt, $\text{C}^4\text{H}^4\text{Pb}^1\text{O}^5 \cdot 3\text{H}^2\text{O}$, is obtained by precipitating neutral acetate of lead with a solution of calcic or potassic malate; it is a

white curdy precipitate, which, when left for some hours in a solution of the acetate, is converted into four-sided needles grouped around a common centre. This salt melts in boiling water to a transparent pitchy mass; it is very slightly soluble in cold, more soluble in boiling water; a strong aqueous solution deposits it in shining needles. It dissolves very easily in nitric acid; acetic acid and malic acid do not dissolve it more freely than pure water. Acetate of lead also dissolves the malate, and deposits it by slow evaporation in silky needles.

According to R. Otto (Ann. Ch. Pharm. cxxviii. 175), a neutral malate of lead having, after drying at 100° , the composition $C^4H^4Pb^1O^5.H^2O$, is obtained by dropping a partly neutralised solution of malic acid into an excess of boiling aqueous solution of basic acetate of lead, boiling for several hours with de-aerated water, and washing by decantation.

Both the active and inactive malates of lead melt with equal facility in boiling water; the only difference observed between the two modifications is that the inactive salt takes a longer time than the active salt to become crystalline, the latter, which is amorphous at the time of precipitation, being converted into needle-shaped crystals in a few hours, whereas the inactive salt may remain amorphous for several days. This character may serve to distinguish between the two salts, when only small quantities of them are at hand. Both salts melt immediately on being immersed in boiling water, but a portion dissolves and is precipitated when the liquid cools and is left at rest; the active malate is then deposited after 24 hours in shining prisms grouped in tufts; the inactive salt, on the contrary, is deposited in the amorphous state, and covers uniformly the sides of the vessel; but after a few days, this amorphous precipitate disappears, and is replaced by needle-shaped crystals, also grouped in tufts, and exactly resembling those of the active malate. (Pasteur.)

Malate of lead in the amorphous state easily parts with the whole of its combined water (14 per cent. = 3 at.) when dried over sulphuric acid. If the salt is crystallised, the water is retained with greater force, and it must be heated to about 150° to dehydrate it.

Neutral malate of lead, which melts easily when thrown into boiling water, does not melt in the hot air chamber, either at 100° or at a higher temperature. It even retains its crystalline aspect up to 170° , in spite of the loss of its water of crystallisation, and only then begins to assume a dull woolly aspect. When heated to 220° , it gives off more water, and is converted into fumarate of lead.

B. A basic salt, $Pb^1O.2C^4H^4Pb^1O^5$, is obtained by digesting the neutral salt with ammonia, or by pouring acetate of lead into the solution of a malate mixed with ammonia, or, according to Otto (*loc. cit.*), by dropping a perfectly neutralised solution of malic acid into excess of a boiling solution of basic acetate of lead. It never becomes crystalline, and does not melt in boiling water, but if acetic acid be added, it melts, with considerable diminution of volume, being then evidently converted into the neutral salt.

Basic malate of lead dissolves in acetate of lead, like the neutral salt, and the solution, if somewhat concentrated, is precipitated by ammonia. It is nearly insoluble in water, either cold or boiling; but sufficiently soluble to blue red litmus paper, when a few moist fragments are placed upon it.

Malates of Lithium.—Both the neutral and acid salt are uncrystallisable.

Malates of Magnesium.—*a.* Neutral salt, $C^4H^4Mg^1O^5.5H^2O$. A dilute solution of malic acid boiled with magnesia yields a liquid which, when evaporated to a pellicle, deposits after some time, rhomboidal prisms of this salt, containing 5 at. water, four of which are given off at 100° . Alcohol added to the concentrated solution precipitates it in anhydrous flocks, which become pasty by heat.

B. The acid salt, $C^4H^4Mg^1O^5.4H^2O$, is obtained in flattened prisms, by half saturating malic acid with carbonate of magnesium, and evaporating to crystallisation. It gives off half its water at 100° , and melts at a higher temperature.

Malates of Manganese.—*a.* The neutral salt, which is uncrystallisable and very soluble, is obtained by saturating the acid with carbonate of magnesium. The acid salt is precipitated as a white powder, on adding malic acid to a solution of the preceding salt. It dissolves in 41 pts. of cold water, and is deposited from boiling water in transparent rose-coloured crystals.

Malates of Mercury.—These salts have not been analysed. When malic acid is digested with mercurous oxide, a crystalline powder is formed. The same salt is obtained on mixing malate of potassium with a dilute solution of mercurous nitrate. It is decomposed by boiling with water.

When mercuric oxide is boiled with a strong solution of malic acid, the filtered

liquid deposits small crystals of an acid salt soluble in water; with excess of mercuric oxide, an insoluble yellow basic salt is formed. (Harff, Arch. Pharm. [3] v. 281.)

Malate of Potassium.—*a. Neutral.* Uncrystallisable, deliquescent, insoluble in strong alcohol (Braconnot).—*β. Acid.* Crystals, permanent in the air, soluble in water, insoluble in alcohol. (Donovan.)

Malate of Silver, $C^4H^4Ag^2O^8$.—Nitrate of silver forms, with a solution of neutral or acid malate of ammonium, a white granular precipitate, which becomes yellow when thoroughly dried. If heated after drying, it melts and decomposes, swelling up a little, emitting an empyreumatic odour, and leaving perfectly white metallic silver. The acid malate of silver has not been obtained.

Malates of Sodium.—The neutral salt is uncrystallisable. The acid salt is crystalline, permanent in the air, soluble in water, insoluble in alcohol.

Malates of Strontium. *a. Neutral salt,* $C^4H^4Sr^2O^8.H^2O$ (at 100°).—Malic acid is not rendered turbid by strontia-water; but, on evaporating the mixture, a crystalline mass is obtained, very soluble in water. When malic acid is digested with carbonate of strontium, a solution is obtained which slightly reddens turmeric, and deposits after concentration mammellated groups of crystals having the above composition.

β. An acid salt is precipitated in the crystalline state on adding malic acid to an aqueous solution of the neutral salt; it is but slightly soluble in cold water, more soluble in boiling water.

Malate of Thallium crystallises with difficulty; it is deliquescent, and melts below 100° . (Kuhlmann.)

Uranic Malate.—Yellow; sparingly soluble in water. (Richter.)

Malate of Yttrium.—1. When an aqueous solution of malic acid is poured upon carbonate of yttrium, part of the resulting salt dissolves, and is obtained by evaporation in small white nodules.—2. Neutral alkaline malates throw down from yttrium-salts—when the solutions of the two salts are concentrated and mixed in due proportion—a white, almost crystalline powder, which remains in white granules when its aqueous solution is evaporated.—The air-dried salt is $C^4H^4Y^2O^8.H^2O$. It does not give off its water at 110° , and is but slowly decomposed at higher temperatures. It dissolves in 74 pts. of water; its solution in aqueous malic acid deposits the neutral salt unchanged. It dissolves abundantly in aqueous malate of sodium, and does not crystallise on evaporation. (Berlin.)

Malates of Zinc. *a. Neutral salt,* $C^4H^4Zn^2O^8.3H^2O$.—When the aqueous acid is saturated with carbonate of zinc at a temperature below 30° , the filtrate deposits, after a while, small shining crystals which gradually but completely give off their 3 at. water at 100° (Hagen). When, on the other hand, the acid is saturated at a high temperature, and the solution filtered from a basic salt which separates on cooling, and further evaporated, crystals are deposited, containing indeed 3 at. water, but having a different form, and obstinately retaining about $\frac{3}{4}$ at. water at 100° (Hagen). They are short hard, strongly lustrous, four-sided prisms (square, according to Lassaigne), perpendicularly truncated, or bevelled with two faces; they redden litmus (Braconnot). They become opaque at 100° , giving off 10 p. c. of water, and at 120° swell up and crumble to a white powder, giving off at the same time 10 p. c. more water (Liebig). They dissolve in 55 pts. (67 pts. at 20° , according to Lassaigne) of cold, and 10 pts. of boiling water, from which the salt does not separate on cooling. (Braconnot.)

β. Acid salt, $C^4H^4Zn^2O^8.4H^2O$.—Obtained by supersaturating the salt *a* with the acid, and washing the resulting crystals with alcohol. It forms elongated square-based octahedrons, which swell up when heated, giving off 8.33 per cent. water, and are converted into a gum; they dissolve in 23 pts. of cold water. (Braconnot.)

γ. Basic salt, $Zn^2O.2C^4H^4Zn^2O^8.4H^2O$.—This salt remains, on dissolving the neutral salt in water, as a crystalline residue, containing 48.11 per cent. zinc-oxide (Braconnot). The solution obtained by continuous boiling of the aqueous acid with carbonate of zinc, solidifies on cooling to a tremulous jelly, which by prolonged boiling with water is converted into a sandy powder. This powder is not decomposed by water at 100° , but at 200° it gives off water, and is partially converted into fumarate of zinc. (Hagen.)

Bromomalic acid. $C^4H^4BrO^8$.—No substitution-products have yet been obtained from malic acid; but when an aqueous solution of dibromosuccinate of sodium is boiled, and then evaporated, a mass of crystals is obtained, having the composition of acid bromomalate of sodium, $C^4H^4BrNaO^8$. From this salt, other bromomalates may be formed by double decomposition; but the acid itself has not yet been obtained.

Acid bromomalate of sodium is distinguished from the bromomaleate (p. 787) and its isomers, by yielding tartrate of calcium when boiled with lime-water. (Kekulé, *Lehrbuch*, i. 185.)

MALIC ACID, AMIDES OF.

Isomalic acid, $C^4H^6O^5$.

An acid, isomeric with malic acid, and perhaps identical with diglycollic acid (ii. 912), the silver-salt of which was deposited from a photographic silver-bath, containing nitrate of silver and milk-sugar, which had been used for a long time for dipping papers soaked in succinic or citric acid. The free acid separated by sulphydric acid from the silver-salt, forms a crystalline mass, or by slow crystallisation, transparent, well-developed crystals resembling those of augite. The acid ammonium-salt, $C^1H^4(NH^4)^+O^2.2H^2O$, remains, on evaporating the neutralised acid with ammonia, as a radio-crystalline mass. The neutral potassium-salt, $C^1H^4K^2O^2.H^2O$, crystallises in monoclinic laminae. The lead-salt is a white precipitate, perfectly insoluble in water, and not melting or baking together in boiling water. The silver-salt, $C^1H^4Ag^+O^2$, which is flocculent at first, is converted, when warmed with water, into microscopic six-sided tables, which do not decompose at 100° . This salt, treated with iodide of ethyl, yields the neutral ethylic ether, $C^1H^4(C^2H^5)^+O^2$, as a colourless liquid, gradually decomposed by water.

The isomals, treated with pentachloride of phosphorus, yield a chloride isomeric with chloride of fumaryl, according to the equation:

This chloride is a liquid, which is partly decomposed by distillation, and, in contact with water, is resolved into hydrochloric acid and isomaleic acid, $C^H O^O$ (p. 788). (Kämmerer, J. pr. Chem. lxxxviii. 321.)

MALIC ACID, AMIDES OF. When ammonia is passed into an alcoholic solution of ethylic malate, small crystals of malamide are gradually deposited:

and when dry ethylic malate is saturated with ammonia-gas, the product soon solidifies to a crystalline mass of ethylic malamate or malamethane, $C^6H^{10}NO^4 =$

$$\left. \begin{array}{l} \text{H} \\ (\text{C}^1\text{H}^3\text{O}^2)'' \\ \text{C}^2\text{H}^5\text{H}^2 \end{array} \right\} \text{O}^2, \text{ the decomposition being represented by the equation :}$$

This latter compound, dissolved in alcohol and saturated with ammonia, likewise yields malamide.

Mulamide crystallises, by slow evaporation, in well-defined crystals. It differs from the metameric compound asparagine (i. 421) by its crystalline form, by not containing any water of crystallisation, and by its property of easily taking up water, and being thereby converted into ammonia and malic acid. It differs also in optical rotatory power: $[\alpha] = -47.5$. (Demondesir, Ann. Ch. Pharm. lxxx. 303.—Pasteur.)

Malamic acid, $C_4H_7NO_4$, which is metameric with aspartic acid (i. 422), has not been isolated.

If malic acid be regarded as triatomic and dibasic, and represented by the formula

$$\left. \begin{array}{c} \text{H} \\ \text{C}^{\text{H}}\text{H}^{\text{O}}\text{O}^2 \\ \text{H}^2 \end{array} \right\} \text{O}^8 \text{ (p. 790), in which two out of the three typic hydrogen-atoms are } \textit{saline},$$

that is, easily replaceable by metals, and the third, *alcoholic*, that is, most easily replaceable by acid-radicles (see ii. 915), the difference between malamic acid and malamide on the one hand, and aspartic acid and asparagine on the other, may be represented by formulae analogous to those of glycolic monamide (the so-called glycollamide, ii. 908) and glycocine (ii. 902), thus:

Aspartic acid bears the same relation to malic acid that glycocine bears to glycollic acid. The saline or basic hydrogen of malic acid is still present in aspartic acid, but the alcoholic water-residue HO of the malic acid is replaced in aspartic acid by the ammonia-residue NH⁺. Asparagine is the amide of aspartic acid. Hence it is that aspartic acid is not decomposed by boiling with alkalis (the ammonia-residue not being in the saline place), and that asparagine, when treated in the same way, gives off only half its nitrogen as ammonia, and is converted into aspartic acid. In malic acid, on

the other hand, the ammonia-residue occupies the saline place; and, consequently, when malamide, which is its amide, is boiled with alkalis, the decomposition does not stop at the formation of malamic acid, but goes on to the formation of malic acid and ammonia.

The neutral amide (triamide) of malic acid, $\left\{ \begin{smallmatrix} \text{H}^2 \\ (\text{C}^2\text{H}^2\text{O}^2)^{\text{'''}} \\ \text{H}^2.\text{H}^2 \end{smallmatrix} \right\} \text{N}^2$, is not known.

Malamic acid and malamide may be derived from the acid and neutral malates of ammonium by elimination of 1 and 2 at. water respectively, and, by further abstraction of water, the other compounds in the following table may be conceived to be formed, though only one of them, viz. fumarimide (ii. 746), has actually been obtained:

$\left\{ \begin{smallmatrix} \text{H} \\ (\text{C}^2\text{H}^2\text{O}^2)^{\text{'''}} \\ \text{H}^2.\text{N} \\ \text{H}^2.\text{N} \end{smallmatrix} \right\} \text{O}^2$	$\left\{ \begin{smallmatrix} \text{H} \\ (\text{C}^2\text{H}^2\text{O}^2)^{\text{'''}} \\ \text{H}^2 \\ \text{H}^2 \end{smallmatrix} \right\} \text{O}$	$\left\{ \begin{smallmatrix} \text{H} \\ (\text{C}^2\text{H}^2\text{O}^2)^{\text{'''}} \\ \text{H}^2 \end{smallmatrix} \right\} \text{N}^2$	$\left\{ \begin{smallmatrix} \text{H} \\ (\text{C}^2\text{H}^2\text{O}^2)^{\text{'''}} \end{smallmatrix} \right\} \text{N}^2$
Neutral malate of ammonium.	Malamide.	(unknown).	Nitrile (unknown).
$\left\{ \begin{smallmatrix} \text{H} \\ (\text{C}^2\text{H}^2\text{O}^2)^{\text{'''}} \\ \text{H}^2.\text{H}^2.\text{N} \end{smallmatrix} \right\} \text{O}^2$	$\left\{ \begin{smallmatrix} \text{H} \\ (\text{C}^2\text{H}^2\text{O}^2)^{\text{'''}} \\ \text{H}^2.\text{H}^2 \end{smallmatrix} \right\} \text{O}^2$	$\left\{ \begin{smallmatrix} \text{H} \\ (\text{C}^2\text{H}^2\text{O}^2)^{\text{'''}} \\ \text{H}^2 \end{smallmatrix} \right\} \text{N}$	$(\text{C}^2\text{H}^2\text{O}^2)^{\text{'''}}.\text{N}$
Acid malate of ammonium.	Malamic acid.	Malimide (unknown).	Nitrile (Fumarimide).

Malic acid was formerly regarded as diatomic as well as dibasic, being represented by the formula $\left\{ \begin{smallmatrix} \text{H}^2 \\ (\text{C}^2\text{H}^2\text{O}^2)^{\text{'''}} \end{smallmatrix} \right\} \text{O}^2$, which agrees perfectly with the constitution of its salts.

Moreover, the formulæ of malamic acid and malamide are easily derived from it; but then the so-called fumarimide cannot be supposed to contain the same radicle, but must actually be regarded as the imide of fumaric acid; thus:

$\left\{ \begin{smallmatrix} \text{H} \\ (\text{C}^2\text{H}^2\text{O}^2)^{\text{'''}} \\ \text{H} \end{smallmatrix} \right\} \text{O}^2$	$\left\{ \begin{smallmatrix} \text{H}^2 \\ (\text{C}^2\text{H}^2\text{O}^2)^{\text{'''}} \\ \text{H}^2 \end{smallmatrix} \right\} \text{N}^2$	$\left\{ \begin{smallmatrix} \text{H}^2 \\ (\text{C}^2\text{H}^2\text{O}^2)^{\text{'''}} \\ \text{H} \end{smallmatrix} \right\} \text{N}$	$\left\{ \begin{smallmatrix} \text{H}^2 \\ (\text{C}^2\text{H}^2\text{O}^2)^{\text{'''}} \\ \text{H} \end{smallmatrix} \right\} \text{N}$
Malic acid.	Malamide and asparagine.	Malamic acid and aspartic acid.	Fumarimide.

But the formation of this compound by heating acid malate of ammonium to 160°—200°, and its conversion into inactive aspartic acid by boiling with strong hydrochloric acid, show that it is intimately related to malic acid, and, therefore, that the triatomic formula of malic acid, which renders it possible to express fumarimide by a formula containing the same radicle as the acid, must be regarded as preferable (Kekulé). Moreover the relation of malic acid to succinic and tartaric acids cannot be adequately expressed by a diatomic formula.

Substances closely resembling fumarimide or malonitrile, are likewise obtained, according to Dessaignes, by the action of heat on acid fumarate and acid maleate of ammonium.

MALIC ACID, PHENYLATED AMIDES OF. These compounds have been more completely studied than the primary amides of malic acid; three of them have been obtained by Arppe (Ann. Ch. Pharm. xvi. 106), viz. diphenyl-malamide, phenyl-malimide, and phenyl-malamic acid.

Diphenyl-malamide. Malanilide. $\text{C}^{10}\text{H}^{10}\text{N}^2\text{O}^2 = \left\{ \begin{smallmatrix} \text{H} \\ (\text{C}^2\text{H}^2\text{O}^2)^{\text{'''}} \\ (\text{C}^6\text{H}^5)^2.\text{H} \end{smallmatrix} \right\} \text{O}^2$.—This compound is formed, together with phenyl-malimide, by melting malic acid with aniline:

The product treated several times with boiling water, is resolved into a nearly colourless solution containing phenyl-malimide, and a strongly coloured residue consisting chiefly of diphenyl-malamide, which may be obtained pure and colourless by crystallisation from boiling alcohol, with the aid of animal charcoal.

It forms colourless scales having a faint lustre; melts, with partial decomposition, at 175°, and at a higher temperature volatilises for the most part unaltered. When set on fire it burns with a bright smoky flame.

It is nearly insoluble in water, and in dilute hydrochloric acid, ammonia, and potash. It dissolves also but sparingly in alcohol and ether. Strong sulphuric acid dissolves it with the aid of heat. Nitric acid dissolves it in the cold, forming a yellow solution.

When boiled with strong caustic *potash*, it dissolves and is for the most part decomposed, a fatty substance rising to the surface of the liquid. On addition of water, the semifluid portion is converted into a white insoluble powder, which may be completely freed from potash by washing with water. This powder dissolves with some difficulty in alcohol, and crystallises therefrom in small crystalline groups and needles. It may be heated, without visible alteration, to 225° ; melts at a higher temperature; and if cautiously heated, yields a crystalline laminar sublimate, and leaves a small quantity of charcoal. This substance gives by analysis 64.17 per cent. carbon and 5.41 hydrogen: hence it appears to be *tartranilide*. (Arppe.)

Phenyl-malimide. Malanil. $\text{C}^6\text{H}^7\text{NO}^3 = \left(\begin{array}{c} \text{C}^6\text{H}^5 \\ \text{C}^6\text{H}^3\text{O}^2 \\ \text{H} \end{array} \right) \left\{ \begin{array}{c} \text{O} \\ \text{N} \end{array} \right.$ — Formed, together

with the preceding compound, by melting a mixture of malic acid and aniline. When the fused mixture is kept in a state of gentle ebullition for about two hours, a brown syrup is obtained, which solidifies on cooling, and when boiled with water, yields a nearly colourless solution of phenyl-malimide, and a coloured residue containing diphenyl-malimide. The solution when evaporated yields phenyl-malimide in the form of a granular mass, still, however, mixed with diphenyl-malimide, from which it is purified by digestion in hot water, and filtration. The solution is then further purified by treatment with animal charcoal, and evaporated to the crystallising point.

From a hot concentrated aqueous solution, phenyl-malimide separates on cooling in delicate needles grouped together; also when its alcoholic solution is evaporated; sometimes, however, it forms nacreous laminae, and from a very dilute aqueous solution it is deposited in very thin, iridescent, rectangular prisms. It melts at 170° , and when heated between two watch-glasses, forms a slight mealy sublimate. It dissolves very abundantly in water, alcohol, and ether.

Phenyl-malimide, boiled with aqueous ammonia, is converted into phenyl-malam to of ammonium.

It dissolves easily in the strongest nitric acid, forming a deep red solution from which water throws down a nearly colourless, indistinctly crystalline body, probably nitro-phenyl-malimide, accompanied by a resinous body which is very difficult to separate. The crystalline body dissolves easily in boiling water, and the solution on cooling yields fine needles. (Arppe.)

Phenyl-malamic acid. Malanilic acid. $\text{C}^6\text{H}^{11}\text{NO}^4 = \left(\begin{array}{c} \text{H} \\ \text{C}^6\text{H}^5\text{O}^2 \\ \text{C}^6\text{H}^3\text{H}^2 \end{array} \right) \left\{ \begin{array}{c} \text{O} \\ \text{N} \\ \text{O} \end{array} \right.$ — This

acid is obtained in the form of an ammonium-salt by boiling phenyl-malimide with aqueous ammonia (*vid. sup.*). The solution of this salt forms with baryta a copious precipitate, which, when mixed with a small quantity of water, and decomposed, with the aid of heat, by an exactly equivalent quantity of sulphuric acid, yields phenyl-malamic acid; and from the solution, filtered while yet warm, the acid crystallises on cooling, and may be purified by recrystallisation from alcohol. The slightest excess of sulphuric acid used in the preparation converts the phenyl-malamic acid into phenyl-malimide; hence it is best to use rather less than the equivalent quantity.

The acid crystallises in white, faintly lustrous granules, composed of very minute needles, and scarcely attaining the size of a pin's head; melts at 145° ; has a very sour taste, reddens litmus, and decomposes carbonates; dissolves readily in water, somewhat less in alcohol, and sparingly in ether. Its salts are also distinguished by their solubility in water.

The solution of the ammonium-salt remains clear when mixed with lime-water, but is slightly clouded by boiling with *potash*; with *acetate of lead*, it forms a white precipitate soluble in water; and with *sesquichloride of iron*, a precipitate of a fine yellow colour.

The barium-salt is very soluble in water, and crystallises in spherical nodules of a dazzling whiteness; it is insoluble in hydrochlorate of ammonia.

Phenyl-malamate of silver, $\text{C}^6\text{H}^{10}\text{AgNO}^4$, forms a white precipitate, which soon becomes coloured by exposure to light; it dissolves in water, and is deposited from the solution in shining cubes.

MALIC ETHERS. These compounds have not been much studied. According to Demondeir (Compt. rend. xxiii. 227), the malates of ethyl and methyl are produced by passing hydrochloric acid gas into a solution of malic acid in alcohol or wood-spirit. The neutral ethers cannot be distilled; they are obtained by neutralising the crude liquid with carbonate of sodium and agitating with common ether, which takes up the ethylic or methylic malate, and leaves it behind on evaporation. The

compound ether thus obtained still contains water and alcohol or wood-spirit, which may be removed by evaporation in a vacuum.

The neutral malates of ethyl and methyl are liquids which are soluble in water, almost completely decomposed by distillation, being converted into the corresponding fumaric ethers, and are converted into malamide by ammonia. They possess optical rotatory power.

Ethyl- and Methyl-malic acids are always formed by the above process simultaneously with the neutral ethers. Their calcium-salts are soluble in alcohol.

Amyl-malic acid, $C^4H^9(C^2H^3O^2)O^2$, is obtained by prolonged heating of malic acid with amyl-alcohol to 120° . It forms a syrup which crystallises on cooling. (Breunlin.)

MALOÏLE. Syn. with OIL OF APPLES (i. 532; ii. 636).

MALONIC ACID. $C^3H^4O^4 = (C^3H^3O^2)'' \left\{ O^2 \right.$ An acid discovered by Des-saignes (Ann. Ch. Pharm. cvii. 251), who obtained it by slowly oxidising malic acid with a cold solution of chromate of potassium:

It is also produced, with evolution of ammonia, by the action of alkalis on cyanacetic acid, or better on cyanacetic ether:

The solution obtained by boiling cyanacetic ether* with potash, forms with sulphate of copper, a green precipitate, which by decomposition with sulphydric acid, and evaporation of the filtrate, yields malonic acid. (Hugo Müller, Chem. Soc. J. xvii. 109.)

Malonic acid forms large rhombohedral crystals, having a laminary structure. It dissolves easily in water and alcohol, melts at 140° , and decomposes at 150° into carbonic anhydride and acetic acid.

The malonates have been but little examined. The neutral potassium- and ammonium-salts are deliquescent and crystallise with difficulty; the acid salts of the same bases crystallise readily. The barium- and calcium-salts are crystalline precipitates sparingly soluble in cold water. The silver-salt is insoluble and crystalline; the lead-salt is likewise insoluble.

An acid called nicotie acid, obtained by Barral (Compt. rend. xxi. 1374) from tobacco, has the composition of malonic acid, and is probably identical therewith. It crystallises in small scales, forms insoluble lead- and silver-salts, and is resolved by heat into carbonic anhydride and acetic acid.

MALT. Grain, chiefly barley, which has become sweet from the conversion of its starch into sugar, by an incipient growth or germination artificially induced, called malting. (See BEER, i. 527; also *Ure's Dict. of Arts, &c.* iii. 18)

MALTA. The mineral tallow of Kirwan, said to have been found on the coast of Finland. It resembles wax. Its specific gravity is 0.77. It is white, brittle, stains paper like oil, melts with a moderate heat, and burns with a blue flame and much smoke. It dissolves readily in oil, and imperfectly in hot alcohol.

MALTHACITE. See MONTMORILLONITE.

MALTOSE. This name is given by Dubrunfaut (Ann. Ch. Phys. [3] xxi. 178), to the sugar produced from starch-paste by the action of malt or diastase. It resembles dextro-glucose in crystalline form and most other respects, but its dextro-rotatory power is, according to Dubrunfaut, three times as great as that of dextro-glucose, and not stronger in a recently prepared solution than after the lapse of several hours (ii. 558). It appears also to be less easily altered by alkalis. It is converted into dextro-glucose by boiling with dilute sulphuric acid.

MANCINITE. A brown mineral from Mancino, near Leghorn, consisting, according to Jacquot (Ann. Min. [3] xix. 703), of sesquisulphate of zinc, $2ZnO.3SiO^2$. It is plumose and shining, with two unequal cleavages inclined to one another at 92° .

MANDELIC ACID. *Formo-benzoic acid*, $C^8H^8O^4$.—This acid, which con-

* The cyanacetic ether was obtained by the action of chloracetic ether on cyanide of potassium, or of iodoacetic ether on cyanide of silver.

tains the elements of bitter almond oil and formic acid, $C^6H^{10}O^6 = 2C^7H^8O + 2CH^2O^2$, and is related to benzoic acid (so far at least as composition is concerned) in the same manner as lactic to acetic acid, was discovered by Winckler (Ann. Ch. Pharm. xviii. 310), who obtained it by heating bitter almond water with hydrochloric acid, the hydrocyanic acid contained in the liquid being then resolved into ammonia and formic acid, which, at the moment of its formation, unites with the bitter almond oil (Liebig, Ann. Ch. Pharm. xviii. 39). It is also produced by the action of fuming sulphuric acid on bitter almond oil (Laurent, Ann. Ch. Phys. [2], lxx. 202), and by heating amygdalin with fuming hydrochloric acid. (Wöhler, Ann. Ch. Pharm. lxxi. 238.)

Preparation.—Bitter almond water.—obtained by distilling 80 oz. of bitter almond paste with 90 lbs. of water till 160 oz. have passed over, then taking 80 oz. of this liquid, and shaking up the distillate with the bitter almond oil—is mixed with 4 oz. of hydrochloric acid of specific gravity 1.12, and evaporated to dryness over the water-bath, till all the hydrochloric acid is expelled. The yellowish crystalline residue, smelling slightly of bitter almonds, leaves pure sal-ammoniac when treated with cold ether; and the ethereal solution yields by spontaneous evaporation a slightly yellow crystalline mass, which, when treated with water, leaves a resinous flocculent body having the odour of bitter almonds. The aqueous solution is transparent and colourless, and contains pure mandelic acid, which crystallises on evaporation (Winckler).—2. When bitter almond oil is treated with one-third of its volume of fuming sulphuric acid, heat is evolved, the liquid becomes brown and thick, and solidifies in a compact mass on cooling. The mass, when treated with water, yields an upper semi-solid layer containing undecomposed bitter almond oil and stilbulous acid, and a lower layer containing mandelic acid and excess of sulphuric acid; the mandelic acid crystallises from the latter on cooling (Laurent).—3. A solution of amygdalin in hydrochloric acid is evaporated over the water-bath, and the syrupy mass treated with ether, which dissolves the mandelic acid. On evaporating the solution, the mandelic acid crystallises. (Wöhler, Liebig.)

Properties.—Mandelic acid forms a scaly crystalline mass (Winckler). It crystallises sometimes in rhombic needles, sometimes in rhomboïdal plates, frequently having their acute angles truncated (Laurent); in plates belonging to the rhombic system (J. Heusser, Pogg. Ann. xciv. 637). It has a very faint odour of sweet almonds, and a strong acid taste, with a somewhat styptic after-taste. It melts easily, with loss of water, into a yellow oil, which, on cooling, solidifies to a translucent gum (Winckler). When a solution of mandelic acid in strong hydrochloric acid is evaporated at a temperature above 100° , it becomes amorphous, and afterwards forms a solution with a small quantity of water, but is precipitated by a larger quantity in the form of a heavy yellowish oil (Wöhler). The acid is very soluble in water, alcohol, and ether.

Decompositions. The acid, heated above its melting point, diffuses an agreeable odour, recalling those of white-thorn blossoms, hyacinth, and gum benzoin. Heated in a distillatory apparatus to a temperature short of carbonisation, it is converted into a dark brown, resinous, balsamic mass, which dissolves sparingly in water, but readily in alkalis and in alcohol. A large quantity of bitter almond oil passes over at the same time. The acid burns with a red, smoky flame, leaving a bulky, easily combustible charcoal (Winckler). When it is boiled with nitric acid, as long as nitrous fumes continue to escape, the formic acid is decomposed, and the bitter almond oil is converted into benzoic acid, which crystallises on addition of water (Liebig). When chlorine gas is passed through an aqueous solution of mandelic acid, an oil smelling like chloride of benzoyl separates at first; and if potash be then added, and the passage of the chlorine continued till this oil has completely disappeared, the solution, when subsequently treated with acid, gives off carbonic anhydride and deposits benzoic acid in the form of a crystalline magma (Liebig). The acid dissolves in oil of vitriol, and the solution, when gently heated, gives off carbonic oxide (Liebig). The aqueous solution, boiled with peroxide of manganese, yields carbonic anhydride and bitter almond oil. (Liebig.)

Mandelates.—The acid neutralises bases completely, and expels carbonic acid from its compounds. (Winckler.)

Mandelate of Ammonium.—This salt is obtained by slightly supersaturating the aqueous acid with ammonia, and leaving the solution to evaporate. It is very difficult to crystallise, and generally forms a yellowish-white mass. It has a very mild taste. When heated, it decomposes in the same manner as the free acid. It dissolves in the smallest quantity of water, and readily in alcohol. (Winckler.)

Mandelate of Barium, obtained by decomposing carbonate of barium with mandelic acid, crystallises readily in small, tolerably hard needles. It is much less soluble in water than the potassium-salt. (Winckler.)

Mandelate of Copper.—A solution of sulphate of copper, precipitated by mandelate of potassium, yields a fine light-blue powder, which, when heated, gives off a large quantity of bitter almond oil.

Mandelate of Lead is precipitated as a white, finely crystalline powder, on adding mandelate of potassium to neutral acetate of lead. When heated, it behaves like the copper-salt. It is scarcely soluble in water. (Winckler.)

Mandelate of Magnesium crystallises readily. (Winckler.)

Mercuric Mandelate is obtained by precipitating mercuric nitrate with mandelate of potassium. Its reactions closely resemble those of the copper-salt. (Winckler.)

Mandelate of Potassium.—Obtained by nearly neutralising carbonate of potassium with the aqueous acid, evaporating to dryness, exhausting the dry mass with alcohol, and leaving the alcoholic solution to evaporate. It is a white, soft, easily friable, soapy mass, having a very mild, scarcely saline taste, faintly resembling that of sweet almonds. It decomposes like the free acid when heated, takes fire easily and burns away completely, leaving pure carbonate of potassium. It dissolves very readily in water and alcohol. (Winckler.)

Mandelate of Silver, obtained by precipitating nitrate of silver with neutral mandelate of potassium, forms a white, heavy, crystalline powder, easy to wash. From its aqueous solution saturated at the boiling heat, it separates in rather hard crystals having a slight yellowish colour. It melts at a somewhat high temperature into a dark mass, and yields the same products of decomposition as the acid, leaving metallic silver. (Winckler.)

MANGAN-AMPHIBOLE. See RHODONITE.

MANGANESE. Synonymes. *Manganese, Mangan, Mangadium.* Symbol, Mn; Atomic Weight = 55.

History.—Black oxide of manganese, a substance long used to decolorise glass, and called *magnesia nigra*, from its resemblance to the loadstone, was formerly included among the ores of iron. It was, however, proved by the researches of Pott in 1740, of Kaim and Winterl in 1770, and of Scheele and Bergmann in 1774, that the metal contained in this mineral is distinct from iron, and possesses characters peculiar to itself. The metal itself was first eliminated by Gahn. Chevallot and Edwards, in 1818, pointed out that *mineral chameleon*—a substance discovered some considerable time before—contained a peculiar acid of manganese. Forchhammer, in 1820, distinguished two acids of manganese; and Mitscherlich, in 1832, fully confirmed the distinction.

Manganese occurs chiefly in the form of peroxide, known as black oxide of manganese; also as manganic and manganoso-manganic oxide; as sulphide, carbonate, silicate, and titanate; in small quantities also, as colouring matter in many siliceous minerals and in very minute quantity in the ashes of plants and in the bones of animals.

Preparation of the metal.—1. Hydrogen and charcoal at a red heat reduce the superior oxides of manganese to protoxide, but do not eliminate the metal; but at a white heat charcoal deprives the metal of the whole of its oxygen. The following process, recommended by John (*Gehlen's Journal für Chemie und Physik*, iii. 452), is commonly used for the reduction of manganese. A finely-divided oxide of manganese, obtained by calcining the carbonate in a well-closed vessel, is mixed with oil and ignited in a covered crucible, so as to convert the oil into charcoal. After several repetitions of this treatment, the carbonaceous mass is reduced to powder, and made into a firm paste by kneading it with a little oil. Finally this paste is introduced into a crucible lined with charcoal (*creuset brasqué*, p. 388), the unoccupied portion of which is filled up with charcoal powder. The crucible is first heated merely to redness for half an hour, to dry the mass and decompose the oil, after which its cover is carefully luted down, and it is exposed for an hour and a half to the most violent heat of an air-furnace that the crucible itself can support without undergoing fusion. The metal is obtained in the form of a semi-globular mass or button in the lower part of the crucible, but not quite pure, as it contains traces of carbon and silicium derived from the ashes of the charcoal. By igniting the metal a second time in a charcoal crucible, with a portion of borax, John obtained it more fusible and brilliant, and so free from carbon that it left no black powder when dissolved in an acid.

2. C. Brunner (*Ann. Ch. Pharm.* cii. 330; *Jahresb.* 1857, p. 201) obtains manganese by reducing the chloride or fluoride with sodium, in a manner similar to Deville's process for the reduction of aluminium: a. 2 pts. fluoride of manganese, and 1 pt. sodium are arranged in alternate thin layers in a hessian crucible; the mixture is well pressed, and covered with chloride of sodium; and over the whole is placed a layer of fluor-spar in small pieces (to prevent spirting). The crucible, with the cover on, is then heated in a blast furnace, first gently, then, when the commencement of the action is indicated by a hissing noise, to bright redness for a quarter of an hour, after which, all the apertures of the furnace are closed, and the whole is left to cool. If the heat

has been strong enough, the manganese is found in a fused mass at the bottom of the crucible; if not, it must be heated again under a layer of chloride of sodium or potassium, mixed with $\frac{1}{10}$ of nitre (borax attacks it too strongly).

B. Instead of fluoride of manganese, a mixture of equal parts of chloride of manganese and finely-pulverised fluor-spar may be used, and reduced with sodium in the manner above described.

Manganese may be obtained in the pulverulent state by heating its amalgam (p. 802) in a tube filled with vapour of rock-oil. (Giles.)

Properties.—Manganese, obtained by reduction of either of its oxides with charcoal, is a greyish-white metal having the aspect of cast iron, very soft and brittle, with a fine-grained structure, and is easily split. Specific gravity 8.013 (Johr). Feebly magnetic. Melts only at the strongest heat of a blast furnace. It oxidises quickly when exposed to the air, and must, therefore, be kept under rock-oil, or in sealed tubes. It decomposes water slowly at ordinary temperatures, and dissolves easily, with evolution of hydrogen, in hydrochloric or dilute sulphuric acid. It does not reduce any simple metallic salts, except the salts of silver and gold, and even then the reduction is very slight.

The metal obtained from the chloride or fluoride by Brunner's process, has also the aspect of cast iron, and is very brittle, but it is not magnetic [? what power was used in testing it]; has a specific gravity of only 7.138 to 7.206; is hard enough to scratch and cut glass like a diamond; may be polished; and does not tarnish, even in moist air, at ordinary temperatures; when heated on platinum-foil, it becomes coloured like steel, and covered with a brown film of oxide. Under water, it oxidises slowly at ordinary temperatures, more quickly at the boiling heat, with scarcely perceptible evolution of hydrogen. When immersed in strong sulphuric acid, it eliminates but a small quantity of hydrogen at ordinary temperatures, but dissolves when heated, with evolution of sulphurous anhydride. In dilute sulphuric acid it dissolves readily, even at ordinary temperatures; also in nitric acid, in very dilute hydrochloric acid, and in acetic acid.

H. Deville (Compt. rend. xlv. 673) attributes the differences between the manganese prepared by Brunner's method, and that obtained by reducing either of the oxides with charcoal, to the presence, in the former, of impurities derived from the rock-oil adhering to the sodium, and to silicium from the fluor-spar. Wöhler found, indeed, that Brunner's manganese, when dissolved in hydrochloric acid, left a not inconsiderable residue of hydrated oxide of silicium; and Brunner himself afterwards found that this residue, from 12 samples obtained in different preparations, varied from 1.6 to 6.8 per cent. By fusing the coarsely-pulverised metal with twice its weight of chloride of sodium containing 1 per cent. of chlorate of potassium, the quantity of silicium could be reduced to 0.1 per cent.; but Brunner did not find that this reduction in the proportion of the silicium made any difference in the colour, fusibility, hardness, or lustre of the metal. (See MANGANESE, SILICIDE OF.)

Manganese enters as a base into two classes of compounds, namely, the manganous compounds, in which it is bivalent, and the manganic compounds, in which it is trivalent. It likewise enters as an acid-radicle into two classes of salts, the manganates and permanganates. Examples of these compounds are given in the following table:—

Manganous chloride	$\text{MnCl}^2 =$	$55 + 2 \cdot 35.5$	$= 126$
Manganous oxide	$\text{MnO} =$	$55 + 16$	$= 71$
Manganic chloride	$\text{Mn}^3\text{Cl}^3 =$	$2 \cdot 55 + 6 \cdot 35.5$	$= 323.0$
Manganic oxide	$\text{Mn}^3\text{O}^3 =$	$2 \cdot 55 + 3 \cdot 16$	$= 158$
Manganate of potassium	$\text{MnK}^2\text{O}^4 =$	$55 + 2 \cdot 39.2 + 4 \cdot 16$	$= 197.4$
Permanganate of potassium	$\text{Mn}^3\text{K}^2\text{O}^8 =$	$2 \cdot 55 + 2 \cdot 39.2 + 8 \cdot 16$	$= 316.4$

Manganese also combines with chlorous elements in other proportions, e.g. the peroxide $= \text{MnO}^2$.

MANGANESE, ALLOYS OF. The compounds of manganese with other metals are not of much importance. It unites with cobalt, nickel, copper (ii. 43), iron (iii. 368), and gold, forming white, brittle, and very refractory alloys.

An alloy of manganese and aluminium, MnAl^3 , is obtained by melting together 10 pts. anhydrous chloride of manganese, 30 pts. of a mixture of the chlorides of potassium and sodium in atomic proportions, and 15 pts. aluminium, and treating the resulting regulus with dilute hydrochloric acid. It forms a dark grey crystalline powder, of specific gravity 3.402, insoluble in cold, but easily soluble in hot concen-

trated nitric acid; also, in concentrated hydrochloric acid; it is decomposed by caustic soda-ley, even when dilute, the aluminium dissolving out. (Wöhler, *Ann. Ch. Pharm.* cxv. 102.)

An amalgam of manganese is obtained by reducing a solution of the chloride with sodium-amalgam. (Giles, *Phil. Mag.* [4] xxiv. 328.)

MANGANESE, ARSENIDE OF. Mn^2As^2 .—This compound occurs as a natural mineral, *Arsenical manganese* or *Kaneite*, in botryoidal masses, or amorphous with foliated or granular structure. Specific gravity 5.55. Hard. Greyish-white. Becomes covered with a blackish-grey powder when exposed to the air. Melts on platinum-foil, and combines with the platinum. Before the blowpipe, it burns with a blue flame, garlic odour, and emission of white fumes of arsenious anhydride. It dissolves completely in nitromuriatic acid, and in a large quantity of nitric acid. Contains, according to Kane's analysis (*Pogg. Ann.* xix. 145), 46.5 per cent. manganese, 51.8 arsenic, and a trace of manganese ($=97.3$), the formula requiring 42.76 Mn and 57.25 As. The specimen examined was supposed to be from Saxony.

MANGANESE, BROMIDE OF. $MnBr^2$.—The anhydrous bromide is obtained as a pale red fused mass, by heating the pulverised metal in bromine-vapour. By dissolving the carbonate in hydrobromic acid and evaporating, the hydrated bromide, $MnBr^2.4H^2O$, is obtained in small, red, deliquescent needles, isomorphous with the ordinary form of hydrated manganous chloride (Maignac, see p. 804). The crystals, when carefully heated in a close vessel, give off their water of crystallisation, and leave the anhydrous bromide; and this, when ignited in contact with the air, gives off bromine-vapour, and leaves manganoso-manganic oxide. It is decomposed by sulphuric acid, the bromine going off partly in the free state, partly as hydrobromic acid. (Löwig.)

MANGANESE, CHLORIDES OF.—*a. Manganous Chloride, $MnCl^2$.* This compound is formed by direct combination, the finely-divided metal taking fire when thrown into chlorine gas. It is also produced by passing dry hydrochloric acid gas over manganous carbonate or the red oxide, heated first gently, afterwards to low redness, the process being continued till the gas is no longer absorbed, and the product forms a clear, colourless liquid. The air must be carefully excluded during the whole of the reaction; the mass must be left to cool in the current of hydrochloric acid; and the excess of the latter finally expelled by a stream of dry air.

Manganous chloride obtained by this process, or by heating the hydrated chloride, is a pale rose-coloured mass, having a lamino-crystalline structure. According to H. Rose, it may be obtained in yellow crystals, by passing chlorine gas over a strongly ignited mixture of manganous oxide and charcoal; also, by exposing a mixture of the peroxide with sal-ammoniac to a gradually increasing heat. Manganous chloride melts to an oily liquid at a dull red heat, but does not volatilise at a temperature above the melting point of glass. It is not decomposed by heat alone, if air be excluded, but when ignited in moist air, it gives off hydrochloric acid, and leaves manganoso-manganic oxide. *Hydrogen gas* does not act upon it at a red heat, but *phosphoretted hydrogen* decomposes it, forming phosphide of manganese and hydrochloric acid. When heated with *sulphur*, it is partly converted into sulphide of manganese. When *water* is poured upon the anhydrous chloride, it becomes hot, and dissolves very easily. It is very deliquescent.

Hydrated chloride, $MnCl^2.4H^2O$.—The protoxide and carbonate of manganese dissolve readily in cold hydrochloric acid; and the higher oxides, with evolution of chlorine, when heated therewith, the product being in all cases manganous chloride. It is contained, together with ferric chloride and other substances, in the waste-liquor of the preparation of chlorine by heating the common black oxide of manganese with hydrochloric acid; and as this liquid accumulates very quickly in chemical laboratories, it may, after proper purification, be advantageously used as a source of the pure chloride, and thence of the other preparations of manganese. The iron, which is the chief impurity, may be removed by boiling down considerably, to expel the excess of acid, afterwards diluting with water, and boiling again with carbonate of manganese, which salt precipitates the whole of the sesquioxide of iron, forming chloride of manganese with its acid. If about one-fourth of the impure solution of chloride of manganese be reserved, and precipitated by carbonate of sodium, a quantity of carbonate of manganese will be obtained, which is sufficient to precipitate the iron from the other three-fourths of the liquid, and may be used for that purpose after it has been washed. The iron may likewise be separated by evaporating the solution of the impure chloride to dryness, heating the residue to low redness in a

crucible, as long as hydrochloric acid continues to escape; then leaving it to cool, exhausting with boiling water, and filtering. The hydrated chloride of iron is resolved by the heat into hydrochloric acid and sesquioxide, while the chloride of manganese remains unaltered, and is easily dissolved out by water, all the iron remaining behind (Everitt, Phil. Mag. [3] vi. 493). Chloride of manganese, when free from iron, is precipitated white, without any shade of blue, by ferrocyanide of potassium, and of a pure flesh-red colour, by sulphide of ammonium: the latter test is the most delicate, the slightest trace of iron imparting a perceptible blackness to the precipitated sulphide. By precipitating the whole of the solution with sulphide of ammonium, the manganese may be freed from barium, calcium, and other impurities present. If copper is present, it must be removed by sulphydric acid, before precipitating with sulphide of ammonium.

The solution of chloride of manganese, obtained by either of these processes, yields by cooling, or by spontaneous evaporation, between 15° and 20° , crystals of the hydrated chloride having the composition above indicated. They are monoclinic, but the determinations of their form by different observers do not agree. According to Schabus (*Beschreibung der Krystallgestalten*, &c.), they exhibit the combination $\infty P. [\infty P\infty]. [P\infty]$. Ratio of clinodagonal, orthodagonal, and principal axis = $0.4101 : 1 : 0.8331$. Angle of inclined axes = $54^{\circ} 50'$; $\infty P : \infty P$ in the clinodagonal principal section = $142^{\circ} 56'$; $[P\infty] : [P\infty] = 111^{\circ} 20'$. But, according to Rammelsberg (*Krystallographische Chemie*, p. 45), and Marignac (*Recherches sur les formes cristallines de quelques composés chimiques*, Genève, 1855; Compt. rend. xlii. 288), the clinod., orthod., and principal axis, are to one another as $1.1525 : 1 : 0.6446$, and the angle of the inclined axes is $80^{\circ} 35'$. Angle $\infty P : \infty P$ in the clinodagonal principal section = $82^{\circ} 40'$; $[P\infty] : [P\infty] = 115^{\circ} 5'$; $\infty P : [P\infty] = 97^{\circ} 15'$.—Marignac has since found (Compt. rend. xlv. 650), that crystals of the same composition, but of different form, isomorphous with those of hydrated ferrous chloride, $FeCl_2 \cdot 4H_2O$, are sometimes obtained when a solution of manganoous chloride, supersaturated by evaporation at a high temperature, is left to stand for some time at a temperature between 0 and $+6^{\circ}$ in a vessel covered with bibulous paper. These crystals are also monoclinic, but the angle of their inclined axes is $69^{\circ} 14'$. They exhibit the combination $0P. +P. -P. [\frac{1}{2}P\infty]$. Angle $+P : +P$ in the clinodagonal principal section = $86^{\circ} 0'$; $-P : -P$ in the same = $105^{\circ} 36'$; $+P : -P$ in the orthodagonal principal section = $103^{\circ} 59'$; $0P : +P = 103^{\circ} 30'$; $0P : -P = 126^{\circ} 30'$; $0P : [\frac{1}{2}P\infty] = 142^{\circ} 30'$. Hydrated manganoous chloride is therefore dimorphous. It must be observed, however, that the crystals last described are of rare occurrence, the solution, even when evaporated under the peculiar circumstances just mentioned, generally yielding the ordinary crystals previously described according to the determinations of Marignac and Rammelsberg. As the crystals measured by Schabus are decidedly different from both, it is probable that he examined a different hydrate.

The crystals ($MnCl_2 \cdot 4H_2O$) placed over oil of vitriol, either in vacuo or in a receiver containing air, lose 2 at. water at ordinary temperatures (Graham). At 25° they become white and opaque (John); between 25° and 37° they give off hygroscopic water with decrepitation, and become hard; at 37.5° they become tough; at 60° semi-fluid; and at 87.5° they form a mobile liquid, which boils at 106° . If the mass be kept for some time at a temperature near 100° , it gives off 28 per cent. (3 at.) of water, and leaves a white powder, which retains 1 at. water. (Brandes.)

Both the anhydrous and the hydrated chloride deliquesce rapidly in the air, one part of the crystals absorbing $1\frac{1}{2}$ parts of water. One part of the crystallised salt dissolves at 10° in 0.66 parts; at 31.25° in $0\frac{1}{3}$; and at 62.5° , 87.5° and 106° , equally, in 0.16 parts of water (Brandes). The solution has a light rose colour, and thin, syrupy consistence.

The salt dissolves readily in alcohol, but is insoluble in ether and oil of turpentine. The alcoholic solution of the hydrated salt is green, and yields on cooling colourless crystals, still containing 4 at. water. The anhydrous chloride, dissolved to saturation in boiling absolute alcohol, crystallises out on cooling, and the remaining solution evaporated in vacuo yields an additional quantity of crystals, containing 0.4 of their weight of alcohol.

A solution of manganoous chloride is not altered by passing chlorine through it; but if chloride of potassium, chloride of barium, &c., be added at the same time, a precipitate of hydrated peroxide of manganese is formed (Sobrero and Selmi, Ann. Ch. Phys. [3] xxxix. 161). According to Millon (Jahresb. 1849, p. 264), the same oxidation is produced by chlorine water which has been exposed to sun-light, and therefore contains hydrochloric and hypochlorous acids.

Manganoous chloride forms two crystalline double salts with chloride of ammonium. One of these, $MnCl_2 \cdot 2NH_4Cl$, forms cubical crystals containing 1 at. water according to Rammelsberg, and 2 at. according to v. Hauer. The crystals when ignited leave man-

MANGANESE, DETECTION AND ESTIMATION OF. 805

ganoso-manganic oxide in microscopic pyramids resembling hausmannite. The other double salt, $\text{MnCl}^{\cdot}\cdot\text{NH}^{\cdot}\text{Cl}\cdot 2\text{H}^{\cdot}_2\text{O}$, forms monoclinic crystals (Hantz). Solution of manganous chloride containing chloride of ammonium yields, on addition of ammonia and exposure to the air, a precipitate of hydrated manganoso-manganic oxide. (Otto)

A compound of *manganous chloride and mercuric cyanide*, $\text{MnCl}^{\cdot}\cdot 2\text{HgCy}^{\cdot}\cdot 6\text{H}^{\cdot}_2\text{O}$, is obtained, by spontaneous evaporation of a solution containing the two salts in atomic proportion, in colourless four-sided prisms, which effloresce quickly in the air, and are very soluble in water. (Poggiale.)

B. Manganic Chloride, $\text{Mn}^{\cdot}\text{Cl}^{\cdot}_3$, is not known in the solid state, but when finely divided manganoso-manganic or manganic oxide is added by small portions at a time, in order to avoid rise of temperature, to cold concentrated aqueous hydrochloric acid, a brown solution is formed, which slowly becomes colourless at ordinary temperatures, and more rapidly when heated or exposed to sunshine—chlorine being evolved and manganous chloride produced: hence the solution dissolves metals as readily as chlorine-water. It likewise converts sulphurous and sulphydric acids into sulphuric, and tartaric into carbonic acid. The addition of water in large quantities precipitates manganic oxide, and gives rise to the formation of manganous chloride. (Förchhammer.)

When chlorine is passed into a solution of 1 pt. manganous chloride in 19 pts. water cooled to $+5^{\circ}$, the liquid gradually solidifies to a yellow crystalline mass which, however, melts for the most part, on slight rise of temperature (John). The crystals thus obtained deliquesce very readily in the air, and are decomposed by gentle heating, just like the solution of manganous oxide in hydrochloric acid.

γ. Perchloride of Manganese, $\text{Mn}^{\cdot}\text{Cl}^{\cdot}_4$? When sulphuric acid is added to a green solution of potassic manganate till the liquid turns red; the solution then evaporated to dryness; the residue, consisting of sulphate and permanganate of potassium, dissolved in strong sulphuric acid; the solution introduced into a tubulated retort; and fragments of fused chloride of sodium added as long as coloured vapours are evolved,—the copper-coloured or green vapours which distil over, condense entirely in a tube attached to the retort and cooled down to -15° or -20° , forming a greenish-brown liquid. The vapours, when brought in contact with moist air in a wide tube, produce a dense rose-coloured cloud, and form on the sides of the tube, with evolution of hydrochloric acid, a deposit of purple-red permanganic acid (Dumas, Ann. Ch. Phys. [2] xxxvi. 81). H. Rose regards this compound as probably analogous to the chromate of trichloride of chromium.

MANGANESE, CYANIDES OF. See CYANIDES (ii. 263).

MANGANESE, DETECTION AND ESTIMATION OF.—1. Reactions in the Dry Way. All compounds of manganese, heated with borax or phosphorus-salt in the outer blow-pipe flame, form an amethyst-coloured bead containing manganoso-manganic oxide, which becomes colourless in the inner flame by reduction of that compound to manganous oxide. This reaction, when not disguised by the presence of other metals forming coloured beads, is extremely delicate, and serves to distinguish manganese from all other metals. Another reaction, equally characteristic, even more delicate, and not likely to be interfered with by the presence of other metals, is obtained by heating the substance under examination with two or three times its weight of carbonate of sodium and a little nitre, on platinum-foil in the outer blow-pipe flame. The smallest trace of manganese will then be indicated by the formation of green manganate of sodium. The best way of applying the heat is to direct the hottest part of the flame on the under side of the platinum-foil immediately beneath the mixture. In testing for traces of manganese in ores which are rich in iron, it is best to treat them with nitric acid, which dissolves the iron as ferric-salt; nearly saturate the solution with carbonate of sodium, and precipitate the iron with acetate of sodium; then saturate the filtrate with ammonia, add one drop of sulphide of ammonium, and test the precipitated sulphide by fusion with nitre and carbonate of sodium, as above.

2. Reactions in Solution.—a. Of Manganous Salts.—These salts have a pale rose tint, which is not destroyed by sulphurous or hydrochloric acid, and must therefore be considered as characteristic. When the solution is colourless, as is sometimes the case, the fact is explained, according to Görgen, by the presence of a salt of iron, nickel, or copper, the green or blue tint of the latter metals producing a white or scarcely perceptible violet tint, when combined with the rose colour of a manganous salt.

Sulphydic acid forms no precipitate in neutral solutions of manganous salts containing any of the stronger acids. In a neutral solution of the acetate, a flesh-coloured precipitate is formed after some time; but not if the solution contains free acetic acid. *Sulphide of ammonium* forms, in neutral solutions of manganous salts, a

806 MANGANESE, DETECTION AND ESTIMATION OF.

flesh-coloured precipitate of hydrated sulphide of manganese, insoluble in excess of sulphide of ammonium, but readily soluble in acids. When exposed to the air, it turns brown on the surface, from oxidation. This reaction is quite characteristic, no other metal giving anything like it; a very small trace of iron or cobalt, however, colours the precipitate black.

Caustic alkalis, added to solutions of manganous salts, throw down the protoxide of manganese in the form of a white hydrate, which soon absorbs oxygen from the air, and becomes brown; when collected on a filter and washed, it ultimately changes into a blackish-brown powder, which is the hydrate of the sesquioxide. A similar change is instantaneously produced by the action of chlorine-water upon the white hydrate, or by the addition of chloride of lime to a salt of the protoxide of manganese; but then the hydrated peroxide is formed. *Ammonia* precipitates the white hydrate from neutral manganous solutions; in solutions containing free acid or ammoniacal salts, it gives no precipitate; but if sufficient ammonia is added, the solution, on exposure to the air, gradually deposits all the manganese as brown sesquihydrate. The *alkaline monocarbonates* precipitate white carbonate of manganese, which does not turn brown in the air, and dissolves sparingly in a cold solution of sal-ammoniac. *Acid carbonate of potassium* precipitates a strong solution immediately, and renders a dilute solution slightly turbid; but if the solution contains a free acid, so that an excess of carbonic acid is set free, no precipitate is formed. The *earthy carbonates* do not precipitate manganous salts. *Alkaline phosphates, arsenates, and oxalates* give white precipitates.

Ferrocyanide of potassium forms in neutral solutions of manganous salts, a white precipitate, having a tinge of red, and soluble in free acids. *Ferricyanide of potassium* forms a reddish precipitate, insoluble in acids.

The least trace of a manganous salt may be detected by heating the solution with a little *dioxide of lead* (or red lead), and *nitric acid*, when an intense purple-red colour is produced, owing to the formation of permanganic acid, or, according to H. Rose, of manganic oxide. The colour is readily perceptible when the excess of lead-oxide has subsided. This is the most delicate test for manganese in the wet way. (W. Crum.)

All compounds of manganese, after boiling with hydrochloric acid, exhibit the reactions of manganous salts.

β. Of Manganic salts.—Solutions of manganic salts are red, and yield with *potash* a black precipitate of manganic hydrate, unless chloride of ammonium is present, in which case no precipitate is formed. They are very unstable, being reduced to manganous salts merely by heating, also by *hydrochloric, sulphurous, or nitrous acid*, or any *organic compound*, the liquid then becoming colourless. Sulphide of ammonium reduces them to manganous salts, and then precipitates the flesh-coloured sulphide.

γ. Of Manganates.—The manganates of the alkali-metals are soluble in water, forming green solutions, which, however, are very unstable, quickly turning red on exposure to the air, from formation of permanganic acid, and depositing the brown hydrated peroxide; this change is retarded by the presence of excess of alkali. *Nitric, sulphuric, or hydrochloric acid*, effects the change at once; with hydrochloric acid, the red solution gradually becomes brown, and, when heated, colourless, owing to the formation of manganous chloride. The solution is also decolorised by *sulphurous and sulphydric acids*, and other reducing agents.

δ. Of Permanganates.—The alkaline permanganates form solutions of a deep purple-red colour. They are very easily reduced by *organic compounds*, and by all reducing agents (e.g. *hydrochloric, sulphurous, arsenious, nitrous, and sulphydric acids, ferrous salts, stannous salts, &c.*), the solution first becoming green and ultimately colourless.

3. Quantitative Estimation and Separation.—The usual method of precipitating manganese from the solution of a manganous salt, is to add carbonate of sodium at the boiling heat. The precipitated carbonate of manganese is then well washed with boiling water, and calcined at a strong red heat, whereby it is converted into manganoso-manganic oxide, Mn_2O_3 , containing 72.11 per cent. of manganese. If the solution contains a considerable quantity of ammoniacal salts, it must be evaporated, after mixing it with excess of carbonate of sodium, and the soluble salts dissolved out of the residue by water.

From the metals of Group I. (i. 217), manganese is separated by the non-precipitation of its sulphide from an acid solution by sulphydric acid. Its separation from the metals of Group II., which, like manganese itself, are precipitated by sulphide of ammonium and not by sulphydric acid, is more difficult.

The methods of separating manganese from iron have been already given under IRON (p. 386). The best is to precipitate the iron (previously brought into the ferric state by succinate or benzoate of ammonium) from a solution carefully neutralised with ammonia.

MANGANESE, DETECTION AND ESTIMATION OF. 807

From cobalt, nickel, and zinc, manganese may be separated by mixing the solution with *acetate of sodium*, and saturating with *sulphydric acid gas*, which throws down the other metals, leaving the manganese in solution. In the case of cobalt and nickel, the solution must not contain much free acid. The separation thus effected is not very complete at first, but it may be rendered almost absolute by repeating the process two or three times. Other methods of separating manganese from cobalt are given under COBALT (i. 1046). One of the best is that which consists in converting the two metals into chlorides, and igniting them in a stream of *hydrogen*, which reduces the cobalt, and leaves the chloride of manganese undecomposed. The same methods may be used for separating manganese from nickel.

From uranium, manganese is separated by precipitating that metal as uranic oxide by means of *carbonate of barium*, which leaves all the manganese in solution. For the separation from chromium, see i. 915.

From the metals which are precipitated by sulphide of ammonium from their neutral solutions as hydrates, viz. those of the earths proper, also cerium, lanthanum, and didymium, manganese may be separated by mixing the solution with a sufficient quantity of *tartaric acid* to prevent the precipitation of those metals by an alkali, then adding excess of *ammonia*, and precipitating the manganese by *sulphide of ammonium*.

From yttrium, thorium, zirconium, cerium, lanthanum, and didymium it may also be separated by precipitating those metals with *oxalate of ammonium*, after adding sal-ammoniac to retain the manganese in solution; from cerium and its allied metals, also by sulphate of *potassium* (i. 833).

For the methods of separation from titanium, tantalum, and niobium, see those metals.

From aluminium and glucinum, manganese, if in small or moderate quantity only, may be separated by boiling the solution with *potash* in an open vessel. The manganese is then precipitated in the form of sesquioxide, while the alumina and glucina are dissolved by the potash. If, however, the proportion of manganese be considerable, this method cannot be used, because the oxide of manganese carries down with it considerable quantities of alumina and glucina. In this case the liquid must be mixed with sal-ammoniac, and the alumina and glucina precipitated by *ammonia*. The precipitate, however, always contains small quantities of manganese, which must be separated by subsequent treatment with potash.

From barium and strontium manganese is easily separated by means of *sulphate of sodium* which throws down the barium and strontium as sulphates; also by *sulphide of ammonium*. From calcium and magnesium it is separated by *oxalate of ammonium*, which, if the solution be sufficiently dilute, precipitates the manganese alone in the form of sulphide. The separation from calcium may also be effected by means of *oxalate of ammonium*, after the addition of chloride of ammonium to keep the manganese in solution.

Manganese is separated from the alkali-metals by means of *carbonate of sodium* or *sulphide of ammonium*, which latter precipitates it in the form of sulphide. The sulphide is washed with water containing a small quantity of sulphide of ammonium; then redissolved in acid; and the manganese precipitated from the solution by carbonate of sodium.

4. *Valuation of Ores of Manganese*.—As the commercial value of manganese ores depends, not on the quantity of metal, but on that of the available oxygen contained in them, the mode of assaying them does not properly come under the estimation of manganese, but will be best considered in connection with the oxides of manganese. (See p. 814.)

5. *Atomic Weight of Manganese*.—The earlier determinations of this number by Berzelius, J. Davy, and Forchhammer, were either too high or too low. Arfwedson in 1818 (Schw. J. xlii. 202), by precipitating the solution of manganous chloride with nitrate of silver, found the atomic weight of manganese to be 28, that is to say, the same as that of iron. Turner, in the same year (Phil. Mag. [2] iv. 22), by a similar method, obtained the number 27.49, and by determining the quantity of manganous sulphate produced by treating a known quantity of manganous oxide with sulphuric acid, he found $Mn = 27.96$. Berzelius in 1830 (Pogg. Ann. xiv. 211) also, by precipitating manganous chloride with nitrate of silver, found that 4.20775 $MnCl$ gave 9.575 $AgCl$; whence, if $Ag = 108$ and $Cl = 35.5$, calculation gives $Mn = 27.5$. Dumas, in 1859 (Ann. Ch. Pharm. cxiii.), found, as a mean of five similar experiments, $Mn = 27.48$.

v. Hauer (Chem. Centr. 1857, p. 88) determined the atomic weight of manganese by converting anhydrous manganous sulphate into the corresponding sulphide. The quantity of oxygen in the sulphate was thus found, as a mean of nine experiments, to be 42.390 per cent. (from 42.351 to 42.428); whence $Mn = 27.49$.

808 MANGANESE, EARTHY—MANGANESE, OXIDES OF.

The most exact of the preceding experiments appear to show that the atomic weight of manganese is 27.5 or 55, according as it is regarded as mono- or diatomic.

R. Schneider (Pogg. Ann. (1859) cvii. 655) has, however, obtained a much lower result: 1. By determining the quantity of water produced in the reduction of manganoso-manganic to manganous oxide by reduction with hydrogen: 2. By determining the ratio between the carbon and manganese in manganous oxalate. The first method gave as a mean, $Mn' = 27.01$; the second 27.02. Schneider therefore assumes 27 as the true atomic weight of manganese, $Mn' = 27$ or $Mn'' = 54$.

MANGANESE, EARTHY. This term is applied to oxides of manganese occurring in amorphous, loosely coherent masses (see p. 813.)

MANGANESE FLUORIDES OF. *Manganous fluoride*, MnF_2 , is obtained by dissolving the carbonate in excess of hydrofluoric acid. On evaporating the excess of acid, the salt separates in small, indistinct, amethyst-coloured crystals, which are insoluble in pure water, but dissolve in water containing free hydrofluoric acid. The fluoride is not decomposed by heat alone, but when heated with sodium, it yields metallic manganese (p. 801).

Manganic fluoride, MnF_3 , is obtained by digesting the sesquioxide or peroxide with excess of hydrofluoric acid. The resulting dark brown solution yields, by spontaneous evaporation, crystals of manganic fluoride, which are ruby-coloured by transmitted light, and yield a rose-coloured powder. They dissolve without decomposition in a very small quantity of water; but the solution is decomposed by dilution into a soluble acid fluoride and an insoluble basic compound or oxyfluoride. Ammonia, added to the solution, throws down manganic hydrate.

Perfluoride of Manganese, Mn_2F_{14} ?—When a fused mixture of peroxide of manganese, hydrate of potassium, and chlorate or permanganate of potassium is mixed with half its weight of fluor-spar, and drenched with strong sulphuric acid, a yellow vapour is formed, which is decomposed and acquires a purple colour by contact with moist air, and corrodes glass, forming fluoride of silicon and permanganic acid. With water, it is resolved into hydrofluoric and permanganic acids, forming a purple solution, which remains unchanged in stoppered bottles, but, when evaporated, evolves oxygen gas and hydrofluoric acid vapour, and leaves a brown shining residue, from which water dissolves manganous fluoride, leaving a black insoluble basic salt. The solution also dissolves copper, mercury, and silver (not gold or platinum), forming fluorides, and at the same time becoming perfectly colourless. (Wöhler, Pogg. Ann. ix. 619; see also Dumas, Ann. Ch. Phys. [2] xxxvi. 82.)

MANGANESE, GREY. A term sometimes applied to manganite and pyrolusite (pp. 810, 811).

MANGANESE, IODIDES OF. *a. Manganous Iodide*, MnI_2 .—A solution of manganous carbonate in aqueous hydriodic acid leaves a white crystalline mass, having a somewhat styptic taste. When kept from contact of air, it may be fused without decomposition; but on the admission of air, it is resolved into vapour of iodine and manganous oxide. It deliquesces in the air, and dissolves readily in water, forming a colourless solution, which, on evaporation, deposits white needles. The solution, when exposed to the air, is slightly decomposed, depositing brown flakes. Bromine and chlorine, as well as concentrated nitric or sulphuric acid, set the iodine free. (Lassaigne.)

b. Manganic iodide.—Very finely-pounded peroxide of manganese, agitated with cold aqueous hydriodic acid, yields a dark yellowish-red solution, which, when heated, evolves iodine, and is rapidly converted into manganous iodide.

MANGANESE, OXIDES OF. Manganese forms four oxides of definite composition, viz.:—

Protoxide or Manganous oxide	MnO
Manganoso-manganic oxide	Mn^2O^3
Sesquioxide or Manganic oxide	Mn_2O^3
Dioxide or Peroxide	MnO^2

The protoxide is a strong base, forming with acids a class of very stable salts: the sesquioxide is a weak base. Manganoso-manganic acid also dissolves without decomposition in certain acids. The peroxide, treated with acids, is resolved into manganous or manganic oxide and free oxygen.

There are also two or three other native oxides, intermediate in composition between the sesqui- and di-oxides, viz. *Varvacite*, *Newkirkite*, &c., but they are not very definite, and are probably mere mixtures. Besides these it is usual to enumerate two higher oxides, MnO^3 and MnO^4 , which are the anhydrides corresponding to manganic and permanganic acid respectively: but they have not yet been obtained, and must therefore at present be regarded as merely hypothetical. (See MANGANIC ACIDS.)

Protoxide, or Manganous oxide, MnO .—This oxide may be prepared by igniting manganous hydrate, carbonate, or oxalate, at a moderate heat in a closed vessel, or better in a stream of hydrogen, and allowing the product to cool in that gas. The best mode of preparation is, however, that recommended by Liebig and Wöhler (Pogg. Ann. xxi. 584), which consists in mixing equal parts of fused manganous chloride and carbonate of sodium with a small quantity of sal-ammoniac, heating the mixture till it fuses, and exhausting the fused mass with water when cold.

Manganous oxide is a greyish-green powder, which, according to Despretz, melts at the heat of a forge-fire to a fine green-coloured mass. By heating it to a cherry-red heat in hydrogen, mixed with a very small quantity of hydrochloric acid gas, Deville (Compt. rend. lii. 1264) obtained it crystallised in transparent regular octahedrons of an emerald-green colour, and adamantine lustre. It is not deoxidised by any heat, however great. Heated in sulphydric acid gas, it yields water and manganous sulphide. When it is fused with sulphur, sulphurous anhydride is evolved, and manganous oxysulphide remains behind.

Hydrated Manganous oxide, or Manganous hydrate, is obtained by precipitating a manganous salt with caustic potash, as a white, milky, flocculent precipitate, which, on exposure to the air, turns brown by oxidation, and is ultimately converted into manganic hydrate. The same change is produced immediately by chlorine-water, or the solution of a hypochlorite. If it be washed in an apparatus from which the air is excluded as completely as possible, then dried in a stream of hydrogen, and heated in that gas just sufficiently to drive off the water, the remaining protoxide is sometimes pyrophoric, and when a red-hot coal is laid upon it, it glows from the point of contact throughout its whole mass, and is converted into manganic oxide. According to H. Davy, the hydrate contains 24 per cent. water.

Both the oxide and hydrate dissolve readily in nitric, sulphuric, and hydrochloric acid, forming solutions of manganous salts.

Sesquioxide, or Manganic oxide, Mn_2O_3 .—This oxide occurs native, as *Braunite*, in obtuse quadratic pyramids, in which the principal is to the secondary axes as 0.985 : 1. Angle of the terminal edges = $109^\circ 53'$; of the lateral edges = $180^\circ 39'$. Cleavage perfect, parallel to P, none parallel to σP . It occurs also massive. Hardness = 6–6.5. Specific gravity = 4.75–4.818. Lustre submetallic. Streak and colour dark brownish-black. Fracture uneven. Brittle. Infusible before the blowpipe. It occurs in veins traversing porphyry at Ochrenstock near Ilmenau; at Eggersberg in Thuringia; also near Ilfeld in the Hartz; at St. Marcel in Piedmont; in the isle of Elba; at Vizianagram in India; and in the state of Vermont (U. S.).

The same oxide is obtained as a black powder by heating manganous nitrate, peroxide of manganese, or manganic hydrate to low redness, the hydrate perhaps yielding the most definite product. If the heat is too strong, the residue consists of manganous-manganic oxide.

According to R. Schneider (Pogg. Ann. cvii. 605) all the lower oxides of manganese are converted into sesquioxide by strong ignition in oxygen gas.

From the experiments of Dittmar (Chem. Soc. J. xvii. 294) it appears that the composition of the product obtained by heating an oxide of manganese depends upon the tension of the oxygen in the surrounding atmosphere as well as on the temperature. By heating peroxide of manganese to bright redness in pure oxygen of various tensions, that when the tension of the oxygen was between 0 and 0.21 atmosphere, manganous-manganic oxide was formed; but when the oxygen-tension was between 0.26 and 1 atmosphere, the sesquioxide was obtained. The exact limit of tension which

determines the stability of one or the other oxide appears to vary with the temperature.

Manganic oxide when strongly ignited in a close vessel, or in the air, gives off oxygen, and leaves manganoso-manganic oxide. By boiling with nitric acid, or with dilute sulphuric acid, it is resolved into protoxide, which dissolves, and peroxide, which remains undissolved. Hot strong sulphuric acid reduces it to manganous oxide, and dissolves it, with evolution of oxygen gas. Hot hydrochloric acid dissolves it, with evolution of chlorine.

Hydrated Manganic oxide, or Manganic Hydrate, $Mn^{(Mn^)}O^{\cdot} \cdot H_2O$, or $\left. \begin{matrix} (Mn^*) \\ H^+ \end{matrix} \right\} O^{\cdot}$.*—This compound is found native, as *Manganite* or *Grey Manganese ore*, in veins traversing porphyry, at Ihlefeld, in the Hartz; at Ilmenau and Oehrenstock in Thuringia; in Aberdeenshire; at Undenæs in Sweden; and at Christiansand in Norway: It forms trimetric crystals, usually exhibiting the face ∞P with ∞P_2 and other vertical prisms, together with ∞P and P_{∞} , or a pyramid P_3 , &c. Ratio of axes, $a : b : c = 0.8440 : 1 : 0.5444$; $\infty P : \infty P = 80^{\circ} 20'$; $\infty P_2 : \infty P_2 = 103^{\circ} 23'$; $P_{\infty} : P_{\infty} = 66^{\circ} 41'$. Also twins with plane of combination P_{∞} . Cleavage very perfect, parallel to ∞P_{∞} . The crystals are longitudinally striated and often grouped. The mineral also occurs columnar and granular. Hardness = 4. Specific gravity = 4.2–4.4. Lustre submetallic. Colour dark steel-grey to iron-black. Streak reddish-brown, sometimes nearly black. Opaque; minute splinters sometimes brown by transmitted light. Fracture uneven. Fusible before the blowpipe.

Manganic hydrate is prepared artificially by exposing moist manganous hydrate to the air, or by passing chlorine, not to saturation, into water in which manganous carbonate is suspended, decanting the liquid, and digesting the brown residue still containing manganous carbonate, in cold very dilute nitric or acetic acid to remove the manganous oxide; when prepared by this latter process however, it is often mixed with hydrated peroxide.

Manganous hydrate artificially prepared is a light powder having a dark brown colour and capable of boiling very strongly. It gives off its water at a temperature above 100° . By boiling with moderately concentrated nitric acid, it is resolved into protoxide, which dissolves, and a residue of hydrated peroxide. (Berthier.)

Manganic oxide dissolves without decomposition in cold hydrochloric acid, forming manganic chloride. Strong sulphuric acid combines with it at temperatures a little above 100° , but does not form a solution. Dilute sulphuric acid does not dissolve it, unless manganous oxide is present, even in very small quantity, in which case a violet solution is formed. (Carius.)

A manganic sulphate may be prepared by mixing finely divided peroxide of manganese with monohydrated sulphuric acid to the consistence of a pulp, and gradually heating the mixture to 135° . It may be heated to 160° without decomposition, but is decomposed at higher temperatures into oxygen and manganous sulphate. It is also quickly reduced by organic substances, and decomposed by water, with separation of manganous hydrate (Carius, Ann. Ch. Pharm. xviii. 53). But the most stable of the simple manganic salts is the phosphate, which dissolves in water without decomposition.

Generally speaking, however, manganic oxide does not form stable salts with acids, unless another base or protoxide is present: with sulphuric acid, for example it forms several double salts having the constitution of alums; thus there is a manganicopotassic sulphate found native on the shores of the Great Salt Lake (see SULPHATES).

Manganoso-manganic oxide, or Red oxide of Manganese. $Mn^{(Mn^*)}O^{\cdot}$ = $MnO.Mn^{(Mn^*)}O^{\cdot}$.—This oxide occurs native, as *Hausmannite*, and together with other manganese ores, with porphyry, near Ilmenau in Thuringia and near Ihlefeld in the Hartz. The crystals are acute quadratic pyramids, in which the principal is to the secondary axes as 1.175 : 1. Angle $P : P$ in the terminal edges = $105^{\circ} 25'$; in the lateral edges = $117^{\circ} 54'$. Cleavage basal, nearly perfect. It also forms twin-crystals, the face of combination being parallel to P_{∞} , the same kind of combination sometimes occurring between four individuals. Also granular, sometimes strongly coherent. Hardness = 5 to 5.5. Specific gravity = 4.722. Lustre submetallic. Colour brownish-

black. Streak chestnut-brown. Opaque. Fracture uneven. Infusible before the blowpipe.

This oxide is the most easily obtained by artificial means of all the oxides of manganese, being always produced when manganous oxide, nitrate, or carbonate, is strongly ignited in contact with the air, or when either of the higher oxides is subjected to very strong ignition. Metallic manganese, exposed to moist air at ordinary temperatures, evolves hydrogen gas of a peculiar odour, and is converted into a reddish-brown powder, which is a mixture of manganese containing charcoal and silicium, with manganoso-manganic oxide, since it dissolves in hydrochloric acid, with evolution of hydrogen gas, and forms a brown solution, which, when heated, becomes colourless and gives off chlorine. The oxidation takes place more rapidly, in proportion as the manganese is more free from charcoal, and the air is warmer and contains more moisture. If the metal is heated in the air, the conversion into manganoso-manganic oxide takes place more rapidly, but without incandescence; in oxygen gas, the finely-divided metal becomes ignited. The red oxide is also produced, with evolution of hydrogen, by heating the protoxide in a stream of aqueous vapour. It is a reddish-brown or cinnamon-coloured powder, which turns black when heated, but recovers its original colour on cooling. When heated to whiteness with charcoal, it is reduced to metallic manganese. By boiling with dilute sulphuric or with nitric acid, it is resolved, like the sesquioxide, into protoxide and peroxide; hot strong sulphuric acid dissolves it as manganous sulphate, with liberation of oxygen; hot hydrochloric acid, with liberation of chlorine. It dissolves without decomposition in a hot, very strong solution of phosphoric acid, and in cold concentrated sulphuric, hydrochloric, oxalic, or tartaric acid, but only in small quantity, and without neutralising the acid. The solutions, treated with caustic potash, yield a brown precipitate, perhaps consisting of manganoso-manganic hydrate. Heat, and the addition of water, or of deoxidising agents, converts these salts (the phosphate excepted) into salts of manganous oxide, with a large excess of acid.

Dioxide or Peroxide. MnO_2 .—This oxide occurs in nature as *Pyrolusite* or *Polyanite*, in trimetric crystals exhibiting the combination $\infty P \infty . \infty P . \infty P \infty . \infty P . \frac{1}{2} P \infty$. Ratio of axes $a : b : c = 0.776 : 1 : 1.066$. Angle $\infty P : \infty P = 93^\circ 40'$. Also columnar, often divergent; also granular, massive, and frequently in reniform coats; often soils. Hardness = 2 to 2.5. Specific gravity = 4.819 (Turner); 4.97 when pure. Lustre metallic. Colour iron-black, dark steel-grey, sometimes bluish. Streak black. Opaque. Rather brittle. Infusible alone before the blowpipe; gives off oxygen on charcoal. It is a valuable ore of manganese, and is extensively worked at Eggersberg, Ilmenau, and other places in Thuringia; also at Vorderbremsdorf near Mährisch-Trübau in Moravia, which place affords annually many tons of the ore. It also occurs in Devonshire, and with psilomelane in many parts of the United States.

Peroxide of manganese is prepared by the following processes:—1. Manganoso-manganic or manganic oxide, is boiled with strong nitric acid.—2. Manganous nitrate is gradually heated to incipient redness, and the residue pounded and freed by boiling nitric acid from any remaining manganous oxide; the insoluble residue is then washed and very carefully heated to low redness, stirring all the while (Berthier).—3. Manganous carbonate is heated in an open vessel to 260° , and any portions of carbonate which may then remain undecomposed, are removed by cold and very dilute hydrochloric acid; whereupon, according to Forehammer, pure peroxide remains behind.—4. Manganous carbonate is carefully heated with fused chlorate of potassium, and the mass, when cold, is well washed with water (Göbel).—5. A solution of a manganous salt, even when very dilute, provided it is perfectly free from iron, deposits peroxide of manganese on the positive pole of a voltaic battery; a feeble current is sufficient for the purpose (Fischer, Kastn. Arch. xvi. 219). Artificially prepared peroxide of manganese is black with submetallic lustre, hard and tough.

Peroxide of manganese, whether natural or artificial, is a good conductor of electricity, and is remarkable for its tendency to become strongly electro-negative in contact with metals, so that powerful voltaic combinations may be made by using a platinum plate covered with it as the negative element. Discs of paper covered with the peroxide are also used in the construction of dry piles. (See ELECTRICITY, ii. 421, 423.)

The peroxide when heated alone gives off part of its oxygen, and is reduced to manganic or manganoso-manganic oxide, according to the degree of heat applied; the decomposition takes place more readily in open than in closed vessels (see p. 809). Heated in a charcoal-lined crucible, it is reduced to protoxide, and if mixed with sulphur, to manganous oxysulphide, with evolution of sulphurous anhydride. When drenched with strong sulphuric acid, it gives off one-fourth of its oxygen and yields a dark red solution of manganic sulphate; and on heating the mixture, another fourth part of the oxygen is given off and manganous sulphate is produced. The reduction is greatly facilitated by mixing the peroxide with organic substances, such as sugar, oxalic acid, &c., carbonic anhydride being then evolved instead of oxygen. With cold hydrochloric acid it forms manganic chloride; on heating, manganous chloride, with evolution of chlorine. With sulphurous acid, it forms a solution containing manganous sulphate and hyposulphate. By ignition with potash in a close vessel, it is resolved into manganous oxide and manganic acid.

The facility with which peroxide of manganese parts with a portion of its oxygen renders it a very valuable oxidising agent, both in the chemical laboratory and in manufactures. It is extensively used for the evolution of chlorine from hydrochloric acid (i. 890), also for discharging the brown and green tints of glass: hence the name *pyrolusite* (from *πῦρ* fire, and *λέω* to wash) applied to the native peroxide, and the somewhat whimsical title, *savon des verriers*, given to it by the French.

Hydrates of the Peroxide.—Peroxide of manganese unites with water in several proportions, according to the mode of preparation.—*α*. In the spontaneous decomposition of manganates or permanganates dissolved in water or in dilute acid, a black-brown hydrated peroxide is precipitated, which cakes together to a black coherent mass containing $\text{MnO}^2 \cdot \text{H}^2\text{O}$ (Mitscherlich). The same hydrate is formed when manganous carbonate suspended in water is treated with chlorine, and the black-brown residue is well washed with dilute acid (Berthier).—*β*. A hydrate containing $2\text{MnO}^2 \cdot \text{H}^2\text{O}$ is obtained when a solution of a manganous salt is precipitated by a mixture of caustic potash and potassic hypochlorite (Winkelblech).—*γ*. The hydrate $3\text{MnO}^2 \cdot \text{H}^2\text{O}$ is deposited on evaporating a solution of manganous bromate (Rammeisberg).—*δ*. $4\text{MnO}^2 \cdot \text{H}^2\text{O}$ is obtained by treating manganoso-manganic hydrate with strong nitric acid (Berthier). See *Gmelin's Handbook*, iii. 206.

According to Görgen (Ann. Ch. Phys. [3] lxxi. 155; Jahresb. 1862, p. 155) peroxide of manganese acts as an acid, uniting with bases, and reddening litmus slightly when suspended in perfectly pure water; hence Görgen proposes to call it manganous acid. (See MANGANIC ACIDS, p. 817.)

Oxides of Manganese intermediate in composition between the Sesquioxide and Dioxide.—Under this head are included several ores of manganese, mostly amorphous, one or two of definite constitution, but the greater number merely mixtures of different oxides, which cannot be regarded as definite chemical compounds or distinct mineral species.

a. Psilomelane. $\text{RO} \cdot \text{MnO}^2 \cdot \text{H}^2\text{O}$, with excess of peroxide mechanically combined: the symbol RO denotes protoxide of manganese, partly replaced by other protoxides, chiefly baryta and potash. This ore occurs massive and botryoidal. Hardness = 5 to 6. Specific gravity = 3.7 to 4.328. Lustre submetallic. Streak brownish-black, shining. Colour iron-black, passing into dark steel-grey; opaque. It is a common ore of manganese, occurring frequently in alternate layers with pyrolusite. It is found in botryoidal and stalactitic shapes in Devonshire and Cornwall, at Ilfeld in the Hartz, and the other localities undermentioned.

B. Varvacite, a mineral from Warwickshire, of crystalline-laminated texture, and specific gravity 4.531 to 4.623, was found by R. Phillips to contain 63 per cent. manganese, 31.6 oxygen, and 5.4 water, agreeing nearly with the formula $Mn^{+0.3}Mn^{+2}O^{+2}.H^{+2}O$. It is probably an altered manganite consisting largely of pyrolusite.

γ. Wad, Earthy Cobalt, Cupreous Manganese.—These ores occur in amorphous and reniform masses, either earthy or compact, sometimes encrusting or as stains. They are mixtures of different oxides, and not distinct mineral species. Their hardness varies from 0.5 to 6; specific gravity from 3 to 4.26; colour dull black.

Wad, or Bog Manganese, consists mainly of oxides of manganese and water, often mixed with silica, alumina, lime, or baryta. *Gravilite* occurs in roundish masses of

brownish-black colour and reddish-brown streak: hardness sometimes from 2 to 3. It is found in Groroi in Mayence, Viedessos in Spain, and Canteen in France.

Cupreous Manganese contains, besides hydraous oxides of manganese, from 2 to 25 per cent. oxide of copper, and 4 to 18 per cent. oxide of cobalt, with various impurities. Specific gravity 3.1 to 3.2. *Pelokonite* is a variety of cupreous manganese, having a liver-brown streak. Hardness = 3. Specific gravity = 2.567.

Earthy Cobalt is a wad in which oxide of cobalt sometimes occurs to the amount of 33 per cent.

Valuation of the Oxides of Manganese.

The numerous applications of the higher oxides of manganese in chemical manufactures, depend upon the quantity of oxygen which they can furnish when exposed to the action of acids, or—what comes to the same thing—the quantity of chlorine which they are capable of eliminating when treated with hydrochloric acid. This will be seen from the following equations, which represent the action of hydrochloric acid on the dioxide, sesquioxide, and red oxide of manganese:

Hence it appears that the quantities of hydrochloric acid required to furnish a given quantity of chlorine, when acted upon by these three oxides, are as the numbers 2 : 3 : 4; or a given weight of hydrochloric acid, acted upon by the three oxides, will yield quantities of chlorine in the inverse ratio of these numbers.

Moreover, as the sesquioxide and red oxide may be regarded (so far as proportional composition is concerned) as compounds of the protoxide and dioxide ($\text{Mn}_2\text{O}_3 = \text{MnO} + \text{MnO}_2$; and $\text{Mn}_2\text{O}_3 = 2\text{MnO} + \text{MnO}_2$), it follows that the commercial value of a manganese-ore may be regarded as proportional to the percentage of dioxide or peroxide contained in it.

The methods of assaying the oxides of manganese may be classed under three heads:—1. The determination of the amount of oxygen disengaged by sulphuric acid.—2. The oxidation of oxalic acid.—3. The evolution of chlorine from hydrochloric acid.

a. The decomposition of peroxide of manganese by sulphuric acid takes place as represented by the equation:

The sample of manganese ore to be tested is heated with strong sulphuric acid in a small retort provided with a bent delivery-tube passing upwards into an inverted bell-jar, filled with and standing in an alkaline liquid, so that any carbonic acid gas that may pass over may be absorbed, and the oxygen alone collected. The contents of the retort are heated to the boiling point, the heat being continued as long as any gas is disengaged. The apparatus is then left to cool, and the volume of gas is measured and corrected for pressure, temperature, and tension of aqueous vapour.

Each atomic proportion (16 pts. by weight) of oxygen evolved corresponds to 1 at. peroxide (87 pts.) in the sample. Moreover, as the reaction is precisely analogous to the decomposition of the peroxide by hydrochloric acid, each at. of oxygen evolved in the one reaction is equivalent to 2 at. chlorine eliminated in the other.

B. By oxidation of oxalic acid.—When oxalic acid is heated with peroxide of manganese and hydrochloric acid, the disengaged chlorine converts the oxalic acid into carbonic anhydride, 2 at. carbonic anhydride evolved representing 2 at. chlorine, and therefore 1 at. peroxide of manganese:

The quantity of carbonic anhydride evolved may be determined by means of the flask-apparatus represented in *fig. 731*, and already described under *ALKALIMETRY* (i. 119). 50 grains of the manganese-ore finely pulverised are introduced into the flask, together with half an ounce of cold water and 100 grains of strong hydrochloric acid in the test-

grains of crystallised oxalic acid are then added, the chloride of calcium tube and the whole quickly weighed; and the process conducted exactly in the same manner as a determination of carbonic anhydride, as described in the article above referred to. The loss of weight of the flask after boiling, gives the quantity of carbonic anhydride evolved, and as 87—the atomic weight of peroxide of manganese—is nearly double that of carbonic anhydride, 44, the loss of weight in the apparatus may be taken approximately to represent the quantity of real peroxide in the 50 grains of the sample. A more exact calculation is easily made.

The quantity of oxalic acid oxidised by a given sample of a manganese-ore may also be estimated volumetrically by means of *permanganate of potassium*. A dilute solution of oxalic acid decomposes permanganates, in presence of sulphuric acid, being itself converted into carbonic anhydride and water, according to the equation:

Under the same circumstances, oxalic acid decomposes peroxide of manganese, atom for atom:

Hence, the amount of peroxide of manganese in an ore may be estimated volumetrically, by allowing it to act upon a known volume of a standard solution of oxalic acid, which is added in excess, and then estimating the amount of undecomposed oxalic acid by a standard solution of permanganate.

The standard solutions required are: 1. *Oxalic acid*.—1 cub. cent. of this solution contains 0.063 grm. of oxalic acid, and corresponds to 0.042 grm. peroxide of manganese. —2. *Permanganate*.—This solution cannot be preserved without decomposition, and is therefore not standardised once for all; but a moderately strong solution is prepared, and its exact value determined before each operation. This is readily done by means of the standard solution of oxalic acid. 5 c. c. of the latter are diluted to 200 c. c.; about 4 c. c. of strong sulphuric acid are added; and the permanganate solution is introduced, drop by drop, from a burette. The dark colour produced by the permanganate disappears slowly at first, but more rapidly as the operation proceeds; the operation is terminated when a faint rose tinge is produced, which remains permanent for a short time. Suppose, for instance, 29 c. c. of the permanganate solution are required: then 1 c. c. of this solution corresponds to $\frac{6}{29} = 0.1724$ c. c. of oxalic acid.

The analysis is conducted as follows:—The ore having been finely powdered and completely dried, 2.1 grms. are treated with about 30 c. c. standard oxalic acid, and 4 c. c. of concentrated sulphuric acid; when the evolution of carbonic anhydride slackens, heat is applied till no more gas is evolved. If any of the ore remains undecomposed, 5 or 10 c. c. more oxalic acid must be added. When the evolution of gas has quite ceased, the clear solution is decanted into a graduated cylinder, and the residue is treated with 2 or 3 c. c. more oxalic acid, and a few drops of sulphuric acid, and again heated. When the decomposition is complete, the solution (residue and all) is washed into the cylinder, and the whole is diluted to a known volume. The mixture thus obtained is never clear; but it need not be filtered, unless it is dark-coloured. A known volume of it is measured off, diluted, acidulated with sulphuric acid, and the amount of non-oxidised oxalic acid is estimated by the permanganate solution, as above; from the result thus obtained, the amount of non-oxidised oxalic acid in the whole mixture is calculated. The number of cubic centimetres of oxalic acid oxidised, multiplied by 2, gives the percentage of peroxide of manganese in the ore. For example, 1 c. c. permanganate solution = 0.1724 oxalic acid. Weight of ore taken = 2.1 grms. Total volume of oxalic used = 48 c. c. The mixture being diluted to 300 c. c., 100 c. c. require 4 c. c. permanganate: hence, the whole 300 c. c. require 12 c. c. permanganate, which correspond to 2.07 c. c. oxalic acid. $48 - 2.07 = 45.93$ c. c. oxalic acid, oxidised by peroxide: whence, percentage of peroxide = $45.93 \times 2 = 91.86$ per cent.

If, instead of 2.1 grms., any arbitrary weight of the ore is taken, the amount of peroxide is calculated by the proportion $100 : 4.2 = \text{number of c. c. oxalic acid used} : \text{amount required}$; the percentage is then calculated as usual.

3. *By the evolution of Chlorine from Hydrochloric acid*.—The ore (the moisture in which is first estimated) is heated in a flask with excess of concentrated hydrochloric acid, and all the chlorine evolved is conducted into a known volume of a standard acid or alkaline arsenious solution, or into excess of iodide of potassium, or into a solution of a known weight of ferrous sulphate, that salt being in excess, and the amount of chlorine is estimated by one of the chlorimetric processes described under CHLORINE, ESTIMATION OF (i. 904). The amount of peroxide of manganese,

corresponding to a given weight of chlorine, is calculated by the proportion $\text{Cl}^2 : \text{MnO} = 71 : 87$.

Each c. c. of the acid arsenious solution (i. 904) corresponds to 0.010 grm. chlorine, and to 0.01183, peroxide of manganese; hence 50 c. c. correspond to 0.5 grm. chlorine, and to 0.5915 peroxide. If the ore is rich, about 1 grm. is sufficient for the analysis; if it be poor, from 1.5 to 2 grm. should be taken.

Each c. c. of the alkaline arsenious solution (i. 904) corresponds to 0.00355 grm. chlorine, and to 0.0042 grm. peroxide; hence 100 c. c. correspond to 0.42 grm. peroxide; and if 0.42 grm. be taken for analysis, the number c. c. of arsenious solution which is oxidised by it gives at once the percentage of peroxide. (*Conington's Handbook of Chemical Analysis*, p. 247.)

MANGANESE, OXYCHLORIDE OF. The perchloride of manganese described by Dumas (p. 805) is perhaps an oxychloride.

MANGANESE, OXYSULPHIDE OF. MnSO .—This compound is produced when manganous sulphate is ignited in a stream of hydrogen, or, together with sulphide of manganese, when an oxide of manganese is ignited in contact with sulphur. It is a green powder which does not alter at ordinary temperatures, but takes fire when heated, and burns to nearly pure manganoso-manganic oxide, especially if strongly heated at the last. It dissolves in acids as easily as sulphide of manganese prepared in the wet way. (Arfvedson.)

MANGANESE, PHOSPHIDE OF. Obtained by exposing an intimate mixture of 10 pts. of pure ignited dioxide of manganese, 10 pts. of white-burnt bones, 5 pts. of white quartz-sand, and 3 pts. of ignited lamp-black for an hour in a closed hessian crucible, to a heat sufficient to melt cast iron; or by strongly igniting 10 pts. of ignited phosphate of manganese, 3 pts. of ignited lamp-black, and 3 pts. of calcined borax in a crucible lined with charcoal. The product is a very brittle, crystalline regulus of the colour of grey cast iron, and of specific gravity 5.951. It is permanent in the air, glows when heated in contact with air, burns with an intense light when heated with nitre. It appears to contain Mn^2P_2 , and is probably a mixture of Mn^2P_2 and Mn^3P_2 , the latter of which compounds is left behind when the substance is treated with hydrochloric acid, while the former dissolves, with evolution of non-spontaneously inflammable phosphoretted hydrogen. (Wöhler, *Ann. Ch. Pharm.* lxxxvi. 371.)

Schrötter (*Jahresb.* 1849, p. 247), by heating finely divided manganese in phosphorus-vapour, obtained a phosphite having the composition Mn^2P_2 , of specific gravity 4.94, insoluble in hydrochloric acid, easily soluble in nitric acid.

MANGANESE, SILICIDE OF. The effect attributed to small quantities of silicium in altering the physical properties of metallic manganese has already been mentioned (p. 802). Wöhler (*Ann. Ch. Pharm.* cvi. 54) has further examined the question by preparing manganese containing larger proportions of silicium. A mixture of about equal parts of fluoride of manganese, water-glass, cryolite, and sodium, pressed into a hessian crucible, and covered with a mixture of chloride of potassium and chloride of sodium, then heated and exposed to a higher temperature, yielded a well fused, hard, brittle regulus containing 11.7 per cent. silicium, exhibiting a somewhat lamino-crystalline structure on the fractured surface, but without visible separation of free silicium; the action of hydrochloric acid upon it was considerably impeded by the separation of oxide of silicium, very dense but not crystalline; the hydrogen gas evolved at the same time contained siliciuretted hydrogen, and deposited amorphous silicium when passed through a red-hot glass tube; hydrofluoric acid dissolved it, with evolution of fetid hydrogen gas. A mixture of fused chloride of manganese and sodium, fluor-spar, water-glass and sodium yielded a well fused, very brittle regulus, containing 13 per cent. silicium, and exhibiting a few cavities filled with steel-grey prismatic crystals. A mixture of fused manganous chloride, fluor-spar, silico-fluoride of potassium, and sodium yielded (after somewhat quicker cooling) a nearly silver-white, very brittle regulus containing 6.5 per cent. silicium and having a conchoidal strongly shining fracture. A mixture of manganous chloride, sodium, fine quartz-sand and cryolite (the two latter in the proportion of 22 : 26) yielded a yellowish regulus containing 11.4 per cent. silicium, with indications of laminar structure. From these results Wöhler is inclined to believe that even a small quantity of silicium is sufficient to account for the peculiarities of the metallic manganese obtained by Brunner's method.

MANGANESE, RED. Native carbonate of manganese, also called Diallogite (i. 788).

MANGANESE, SULPHIDE OF. Manganous sulphide, MnS , which is the only known sulphide of manganese, occurs native as *Manganese-blende* or *Alabandine*, in the gold mine of Nagvag in Transylvania, sometimes crystallised in cubes and regular octahedrons, with perfect cubic cleavage, but more generally granularly massive. Hardness = 3.5 to 4. Specific gravity = 3.95 to 4.814. It has sub-

metallic lustre and iron-black colour, tarnished brown on exposure. Streak green. Fracture conchoidal. Before the blowpipe it melts only on the thinnest edges.

The same compound is produced artificially in the dry way, by heating the peroxide with sulphur. Sulphurous anhydride is disengaged and a green powder remains, which dissolves in acids, with evolution of sulphydric acid. The same compound is obtained in the hydrated state by decomposing acetate of manganese with sulphydric acid, or any manganous salt with sulphide of ammonium.

A crystalline sulphide of manganese is obtained by passing the vapour of sulphide of carbon over hydrated manganic oxide ignited in a porcelain tube. The crystals are iron-black rhombic prisms, having a tinge of green and yielding a dingy green powder.

Artificially prepared manganous sulphide soon turns brown by oxidation on exposure to the air. When ignited in the air, it easily gives off all its sulphur as sulphurous anhydride, and leaves manganoso-manganic oxide. Heated in hydrogen gas, it gives off sulphydric acid. It detonates when heated with nitre. Chlorine acts but slowly on it, forming chloride of sulphur. The hydrated sulphide boiled with potash, yields sulphide of potassium and manganous hydrate.

Manganous sulphide dissolves very easily in acids, even in acetic acid; sulphurous acid converts it into hyposulphite with separation of sulphur. When the precipitate is mixed by agitation with neutral metallic solutions, e.g. sulphate of cadmium, acetate of lead, ferric chloride, nitrate of silver, sulphate of copper, &c., these metals unite with the sulphur, and the manganese is taken up in their place.

Manganous sulphide forms definite compounds with the sulphides of potassium and sodium.—The *potassium-salt*, $K_2S \cdot 3MnS$ or $Mn^2K_2S^4$, is prepared:—1. By fusing anhydrous manganous sulphate with $\frac{1}{3}$ of its weight of lump-black, and 3 times its weight of carbonate of potassium and sulphur. A gentle heat is applied at first, till the carbonic anhydride is expelled and sulphide of potassium formed; afterwards the heat is raised to bright redness. On cooling, a perfectly fused mass is obtained, which, after the excess of sulphide of potassium has been removed by cold water previously de-aerated by boiling, leaves large dark red scales collected together in masses: these masses may be readily split, like mica, into thin, transparent, dark red laminae.—2. By substituting peroxide of manganese for the manganous sulphate, a similar compound is obtained, but of less brilliant colour.—The scales, when moist, are rapidly oxidised in the air, becoming black and opaque; but, when perfectly dry, they remain permanent for a considerable time. They are nearly insoluble in water, alcohol, and ether. They detonate violently with nitre. Acids dissolve them, with rapid evolution of sulphydric acid gas. When heated on platinum wire, they become covered with a green powder of oxysulphide of manganese. They are gradually dissolved by water containing air, into sulphate and sulphide of potassium, and manganous hyposulphite, which dissolve, and an insoluble mixture of sulphur and manganic oxide. (Völker, Ann. Ch. Pharm. lix. 35.)

The *sodium-salt*, $Mn^2Na_2S^4$, obtained in a similar manner to the potassium compound, forms small, shining, light red needle-shaped crystals, resembling those of sulphide of manganese and potassium in most of their properties, but more readily oxidisable. When treated with distilled water, they rapidly become opaque and dark-coloured. If in this state they are placed over oil of vitriol in a vacuum, they rapidly absorb oxygen as soon as they become moderately dry; and the absorption is attended with so violent a disengagement of heat, that the crystals frequently take fire, and burn like a pyrophorus. (Völker.)

MANGANESE-ALUM. *Manganico-potassic sulphate*, $\left. \begin{matrix} (SO_4)^2 \\ Mn \\ K \end{matrix} \right\} O^4.12H^2O$, found

native on the shores of the Great Salt Lake.—A *manganese-magnesium alum* has been found in the Canton Uri in Switzerland. (See SULPHATES.)

MANGANESE-BLENDE. Native manganous sulphide (p. 816).

MANGANESE-GLANCE. Syn. with MANGANESE-BLENDE.

MANGANESE-SPAR. Syn. with DIALLOGITE. Native carbonate of manganese.

MANGANIC ACIDS. Two oxygen-acids of manganese have long been known, viz. manganic acid and permanganic acid, the potassium-salts of which are represented by the formulæ:

Manganate of potassium	MnK^2O^4
Permanganate of potassium	$Mn^2K^2O^6$

Manganic acid cannot exist in the free state; but permanganic acid, $Mn^2H^2O^6$, has been obtained as a liquid, and appears to be capable of existing in the solid state. The anhydrides corresponding to these acids, viz. MnO^3 and Mn^2O^7 , have not been obtained.

Recent experiments by Gorgeu (*Ann. Ch. Phys.* [3] lvi. 153) appear to show that dioxide of manganese, MnO_2 , is capable of uniting with alkaline bases, and forming salts which may be called manganites. They appear to have the composition $\text{R}^2\text{O} \cdot 5\text{MnO}_2$ (R denoting a monatomic metal). The potassium-salt is soluble in water; the calcium-salt is a brown precipitate, obtained by adding a solution of manganous nitrate to hypochlorite of calcium.

Manganates. MnR^2O^4 .—These salts are isomorphous with the sulphates, selenates, and chromates. Only three of them have, however, been obtained, viz. the barium-, potassium-, and calcium-salts. They have a green colour, but are very unstable, especially in solution, being quickly converted into permanganates, with separation of manganic oxide: the decomposition is accelerated by the presence of acids, and retarded by alkalis.

Manganate of Barium. MnBaO^4 .—This salt is obtained by igniting peroxide of manganese with nitrate of barium, or better, by adding the peroxide in fine powder, and by small portions, to a mixture of hydrate of barium and chlorate of potassium, heated to fusion, and afterwards dissolving out the chloride of potassium by water. It is a green powder, insoluble in water. It may, however, be obtained in the crystalline state by mixing a solution of permanganate of barium with baryta-water, and leaving the liquid to stand in a loosely-covered vessel. (Mitscherlich.)

Manganate of Potassium. MnK^2O^4 .—When dioxide of manganese is strongly ignited with hydrate or carbonate of potassium in excess, manganic acid is formed, under the influence of the alkali, together with a lower oxide of manganese. Ignition in open vessels, or with an admixture of nitrate of potassium, increases the production of the acid, by the absorption of oxygen which then occurs. The product has long been known as *mineral chameleon*, from the property of its solution, which is green at first, to pass rapidly through several shades of colour. A more convenient process for preparing manganate of potassium is that recommended by Dr. Gregory. He mixes intimately 4 pts. of dioxide of manganese in fine powder with $3\frac{1}{2}$ pts. of chlorate of potassium, and adds the mixture to 5 pts. of hydrate of potassium dissolved in a small quantity of water. The mixture is evaporated to dryness, powdered, and afterwards ignited in a platinum crucible, but not fused, at a low red heat. The ignited mass, digested in a small quantity of cold water, forms a deep green solution of the alkaline manganate, which may be obtained in crystals of the same colour by evaporating the solution over sulphuric acid in a vacuum.

Manganate of potassium is not soluble in water without decomposition. When water is poured upon the crystals, they are resolved into permanganate of potassium, and a black crystalline compound of potash with peroxide of manganese (manganite of potassium) which almost immediately gives up its potash to the water, and leaves pure hydrated peroxide of manganese. (Mitscherlich.)

According to Gorgeu (*loc. cit.*), when carbonic anhydride is passed through a solution of potassic manganate till the alkali is completely converted into carbonate, permanganate of potassium is formed, together with a yellow hydrated precipitate containing *manganite of potassium*, $\text{K}^2\text{O} \cdot 5\text{MnO}_2$, or $\text{Mn}^2\text{K}^2\text{O}^{11}$.

Manganate of potassium dissolves without decomposition in water containing free alkali. If potash be added, not in too great excess, but still sufficient to form a green solution, this solution sometimes turns red when warmed, and remains so after cooling; but if briskly stirred, it turns green again.

When a very strong solution of potassic manganate is exposed to the air till the potash has absorbed carbonic acid, crystals are sometimes formed consisting, according to Mitscherlich, of *acid manganate of potassium*, MnKHO^4 .

Manganate of Sodium.—Obtained by igniting peroxide of manganese with caustic soda. It is so very soluble in water, that it cannot be obtained in the crystalline state (Mitscherlich). According to Gentile, however (*J. p. Chem.* lxxii. 58), manganate of sodium is obtained in nearly colourless crystals resembling Glauber's salt, and containing $\text{MnNa}^2\text{O}^4 \cdot 10\text{H}^2\text{O}$, by heating equal parts of finely-pulverised peroxide of manganese and nitrate of sodium in a muffle to a bright red heat for 16 hours, boiling the pulverised black mass with water, and leaving the solution to stand in a cold place. The crystals dissolve in water with slight decomposition, yielding a green solution. According to Wöhler (*Ann. Ch. Pharm.* cxix. 375), on the other hand, this process does not yield a trace of sodic manganate, because the nitrate of sodium is decomposed before the temperature required for the formation of the manganate is attained; in fact, the decomposition is so complete, that the process might be used for the preparation of pure hydrate of sodium. [But why does not this hydrate of sodium act on the peroxide of manganese so as to form sodic manganate and a lower oxide?]

Permanganates. $Mn^2R^2O^8$.—These salts are more stable than the manganates, and are, in fact, produced by their oxidation. They are isomorphous with the perchlorates, ClO^4 ; a fact which affords a strong argument in favour of the diatomicity of manganese, inasmuch as if the metal be regarded as monatomic, the formulae of the permanganates and perchlorates do not exactly correspond, the one containing 2 at. Mn, whereas the other contains only 1 at. Cl.

Permanganate of Ammonium. $Mn^2(NH^4)^2O^8$.—When permanganate of silver is triturated with an equivalent quantity of sal-ammoniac and with water, a purple-red solution is formed, which, when decanted from separated chloride of silver, yields by evaporation, crystals corresponding in composition with the above formula, and not containing any water of crystallisation. They are trimetric, and similar in form to the potassium-salt, but with somewhat different angles: $a : b : c = 0.8050 : 1 : 0.6519$. $\infty P : \infty P = 77^\circ 40'$; $P_\infty : P_\infty = 78^\circ 0'$. When dried by heat, they quickly decompose.

Permanganate of Barium. Mn^2BaO^8 .—This salt may be prepared by passing carbonic anhydride through water in which impure manganate of barium, obtained by calcining peroxide of manganese with nitrate of barium, is suspended, till the salt is completely decomposed, then decanting, boiling for a while in order to decompose the resulting acid carbonate of barium, and evaporating the clear solution to the crystallising point. Or permanganate of silver is decomposed by an equivalent quantity of chloride of barium dissolved in water, and the solution is evaporated.

Permanganate of barium forms black prisms, permanent in the air, and isomorphous with anhydrous sulphate and selenate of sodium (Mitscherlich). When the red solution of this salt is mixed with baryta-water, it acquires a violet colour, loses after a while its alkaline reaction, and yields by evaporation crystals of manganate of barium.

The permanganates of calcium, copper, magnesium, sodium, strontium, and zinc are prepared like the ammonium-salt: they are deliquescent and difficult to crystallise. The lithium-salt crystallises more rapidly.

Permanganate of Hydrogen, or Permanganic acid. $Mn^2H^2O^8$.—This acid may be obtained in the state of aqueous solution, by decomposing the barium-salt with sulphuric acid. As thus obtained by Mitscherlich, the free acid appeared to be a body not more stable than peroxide of hydrogen, being decomposed between 30° and 40° , with escape of oxygen gas and precipitation of hydrated peroxide of manganese. It bleached powerfully, and was rapidly destroyed by all kinds of organic matter. Hünefeld, on the other hand, obtained permanganic acid in a state in which it could be preserved, evaporated, redissolved, &c. He washed the manganate of barium with hot water, by which it is resolved into dioxide of manganese and permanganate of barium, and then added to it the quantity of phosphoric acid exactly necessary to neutralise the baryta. The liberated permanganic acid was dissolved out, evaporated to dryness, and by a second solution and evaporation, obtained in the form of a reddish-brown mass, crystalline and radiated, which exhibited the lustre of indigo at some points and was entirely soluble in water. When the dry permanganic acid was fused in a retort with anhydrous sulphuric acid, and afterwards distilled at a higher temperature, an acicular sublimate of a crimson red colour was obtained, which appeared to be a combination of permanganic and sulphuric acids. (Berzelius' *Traité*, i. 522.) When monohydrated sulphuric acid is poured upon a somewhat considerable quantity of crystallised permanganate of potassium, the salt is decomposed, with great evolution of heat, red flames bursting out, oxygen being given off, and manganic oxide being set free in dark-brown flakes and shreds like spider-lines. The red flames seem to show that permanganic acid is gaseous at the high temperature produced by the reaction. Its volatility has been further demonstrated by Terreil (Bull. Soc. Chim. de Paris, 1862, p. 40), who makes use of this property to obtain the acid in the pure state. For this purpose, permanganate of potassium is dissolved in sulphuric acid (H^2SO^4) diluted with 1 at. water; and the greenish-yellow solution is distilled over the water-bath at 60° or 70° . The apparatus then becomes filled with violet vapours, which condense to a soluble greenish-black liquid, not containing either chlorine or sulphuric acid, but consisting of pure permanganic acid. It is difficult, however, to prepare a large quantity of the acid at once in this manner, inasmuch as, at a certain moment, as soon as the quantity of the distillate has become somewhat considerable, it decomposes spontaneously, with slight detonation and separation of manganic oxide.

Permanganic acid thus obtained is a thick, greenish-black, metallic-shining liquid, which appears to be capable of solidifying. It greedily attracts moisture; its solution has a violet colour, and, if protected from dust, may, when dilute, be preserved with tolerable facility. When quickly heated, it detonates; but if slowly warmed, it

volatilises in violet vapours, having a peculiar metallic odour. It possesses very great oxidising power, instantly setting fire to paper and alcohol, the latter with explosion. In contact with fatty bodies, it detonates with violence. When a few drops of aqueous sulphite of potassium are let fall on permanganic acid, a very brisk reaction takes place; part of the acid is carried forward in vapour, and the vapour decomposes as it diffuses through the air, depositing a shower of brown flocks. Permanganic acid dissolves to a certain extent with green colour in strong sulphuric acid. The solution in acid containing 3 at. water, is violet; a difference which seems to indicate the existence of an anhydrous and a hydrated permanganic acid. (Terreil.)

Permanganate of Lead, Mn^2PbO^6 , is formed, on mixing a solution of nitrate of lead with permanganate of potassium, as a brown precipitate, soluble without residue in nitric acid.

Permanganate of Potassium. $Mn^2K^2O^6$.—This salt may be prepared by the following processes:—1. One pt. of peroxide of manganese is ignited with 1 pt. of hydrate of potassium (or 1·8 of nitre); the resulting mass dissolved in water; and the red solution decanted and evaporated, rapidly at first till small needles appear, afterwards cautiously, so that the crystallisation may go on regularly (Chevillot and Edwards).—2. Chlorate of potassium being kept in a state of fusion over a spirit-lamp, hydrate of potassium is first added to it, and then an excess of finely-divided peroxide of manganese, which immediately dissolves, forming a splendid green solution. The mixture is then heated till the whole of the chlorate is decomposed; and the mass, when cold, is boiled with a small quantity of water, whereupon the green colour of the solution changes to red; finally, the liquid is decanted from the peroxide of manganese while still hot, and set aside to crystallise by cooling (Wöhler, Pogg. Ann. xxvi. 626). (Gregory (J. Pharm. xxi. 312) adds a solution of 10 pts. (3 at.) of hydrate of potassium in a very small quantity of water to a finely-divided mixture of 8 pts. (3 at.) of peroxide of manganese and 7 pts. (1 at.) of chlorate of potassium; evaporates to dryness, during which a small quantity of mineral chameleon is formed; ignites the finely powdered mass in a platinum crucible over a spirit-lamp, till the whole of the chlorate of potassium is decomposed (for which a low red heat is quite sufficient); reduces the semi-fused mass to coarse powder; boils it in a larger quantity of water; allows the insoluble portion to subside, and decants; evaporates the clear solution rapidly; again decants from the freshly precipitated peroxide of manganese; and leaves the solution to crystallise by cooling. The crystals are then washed with a small quantity of cold water; dissolved in the smallest possible quantity of boiling water; and the solution is left to crystallise by cooling. In this manner needles are obtained three-quarters of an inch in length, and amounting in weight to about a third of the peroxide of manganese employed. If it be desired to filter the solution, in order to avoid the loss arising from decantation, a funnel may be used, having its neck filled with asbestos.

The salt crystallises in dark purple-red needles, having first a sweet, and afterwards a rough taste; it does not redden turmeric, and is permanent in the air. The crystals are trimetric; $a : b : c = 0·79523 : 1 : 0·6478$; $\infty P : \infty P = 76^\circ 59'$; $P\infty : P\infty = 78^\circ 20'$. They are prismatic, exhibiting the combination $\infty P \cdot P\infty$, the latter often predominant; frequently, also, with oP and other faces. The salt dissolves in 16 pts. water at 15° .

The crystals decrepitate when heated, evolve 10·8 per cent. of oxygen gas, and are converted into a black powder from which water extracts manganate of potassium, leaving 54 per cent. of black manganic oxide. When heated in an atmosphere of hydrogen gas, they become red-hot and diminish in bulk, at first rapidly, afterwards slowly, with formation of a green mixture of hydrate of potassium and protoxide of manganese. The salt, when triturated with sulphur, produces a series of small detonations. Mixed with an equal weight of sulphur and heated to 177° , it explodes with flame. Phosphorus produces a much louder detonation when triturated with it, also when heated with it to 70° . Charcoal, arsenic, and antimony likewise take fire when heated with the salt.

A solution of permanganate of potassium containing perchlorate, deposits crystals containing the two salts in the same proportion as the solution. In presence of a very large excess of perchlorate, they are red; but if the proportion of permanganate amounts to one half, they appear black.

Permanganate of Silver, $Mn^2Ag^2O^6$, is obtained, according to Mitscherlich, on mixing warm solutions of nitrate of silver and permanganate of potassium, the solution as it cools depositing the salt in large regular crystals, which require 190 times their weight of water at 15° to dissolve them. In warm water they are much more soluble, but they cannot sustain a boiling heat without decomposition.

The manganates and permanganates, especially the latter, are used as oxidising agents for a variety of purposes. A solution of permanganate of potassium is quickly decolourised, and consequently decolorised, by sulphurous acid, by neutral solutions of

sulphides and pentathionates, and by acid solutions of sulphites, hyposulphites, tetrathionates, sulphyocyanates and nitrites; more slowly by trithionates. Acidulated solutions of mercurous, ferrous, stannous and antimonious salts, and acid solutions of arsenious acid, likewise rapidly decolorise a solution of a permanganate. A solution of permanganate of potassium constitutes a test-liquid of great use in volumetric analysis, as we have already had occasion to notice (see i. 263; ii. 59; iii. 384).

The manganates and permanganates likewise act very rapidly on organic matter, and may therefore be employed as disinfecting agents. Solutions of these salts have, in fact, lately been prepared on the large scale for this purpose by Mr. Condy. Putrid water from stagnant pools is rapidly deodorised by these solutions. Their freedom from odour and perfectly innocuous character render them available for many purposes for which other disinfectants cannot be used, as for application to wounds and festid sores: they may also be advantageously used for the purification of tainted provisions. On the other hand, their fixed character renders them less adapted for purifying infected atmospheres than the hypochlorites, which evolve a gas capable of acting on the organic matter in the air. (See Hofmann's *Report on Chemical Products and Processes in the International Exhibition of 1862.*)

MANGANITE. Native manganic hydrate (p. 810).

MANGIFERA GABONENSIS. The tree which yields the so-called Dika bread (ii. 330).

MANGOLD WURZEL. See BETA (i. 582). On the changes which take place in the composition of the plant during its growth, see R. Hoffmann. (Bull. Soc. Chim. de Paris, 1864, p. 393.)

MANGOSTIN. $C^{12}H^{12}O^4$. (W. Schmid, Ann. Ch. Pharm. xciii. 83).—A substance contained in the husk of the fruit of *Garcinia Mangostana* (ii. 771). To obtain it, the dry husks are boiled with water to extract tannin, then treated with hot alcohol, and the alcoholic extract is left to evaporate, whereupon it deposits mangostin as a yellow crystalline substance, mixed with a large quantity of yellow amorphous resin. To remove the latter, the whole is dissolved in alcohol, and the solution is mixed with sufficient water to render it opalescent; it then, on cooling, deposits, first the resin, afterwards the mangostin in small yellow laminae. For further purification, the alcoholic solution is precipitated with basic acetate of lead; the washed precipitate is suspended in water, and decomposed by sulphydric acid; the filtrate is mixed at the boiling heat with water, till it becomes milky; and the mangostin which separates from it on cooling is finally purified by crystallising it several times from dilute alcohol.

Mangostin thus prepared forms thin golden-yellow laminae, destitute of taste and smell. It melts at about 190° , without loss of water, to a dark-yellow liquid, which solidifies to an amorphous mass; by a stronger heat, the greater part of it is decomposed, the remainder subliming unaltered. It is insoluble in water, but dissolves easily in alcohol and in ether, forming neutral solutions. Warm dilute acids dissolve it without alteration; by heating with strong nitric acid, it is converted into oxalic acid. Alkalies dissolve it with yellow or brownish colour. It reduces the noble metals from their solutions: with ferric chloride, it forms a dark greenish-black solution, the colour of which disappears on the addition of acids. It is not precipitated by any metallic salt, excepting basic acetate of lead. The yellow precipitate thrown down from the alcoholic solution by neutral acetate of lead and a little ammonia, gave by analysis (at 100°), in one experiment, numbers agreeing nearly with the formulae $4C^{12}H^{12}O^4 \cdot 5PbO$.

MANIHOTIC ACID. An acid said to have been obtained from the root of *Jatropha Manihot*; it crystallises in prisms, having an acid taste, and forms, with baryta, lime, and magnesia, neutral, easily fusible salts, crystallising in nodules; but its existence is not well established. (Handw. d. Chem. v. 113.)

MANILA GUM. A resin of unknown origin, resembling Copal and Dammar resin. It dissolves for the most part in alcohol of 90 per cent., and melts easily, diffusing an odour like that of the resin of the Coniferae. (Buchner.)

MANIOC. The Indian name of the nutritious matter of *Jatropha Manihot*, from which cassava and tapioca are made in the West Indies. It has been analysed by Payen. (Compt. rend. xlv. 401.)

MANNA. A saccharine juice which exudes from certain species of ash and other plants. It has a strong smell, a sweetish, slightly nauseous taste, and acts as a mild purgative, but is also more or less nutritious.

The trees which yield the manna of commerce are two species of ash growing in the warmer parts of Europe and in the East, viz., *Fraxinus Ornus*, Linn., which grows in the South of Europe, in mountainous situations, especially in Calabria and Sicily; and

Fraxinus rotundifolia, Lamareck, or *Ornus rotundifolia*, Persoon—the round-leaved, flowering, or manna ash, which grows in Calabria and in the East. According to Decandolle, it is from this latter tree that manna is chiefly obtained. The manna flows naturally from the trees, and attaches itself to their sides in the form of white transparent drops; but the extraction of the juice is facilitated by incisions made during summer.

The finest kind of manna is called flake manna (*Manna cannulata* vel *canellata*). It is white or yellowish-white, light, porous and friable, the fractured surface exhibiting a number of small capillary crystals. Its odour somewhat resembles that of honey; its taste is sweet, but afterwards rather acrid.

Inferior sorts are: 1. The *Sicilian manna*, which is the commonest in English commerce, consisting of small, soft, round fragments of a dirty yellowish-brown colour, intermixed with particles of dark flake-manna: this kind contains many impurities.—2. *Manna in sortis* (in *sortis*), which may be subdivided into: *a. Gerace*, which approaches most nearly to flake manna; and, *β. Capace*, which comprises not only that from the district so called, but also that of Cinesi and Faberetti in Sicily; it is fatty, sticky, and hard, though clearer in appearance than the last.—3. *Manna calabrina*, which stands between the last two (*a* and *β*), but is now of rare occurrence in commerce.—4. An inferior kind, known as *Manna communis*, is found in the Neapolitan province of Capitanata, on the declivities of Mount St. Angelo. It is not fatty, but very damp, and is chiefly consumed in Italy, and sent to the Levant. The yearly production of this kind of manna amounts to more than 200 tons.

Analyses of Manna.

There are also several varieties of saccharine exudations, known under the name of manna, not produced by the ash. Of these Landerer enumerates eight, viz.: 1. *Manna larinica*, from the leaves of *Larix europea*; also called Briançon manna. According to Berthelot, it contains melezitose (*q. v.*).—2. *Manna cedrina*, from the branches of *Pinus cedrus*. This variety is brought from Mount Lebanon, and has great repute in Syria.—3. *M. celastrina*.—4. *M. quercina*.—5. *M. australis*, produced by *Eucalyptus resinifera*.—6. *M. cistina* s. *labdanifera*, a rare variety met with in Greece. This is derived from several species of *Cistus*, and is called *Cistus manna*.—7. *M. Althagnia*, the exudation of *Hedysarum Alkago*, a plant indigenous in Arabia, and growing also in the maritime districts of Greece. This manna is supposed to exude from the *Hedysarum*, which covers extensive plains in Arabia and Palestine, as a result of the wounds produced on the plants by the browsing of sheep and goats. It is used as nutriment by the Arabs, as well as by those who form the caravans which cross the Desert. According to Landerer, it is this variety, and not the produce of the ash, which corresponds to the *mel ex arbore* of Pliny, and the *humor melicus* of Theophrastus.—8. *Manna tamariscina*, called also *Manna Israëlitica*, and believed by Landerer to be the manna mentioned in the Old Testament. He informs us that this exudation is produced by the puncture of *Coccus manniferus*, an insect inhabiting the trees of *Tamarix mannifera*, which grow abundantly in the neighbourhood of Mount Sinai. The manna exudes as a thick transparent syrup, covering the smaller branches, from which it flows. It is collected by the monks of the district in the month of August. The collection takes place very early in the morning, at which time, owing to the coolness of the night, the saccharine juice has become to some extent congealed. The tamarisk manna is eaten in Palestine, and in the district of Sinai, as a delicacy, and is said to be efficacious in diseases of the chest. It is soluble in water and alcohol, and the aqueous solution

readily undergoes fermentation. The alcohol which it yields has a peculiar odour, resembling that from the fruit of *Ceratonia siliqua*, which contains butyric acid. The manna must therefore contain fermentable sugar, in place of mannite [or together with the latter]. (*Pereira's Materia Medica*, 4th ed. vol. ii. [1] p. 673.) According to Berthelot (Compt. rend. liii. 583), the tamarisk manna from Sinai contains 55 per cent. cane-sugar, 25 inverted sugar (ii. 863), and 20 dextrin, &c.; manna from Kurdistan contains 61 per cent. cane-sugar, 15.6 inverted sugar, and 22.5 dextrin, &c.

MANNIDE.**MANNITAN.**

} See the next article, p. 325.

MANNITE. *Sugar of Manna. Sugar of Mushrooms.* $C_6H_{14}O_6$.—This substance was discovered by Proust (Journal f. Chem. u. Phys. v. Gehlen, ii. 83), and has been investigated by many chemists, including, among others, Liebig, Frémy, Strecker, Berthelot, Wanklyn, Erlenmeyer, and Linnemann. (For references, see *Gmelin's Handbook*, xv. 356.)

The following plants and parts of plants contain mannite ready formed: the roots of *Aconitum Napellus*; of celery, from *Apium graveolens*; of *Meum athamanticum*; of *Eranthe crocata*; of *Polypodium vulgare*; of *Scorzonera Hispanica*; the root-bark of *Tunica Granatum* [constituting Latour's *Granatin*]; the roots of *Triticum repens*. The bark of *Canella alba* contains about 8 per cent. of mannite; that of *Praxinus excelsior* contains mannite. The leaves and young twigs of *Syringa vulgaris* contain mannite [which, mixed with *Lilacin*, constitutes Bernays' *Syringin*]; also, the leaves of *Ligustrum vulgare*; celery-leaves; the foliage of *Cocos nucifera*; the fruit of *Laurus Persea*, of *Cactus opuntia*. Coffee-beans contain mannite, according to Döbereiner. Ergot of one year contained mannite, that of another year mycose. Many fungi contain mannite. On algae there is often found an efflorescence of mannite, which, according to Stenhouse, may also be obtained from the dry algae; according to Phipson, mannite does not exist in fresh algae, but is formed from vegetable mucilage by fermentation. It is formed very abundantly during the viscous fermentation of sugar, and to a greater or less extent during fermentation generally. In the transformation of starch into glucose by boiling with dilute sulphuric acid, it is also formed as a secondary product. Finally, Linnemann (Ann.-Ch. Pharm. exxiii. 186) has obtained it by the action of sodium-amalgam on glucose.

Mannite is usually prepared from manna, which is treated with boiling alcohol, and the alcoholic solution allowed to crystallise. On cooling, mannite is deposited. It is purified by recrystallisation, and appears to be very easily obtainable in a high state of purity.

Mannite crystallises in thin four-sided prisms, which sometimes grow to a considerable size. One of the characteristics of mannite is the ease with which it may be crystallised from its solution in water or in alcohol. The crystals contain no water of crystallisation, and are but very slightly hygroscopic.

At 18°, 1 pt. of mannite dissolves in 6½ pts. of water. At 15°, 1 pt. of mannite dissolves in 80 pts. of alcohol (specific gravity 0.898), and in 1,400 pts. of absolute alcohol. In boiling alcohol, it is much more soluble. In ether, it does not dissolve at all.

An aqueous solution of mannite does not become syrupy on being spontaneously evaporated; in this respect it differs strikingly from a solution of sugar. It is only slightly sweet to the taste. It does not exert any action on polarised light.

Mannite differs from sugar in its power of resistance to the action of heat. It melts between 160° and 165°; at about 200° it begins to boil, and may be distilled with very little decomposition, even at the ordinary atmospheric pressure. In sealed tubes it will bear a heat of 250° without suffering much decomposition; at higher temperatures it carbonises.

It does not ferment except under very unusual conditions. It does not reduce oxide of copper to the state of suboxide; but hinders the precipitation of sulphate of copper by the fixed alkalis, causing the formation of a beautiful blue-purple solution instead. It may be boiled with solution of potash without imparting a brown colour to the solution.

The composition of mannite was determined some years ago by Liebig, who fixed upon the formula which is at present admitted; but, as was shown a short time ago (Proceed. Roy. Soc. Edinburgh, 1861-62; Ann. Ch. Pharm. exxiii. 372; Chem. Soc. J., xvi. 221), this must have been by accident; for, until quite recently, nothing was known about mannite which could lead to the adoption of one rather than another of three or four formulae, each of them equally probable.

The close analogy subsisting between mannite and glycerin was shown by Berthelot (*Chimie organique fondée sur la Synthèse*, par M. Berthelot), who obtained a great variety of salts of mannite by heating a mixture of mannite with different acids to a temperature of between 200° and 250°: nitro-mannite, which is really the nitrate of

MANNITE.

the series, had been previously discovered by Flores Domato and Menard (1847), and then investigated by Strecker.

The connection between mannite and the hexylic group was shown by Wanklyn and Erlenmeyer in 1861, by the conversion of mannite into iodide of hexyl, by means of hydriodic acid:

By this transformation the formula of mannite, which up to that time was doubtful, was fixed with certainty.

The chemical character of mannite is that of a polyatomic alcohol: it is a hex-atomic alcohol:

Or, it may be regarded as hydride of hexyl in which 6 atoms of peroxide of hydrogen replace 6 atoms of hydrogen:

It is closely related to the sugars, glucose becoming mannite when acted upon by nascent hydrogen, whether that hydrogen be a product of fermentation or of the action of sodium-amalgam on water:

Glucose is probably derived from the hydrocarbon C^6H^{12} , being $\text{C}^6\text{H}^8(\text{HO})^6$.

On being heated to a temperature of 200° , mannite loses water and passes into mannitan (Berthelot):

This conversion seems to be partial. Mannite is likewise converted into mannitan by prolonged boiling with strong hydrochloric acid.

When mannite is oxidised with *nitric acid*, it is converted into saccharic acid, and not into mucic acid: on pushing the oxidation further, oxalic acid is obtained.

Fusion with *caustic potash* causes disengagement of hydrogen, and production of formate, acetate, and propionate of potassium. Distilled with *lime*, it appears to give acetone.

With *fuming nitric acid*, or better with a mixture of *nitric* and *sulphuric acids*, it gives nitro-mannite, $\text{C}^6\text{H}^8(\text{NO})^6$.

With *sulphuric acid* it gives a coupled acid, sulpho-mannitic acid:

Heated for some hours to a little over 200° with organic acids, it forms salts which bear a considerable resemblance to the fats. (Berthelot.)

When it is heated with *bromide of ethyl* and *potash*, it furnishes ethyl-mannite.

According to Berthelot, when it is kept for several weeks in contact with *water*, *chalk* and *cheese*, or other protein-compound, at a temperature of 40° , it gives rise to alcohol, carbonic, lactic, butyric and acetic acids, and hydrogen: at the same time there is no production of yeast, and no fat, nor glycerine nor sugar. If a slit testicle be employed as a ferment, then there is production of sugar.

Inasmuch as glycerin has been produced artificially from a derivative of propylene, viz., from $\text{C}^3\text{H}^3\text{Br}^2$, there is reason to expect that mannite will be made from a derivative of hexylene. Up to the present time, however, the synthesis of mannite has not been realised.

Salts of Mannite.—In Berthelot's *Chimie organique*, &c., a number of organic salts of mannite are described, i. e., acetate, butyrate and dibutyrate, palmitate, stearate, oleate, benzoate, and tribenzoate. They are prepared in general by heating mannite or mannitan with the acid to a temperature ranging between 200° and 250° for from 12 to 15 hours. At the end of this process more or less of the salt is found. In order to purify the salt, the crude product is treated with excess of an alkali (baryta or carbonate of sodium) which combines with the acid that has not been used up by the mannite or mannitan, but does not attack the organic salt which has been produced. Ether is then added and dissolves the salt. The ethereal solution, on being evaporated, yields the salt, which is an oil or a fat according to acid employed.

Of the salts above mentioned the butyrate appears to be the easiest to prepare; but in all cases only a portion of the mannite or mannitan undergoes conversion into a salt. There is the closest resemblance, both physically and chemically, between the salts of glycerin and these salts of mannite.

Berthelot regards these salts as derivatives, not of mannite, $\text{C}^6\text{H}^8\text{O}^6$, but of mannitan, $\text{C}^6\text{H}^{12}\text{O}^5$. Their formulae (given under Ethers, ii. 521) require confirmation.

MANNITIC ACID.

Derivatives of Mannite.

Mannide. $C^6H^{10}O^4 = C^6H^{10}O^6 - 2H^2O$.—Discovered by Berthelot, who obtained it by acting upon mannite with butyric acid. It constitutes a syrup, which is at first sweet to the taste, and afterwards bitter. It is very soluble in water and in absolute alcohol, even in the cold.

A remarkable circumstance connected with it is its volatility. It is sensibly volatile at 100° , and evaporates rapidly at 140° .

It is highly deliquescent, passing gradually into mannite when it is exposed to a moist atmosphere. Exposed in an open vessel to the air in the usual state, it absorbs as much as 40 per cent. of moisture, whilst in air saturated with moisture, it will sometimes take up as much as 80 per cent.

Mannide is not an ether, but a derivative of the hydrocarbon C^6H^{12} , viz., $C^6H^8(HO)^4$.

Mannitan. $C^6H^{10}O^3$.—Discovered by Berthelot. Obtained, but only in small quantity, by heating mannite to about 200° . A better method of preparation is by the long-continued boiling of mannite with strong hydrochloric acid; or by the saponification of a salt of mannite. It is a curious fact, that the salts of mannite always give mannitan on saponification, the mannitan passing subsequently more or less completely into mannite.

Mannitan is a syrup with a slightly sweetish taste. It may be very readily distinguished from mannite by its solubility in absolute alcohol, which thus affords a means of effecting a separation of these two substances. It is very soluble in water, but insoluble in ether.

On being exposed for a length of time to the atmosphere, it undergoes a very partial conversion into mannite. Boiling with alkalis or dilute acids accelerates this change.

When heated above 140° , it partly volatilises.

With respect to its rational constitution, it appears to the writer of this article that mannitan is not an ether of mannite. It would seem rather to be derived from a lower hydrocarbon:

Mannite being derived from C^6H^{14} , i. e., $C^6H^8(HO)^4$.

Mannitan „ from C^6H^{12} , i. e., $C^6H^8(HO)^3$.

The ease with which hexylic compounds pass into hexylene is again encountered in the mannite compounds, which are hexyl-compounds that have suffered replacement of hydrogen by peroxide of hydrogen. (See HEXYL-COMPOUNDS.)

Nitro-mannite. $C^6H^8(NO^3)^4$.—Prepared by treating mannite with the strongest nitric acid and sulphuric acid. It forms beautiful fine white acicular crystals, insoluble in water, but soluble in alcohol or ether. It explodes very violently on being struck with a hard substance. If carefully heated, it may be decomposed without explosion; but when it is suddenly heated, it explodes, but not with great violence. It seems to suffer spontaneous decomposition on being kept for a long time.

It has been proposed to use nitro-mannite for charging percussion-caps, but apparently without success.

A reaction of nitro-mannite which is of considerable theoretical interest is that with sulphide of ammonium, by which reagent it is converted, not into a nitrogenous organic base, but into mannite.

Sulpho-mannitic acid ($C^6H^{10}O^4SO^3$). A kind of mannite-sulphovinic acid, is formed by the action of strong sulphuric acid upon mannite. A barium-salt, $C^6H^{10}Ba^2O^4SO^3$, and other salts of this acid, have been obtained. J. A. W.

MANNITIC ACID. $C^6H^{12}O^7$.—An acid produced, together with mannitose, by the oxidation of mannite under the influence of platinum-black; it was first observed by Döbereiner, and more completely investigated by Goup-Besanez (Ann. Ch. Pharm. cxviii. 267). To prepare it, mannite is mixed with twice its weight of platinum-black; and the mixture, moistened with water, is exposed to a temperature not exceeding 30° or 40° at the utmost, as long as it contains any undecomposed mannite (about three weeks for 20 or 30 grains of mannite). The mass is then exhausted with water; the solution precipitated with basic acetate of lead; the well-washed precipitate decomposed by sulphydric acid; and the solution is evaporated, first over the water-bath, then in the cold over sulphuric acid.

Mannitic acid is not crystallisable, but forms a gummy mass, soluble in water and in alcohol, nearly insoluble in ether. It reduces cuprous oxide from an alkaline cupric solution, and throws down metallic silver from the nitrate.

The mannitates have not yet been obtained in the crystalline form. The composition of the salts analysed by Goup-Besanez corresponds with the formula $C^6H^{10}M^2O^7$. The calcium-salt, $C^6H^8Ca^2O^7$, is precipitated from its aqueous solution by alcohol. The copper-salt, $C^6H^8Cu^2O^7$, remains as a green amorphous mass when its aqueous

solution is evaporated. The *lead-salt*, $C^6H^{10}Pb^1O^1$, separates on cooling from the solution obtained by boiling mannitic acid with lead-oxide. The *silver-salt*, $C^6H^{10}Ag^1O^1$, separates as a greenish-yellow precipitate on mixing a concentrated solution of the calcium-salt with nitrate of silver.

MANNITOSE. $C^6H^{12}O^6$.—A kind of sugar, isomeric with glucose, produced, together with mannitic acid, in the oxidation of mannite under the influence of platinum-black (Görup-Besanez, *loc. cit.*). It is fermentable, but does not act on polarised light. It exhibits, with alkalis, alkaline cupric solutions, basic nitrate of bismuth, carbonate of sodium, and other reagents, the same behaviour as dextro-glucose (ii. 860), but does not unite with chloride of sodium; its alcoholic solution mixed with alcoholic potash containing 11·27 per cent. potash, forms a semifluid yellow precipitate, corresponding with the formula $K^2O \cdot 2C^6H^{12}O^6$. (Gmelin's *Handbook*, xv. 339.)

MANURE. *Dünger. Engrais.*—This term, in its widest signification, is applicable to any material used in agriculture and horticulture for the purpose, and with the effect, of accelerating vegetation, or of increasing the production of cultivated plants. In a usual and more limited sense, it signifies the accumulated refuse of the dwellings, stables, and cattle-yards of a farm—including animal excreta, decaying remains of plants, &c. (See Voelcker, 1856–9, *Journal of the Royal Agricultural Society of England*, xvii. 191; xviii. 111; xix. 112; xx. 134; On the Composition of Farm-yard Manure.—Lawes, 1862 *ibid.* xxiii. 45.) Burnt lime, marl, clay, gypsum, &c. are also commonly used as manure.

In addition to these kinds of manure which are produced upon the farm as the result of its internal economy, or obtained in the immediate neighbourhood of the land to which they are applied, a variety of other materials are employed for the same purpose, under the name of *artificial manure*. These materials are chiefly obtained by the farmer from extraneous sources, and sometimes from considerable distances, according to their value. They comprise guano (ii. 952), bones (i. 619), prepared phosphatic minerals (APATITE, i. 348; COPROLITES, i. 82), ammonia-salts, nitrates, the refuse of slaughter-houses and of various manufactures; fish, sea-weed, &c.; the refuse of towns, in the form either of night-soil or sewage; and artificial saline mixtures. (See Ure's *Dictionary of Arts, Manufactures, and Mines*, iii. 36 *et seq.*; also Way 1849, *Journ. Roy. Agric. Soc. Eng.* x. 196—Composition and Value of Guano, 1851, *ib.* xii. 204—On Superphosphate of Lime, 1856, *ib.* xvi. 533—Value of Artificial Manures.—Voelcker, 1861–2, *ibid.* xxi. 350; xxiii. 277—Chemical Composition and Commercial value of Phosphatic Manures and Artificial Manures.)

The fertilising influence of manure is a fact which has been established by universal experience wherever the cultivation of plants has been practised. In agriculture—considered as that branch of industry which is concerned in the manufacture of food for man and domesticated animals, and therefore the most important art of civilised life—manure may be regarded as being, to a great extent, the raw material employed. A complete knowledge of the causes to which the efficacy of manure is due, and of the mode in which it acts, would comprise the whole chemistry of agriculture. The right management of the manure naturally resulting from systematic agriculture is the basis on which rests the profitable practice of the art, the fundamental principle which should regulate all the operations of the farm, and determine all their details. It is only by means of such knowledge that it can be possible to modify and improve the method of culture, or to make a right selection and use of other materials, besides the natural manure of the farm, with the object of augmenting, artificially, the produce of land, by rendering effective, in a higher degree, the natural sources of fertility.

The principles involved in the action of manure are to some extent deducible from that knowledge of the general phenomena of vegetation which has been acquired chiefly within the present century, and has begun to assume consistency and system only within the last five-and-twenty years. The data upon which that knowledge is founded were contributed chiefly by the successive researches of Priestley, Ingenhousz, Sennebier, Woodhouse, Saussure, and Davy. But though they afforded materials for a view of the chemistry of vegetation, more correct than that which considered decaying animal and vegetable substances as the chief food of plants, they were but little regarded; and though the researches of Saussure were conducted with special reference to agricultural practice, still the humus theory of plant-nutrition held its ground, and was adopted by Davy in his lectures on the "Elements of Agricultural Chemistry," delivered before the Board of Agriculture between 1802 and 1812. In those lectures he did little more than state the general problem to be solved in the application of chemistry to agriculture, and insist upon the important relation between the science and the art; but they afford some remarkable illustrations of the correct appreciation of natural facts which was characteristic of his genius. (Priestley, 1772, *Phil. Trans.* 72; lxii. 167–200.—Ingenhousz, 1779, *Experiments on Vegetables, &c.*; 1782 *Phil. Trans.*; 1784, *Sur l'Economie de Végé-*

taux, *Jour. Phys.* xxiv. ; 1798, *Essay on the Food of Plants and the Renovation of Soils*.—Hassenfratz, 1792, *Jour. Phys.* xiii., xiv. Sur la Nutrition des Végétaux.—Kirwan, 1794, *Trans. Roy. Irish Acad.* v. 123. What are the manures most advantageously applicable to various sorts of soils, and what are the causes of the beneficial effect in particular instances?—Senebier, 1800, *Physiologie végétale*, &c.—Woodhouse, 1802, *Nicholson's Journ.*—Saussure, 1804, *Recherches chimiques sur la Végétation*.—Davy, *Collected Works*, vii., viii.)

Following in the track of Saussure's researches, Boussingault entered upon the study of the same subject, conducting his experiments on a much larger scale, and with a more direct relation to agricultural practice than had hitherto been attempted. In this country, Lawes was also led, by the suggestive work of Saussure, to study the effects of various earthy and saline substances upon the growth of different plants, and the researches of both have been continued to the present time. Boussingault's first memoirs on the subject were published in 1836, and in the year 1839 he had made known results of his investigations, which—besides establishing the composition of the most important kinds of agricultural produce; the efficacy of various materials in feeding animals, and the general relations between the composition of the crops obtained and the manure used in the ordinary routine of practice in his locality—had led him to adopt the conclusions, that the carbon and nitrogen obtained in the several crops comprised in a rotation, amounted to much more than was contained in the manure supplied within the same time; and consequently, that those constituents must be derived in some way from the atmosphere during vegetation; that those alternations of crops which admitted of accumulations of carbon and nitrogen being gathered from the atmosphere, and conserved upon the farm most largely, in the form of manure, were the most advantageous; that certain plants were better fitted for this purpose than others; and that the value of manure was, to a great extent, indicated by the amount of ammonia or nitrogen which it contained. (See Boussingault, 1836, *Ann. Chim. Phys.*; *Recherches sur la quantité d'Azote contenu dans les Fourrages, et sur leur Equivalens*, lxiii. 225-244, 1838, lxvii. 408-421; *Examen comparatif des Circonstances météorologiques sous lesquelles végètent certaines Plantes alimentaires, à l'équateur et sous la zone tempérée*, *ib.* 337-358; 1837, *Des Influences météorologiques sur la Culture de la Vigne*, lxiv. 174; *Mémoire sur la quantité de Gluten contenue dans les Farines de plusieurs espèces de Froment cultivées dans le même sol*, lxv. 301; *De la Discussion de la valeur relative des Assolements par l'analyse élémentaire*, *Compt. rend.* vii. 1149; viii. 54.)

Ingenhousz and Saussure had already adopted the opinion that the carbon of plants was, to a great extent, derived from the atmospheric carbonic acid; and the same view had been put forward by Brongniart, in reference to the origin of the coal strata, as more probable than the humus theory. (Brongniart, 1837, *Compt. rend.*, *Considérations sur la Nature des Végétaux qui ont couvert la surface de la Terre aux diverses époques de sa formation*, v. 403-415.)

But it was not until the year 1840 that a comprehensive theory of plant-nutrition was propounded by Liebig, with such perspicuity and force as to excite universal attention. The fundamental proposition of that theory was, that the food of plants, the materials from which the chief mass of their substance is produced in vegetation, consists solely of carbonic acid, water, and ammonia. The chemical arguments by which this view was supported, in opposition to the prevailing opinion, that plants derived their carbon, hydrogen, oxygen, and nitrogen from humus, and from other vegetable and animal substances, were conducted in such a convincing and logical manner, that Liebig has been generally regarded as being entitled to the same honour in the establishment of this theory of plant-nutrition, as if the data on which it was based had altogether originated with himself. Liebig's researches on the phenomena of the decay of animal and vegetable materials afforded, together with the existing knowledge of the phenomena of animal life, the most conclusive evidence that the ultimate products of those processes were carbonic acid, water, and ammonia, precisely those materials constituting the chief food of plants. Moreover, these substances cannot be combined, in any way, so as not to contain a far greater amount of oxygen than the substances of which plants collectively consist, and which are produced in vegetation. This fact showed that elimination of oxygen was a necessary feature of vegetation, and threw an entirely new light upon the known constitution of the atmosphere and the decomposition of carbonic acid by growing plants; at once establishing a most remarkable relation between the phenomena of vegetation and of animal respiration, and demonstrating the essential interdependence of the processes of animal and vegetable life.

From the fact that the food of animals is provided exclusively by the vegetable kingdom, either directly, in the form of corn, roots, fruit, &c.; or indirectly, through the medium of animal life, as the flesh of herbivorous animals, the importance of a knowledge of the chemistry of vegetation, in reference to the cultivation of plants as a source of food for animals, is self-evident. Consequently, Liebig's exposition of

his theory of plant-nutrition had especial reference to the practice of agriculture, just as the researches of Saussure, Boussingault, Lawes, and others, had been prosecuted in the same direction; and it was developed, in its application, into a theory of agriculture. (Liebig, 1840, *Chemistry in its Applications to Agriculture and Physiology*.)

In order to illustrate fully the chemistry of manures, and the principles involved in their use, as well as in the general routine of agricultural practice, it will be necessary to give a brief statement of the general features of the chemistry of vegetation, considered from an abstract point of view, so far as the present knowledge of that subject will permit; then to describe the conditions which exercise the chief determining influence upon vegetation, in regard to the object appertaining to agriculture generally, and the different means adopted for the attainment of that object, according to the modification it receives by the various special circumstances under which the art is practised.

The ultimate result of the growth and development of plants consists in the production of a number of oxygenated and nitrogenous hydrocarbon compounds:—starch, sugar (ii. 855), gum (ii. 953), lignin (i. 818), fat (ii. 616), albumin (i. 69), gluten (ii. 873), legumin (iii. 568), fibrin (ii. 643), &c., which, in some form of subordinate modification, are universal constituents of all plants; and a great variety of other analogous substances, which are special constituents of particular plants or of particular plant-organs.

The chief mass of the solid portion of plants consists of these substances; it is the main function of vegetation to produce them, and thus to provide food for animals. (See NUTRITION.)

These constituents of plants were formerly termed, in a chemical sense, "organic" substances, in conformity with the opinion that they could be produced only by the plant-organism, under the influence of vital action; and that they were totally distinct, in their chemical nature, from the compounds producible artificially, and from those belonging to the mineral kingdom, which were termed "inorganic" to distinguish them chemically from the proximate constituents of organised bodies—either plants or animals—and from the derivatives of those compounds. Modern chemistry, however, has discarded that opinion, and with it the use of the terms organic and inorganic, as expressive of a distinction which no longer represents a recognised difference; but the term "organic" is still conveniently applied to the constituents of plants and animals without involving such a distinction. (Gerhardt, 1853, *Traité de Chimie organique*, i. 1-6.)

The materials from which the proximate constituents of plants are produced in vegetation are few. According to the present state of knowledge, carbonic acid is the principal source of the carbon; but in the case of some plants, a further portion of carbon may possibly be derived from other carbon-compounds. (See HUMUS, iii. 76, and ULMIN.) Water is the source of hydrogen and oxygen, while nitrogen is derived chiefly from ammonia; to some extent also from nitric acid; possibly from nitrogenous substances analogous to humus, and from the elementary nitrogen of the atmosphere; but whether directly or indirectly, or even at all, has not been ascertained. The preponderance of evidence is in favour of the opinion that elementary nitrogen is not directly assimilated by plants. See on this subject: SAUSSURE, 1804, *Recherches &c.*—Davy, *Collected Works*, vii., viii.;—Boussingault, 1838, *Ann. Chim. Phys.* lxxvii. 1-54, lxi. 353-367; *Recherches chimiques sur la Végétation, entreprises dans le but d'examiner si les Plantes prennent de l'azote à l'atmosphère*, 1854 [3] xli. 1-60; 1855, xliii. 149-223; 1856, xlii. 1-41; 1858, *Compt. rend.* xlvii. 807; 1838, *Compt. rend.* vi. 129; 1839, vii. 889.—Liebig, 1840, *Chemistry*, &c.—Mulder, 1846, *The Chemistry of Vegetable and Animal Physiology*.—G. Chem.* lxx. 101-105.—Lawes, Gilbert, and Pugh, 1862, On the Sources of Nitrogen in Vegetation, *Phil. Trans.* for 1861, p. 431 *et seq.* and, 1863, *Journ. Chem. Soc.* (2) I. 100.—Lehmann, *Physiological Chemistry*, Cavendish Soc. iii. 178.—Mohl, *The Vegetable Cell*, by Henfrey, pp. 77-88.

Among the substances above named, carbonic acid, water, and ammonia constitute the chief materials of plant-food; and since it is from them that the organic constituents of plants are principally produced in vegetation, they have been sometimes called the "organic materials of plant-food" (*Quarterly Review*, lxi. 336; Schleiden, *The Plant*, p. 173). Under natural conditions, these substances are constantly supplied to plants by the atmosphere (i. 437-439), which contains them in small proportion, but in large aggregate quantity, continually replenished by the process of animal life (see RESPIRATION); by the decay of dead animals and plants (EREMACUSIS, ii. 497); by

several natural phenomena of the mineral kingdom (i. 770, ii. 835); by industrial and economic operations (COMBUSTION, i. 1095; FUEL, ii. 722); by rain, dew, and the evaporation of water from the ocean, lakes, and rivers (see WATER and AMMONIA, i. 182). It is immaterial whether these substances are supplied to plants exclusively by the atmosphere, or whether they are derived from other sources as well; in either case their value in regard to vegetation is the same. They may, therefore, be termed collectively the air-food of plants; and the organic substances produced from them in vegetation may be designated the air-derived constituents of plants. So far as relates to the merely abstract view of the chemistry of vegetation, it is a matter of indifference whether the materials, constituting the air-food of plants, are derived exclusively and directly from the atmosphere, or whether they are to some extent derived from other sources also, and indirectly; as, for instance, by the decay of humus or nitrogenous animal or vegetable substances contained in the soil, or supplied to it as manure. The cases are different, however, when vegetation is regarded from a practical point of view—as the means of producing food for animals artificially—and when the objects and circumstances of the practice of agriculture have to be included in the consideration of that subject, the difference is of the highest importance.

But there are also other materials concerned in vegetation besides the carbonic acid, water, ammonia, &c., from which the plant constructs its chief substance. In almost all plants, and in every organ of a plant, there are certain substances—indestructible by fire—which remain as ashes when plants are perfectly burnt. (See ASH, i. 416 *et seq.*)

The ash of all plants contains potash, soda, lime, magnesia, phosphoric acid, sulphuric acid, silica, iron, &c., which, in the case of land-plants, are derived exclusively from the soil on which the plants grow. The relative proportions of these substances vary considerably in different plants, and in the different organs of the same plant; sometimes also, though in a less degree, according to the character of the soil on which the plant grows; but most of them are, in greater or less amount, constant constituents of plants, and are therefore to be regarded as necessary to their existence and essential to vegetation. (See Kirwan, 1794, *op. cit.* 145, 148—Saussure, 1804, *Recherches chimiques sur la Végétation*, pp. 261, 269.)

In connection with the chemistry of agriculture, these substances have been commonly called the “mineral” or the “inorganic” constituents of plants; mineral,* in accordance with the recognised classification of natural objects, into mineral, vegetable, and animal, because they are earthy in their nature, and are likewise derived from the earth; inorganic, to distinguish them from the organic constituents of plants, which are produced in vegetation from carbonic acid, water, and ammonia. (H. Davy, *Elements of Agricultural Chemistry*, 1827, Collected Works, viii. 40, *et seq.*; Liebig, *Chemistry in its applications to Agriculture and Physiology*, 1840, p. 92, *et seq.*)

The condition in which the above substances are found in the ashes of plants is doubtless very different from that in which they exist in the plants themselves, and very little is known as to what that may be. The functions they perform in vegetation

* This use of the epithet “mineral” to denote those constituents of plants which are not dissipated by fire, as well as to distinguish them from the other constituents, and from other materials of plant-food—carbonic acid, water, and ammonia—has recently been objected to by a high chemical authority, as an error in nomenclature, indicating confusion of ideas, since the epithet “mineral” applies “equally to all the elements, both volatile and fixed, of plant-food” (Hofmann, *Chemical Products and Processes—International Exhibition*, 1862, Class II. Section A. *Reports by the Jurors*, p. 159). Since the chemistry of agriculture is a subject concerning which it is especially desirable that any real or supposed confusion, whether of terms, or of ideas, or of facts, should be stringently eradicated, and kept clear, of I shall, in submission to that authority, abstain from such use of the term “mineral,” substituting for it the term “ash,” to denote those constituents of plants which, being earthy, are derived exclusively from the soil; and shall follow the same rule in reference to the materials of plant-food which are supplied exclusively by the soil, in order to distinguish them from the other materials of plant-food—carbonic acid, water, and ammonia. In doing so, however, I may remark that the use of the term “mineral,” which is now condemned, has long been common among chemists; and will venture to suggest that there is no reason, beyond obedience to authority, for abstaining from that use of the term which has been customary. For though the epithet “mineral” unquestionably does apply “equally to all the elements, both volatile and fixed, of plant-food,” still it does so only in a natural history sense, not as synonymous with the chemical term “inorganic,” when used in its true sense as the antithesis to “organic.” Nor has the use of the term “mineral,” in special reference to the chemistry of agriculture, been such as to indicate its equivalence to, or confusion with, the term “inorganic,” when used in its true chemical sense. On the contrary, the term “mineral” has been used in reference to that subject, during the last fifty years at least, for the specific designation of the ash-constituents of plants; and during the last thirty years, to distinguish those substances from the other “inorganic” materials of plant-food—carbonic acid, water, and ammonia. This is aptly illustrated in “*An Address to the Agriculturists of Great Britain, explaining the Principles and Use of Artificial Manures*,” by Professor Justus Liebig—Liverpool, 1843, p. 8—by the description, “They are mineral substances, and as such, are indestructible by fire; and, consequently, remain as ashes after the incineration of the plants,” so used, has a real advantage, in being precise than the term “inorganic,” also used, in some instances, by Liebig and others, for the more precise than the term “inorganic,” also used, in some instances, by Liebig and others, for the special designation of the fixed, ash, or soil-constituents, as contradistinguished from the other materials of plant-food—carbonic acid, water, and ammonia—which, in a chemical sense, are also “inorganic,” but which have frequently been called the “organic” materials of plant-food. (See Liebig, 1840, *Chemistry in its applications to Agriculture and Physiology*, pp. 3, 92, 114—Housington, 1844, *Rural Economy*, p. 420—*Quarterly Review*, 1842, lxx. 325, *et seq.*—Lawes and Gilbert, 1847—48, *Journ. Roy. Agric. Soc.* vii. xli. xvi. xviii. xxi. xlii. &c.—B. H. F.

are also little understood. The amount of them contained in plants is comparatively very small; but those which are constant and essential constituents of particular plants being necessary to vegetation, must be regarded as indispensable constituents of plant-food. (See Kirwan, *op. cit.* 149, 157—Saussure, *op. cit.* p. 261.) This is evident from the fact that plants will not grow to maturity under conditions which exclude a supply of the ash-constituents found in them under ordinary circumstances. The necessity of the ash-constituents in vegetation is rendered still further apparent by the fact that the fluids and organs of animals contain precisely those ash-constituents which are always found in fully-developed plants. (BILE, i. 587; BLOOD, i. 609; BONE, i. 619; CHYLE, i. 961; FLESH, ii. 663; GASTRIC JUICE, ii. 822; MUSCULAR TISSUE; NERVOUS TISSUE.)

Moreover, the functions of these ash-constituents in the process of animal life, have been so far traced, that there cannot be any doubt of their being essential to it, both in the growth of animals—when they partly remain in the body, contributing to its increase—and during the life of mature animals, when they no longer remain and accumulate in the body, but are eliminated, either directly or indirectly, in common with the rest of the daily food, in the excretions, after having performed their quota in the chemical process of animal life. (See NUTRITION.)

The ash-constituents of plants have, therefore, a two-fold importance, being essentially concerned both in vegetation and in animal life. Since they cannot be derived from the atmosphere, it is evident that the soil on which plants grow has a far more important share in vegetation than that of affording merely mechanical support: that it is likewise the source of an essential portion of their food. (See *ante*, p. 829.)

The mode in which the materials of plant-food are taken up into the organism of the plant is twofold: partly by means of the leaves, and partly by the roots. The absorption of carbonic acid by the leaves and green parts of plants, first observed by Priestley (1772, *Phil. Trans.* lxi. 166), and more fully demonstrated by Saussure and Sennelier, is one means by which plants may appropriate carbon, and perhaps water; but whether they obtain nitrogen in the same way, has not been proved (see Mohl, *The Vegetable Cell*, p. 86). The ash-constituents of plants can be introduced into their organism only by the roots, and the structure of plants justifies the opinion that they are taken up in the state of solution in water (Mohl, *op. cit.* p. 65). But, besides the ash-constituents, other food-materials are taken up by the roots, especially in cultivated plants—carbonic acid, ammonia, or other nitrogenous substances, resulting from the decomposition of humus, and perhaps also carbonaceous compounds other than carbonic acid. (See Mohl, *op. cit.* pp. 80, 81.—Mulder, *The Chemistry of Vegetable and Animal Physiology*, pp. 142–188.—Trinchinetti, *Sul Facoltà assorbente della Radici*, p. 65.—Boussingault, *Rural Economy*, p. 41 *et seq.*)

Scarcely anything is known as to the precise influence exercised upon the growth and development of plants by the relative amounts of air-food supplied by the atmosphere and from within the soil, or of the modifications of growth which may result from such influences; though there are numerous facts, established by agricultural experience, which apparently indicate that this circumstance is in some cases of especial importance in determining the character of the produce. (See pp. 841, 844.)

Nor are the special functions of particular materials of plant-food in the growth of plants any better understood, though experience appears to indicate that they are useful in some other way than by directly contributing to the increase of mass in the plant; and it is far from being established that either the kind or amount of the substances of which plants consist afford a quantitative indication of the food-materials which are necessary in their growth. This is especially the case with cultivated plants which are frequently grown with special objects, requiring a disproportionate development of particular organs and constituents.

These circumstances render it very doubtful whether the requirements of plants during their growth, can be correctly measured by a knowledge of their composition alone, any more than it would be possible, in the case of animals, to determine the quantities of food required during their existence, merely from a knowledge of the qualitative and quantitative composition of the animal at any period of its life.

The various materials concerned in vegetation as plant-food, are all equally necessary for the growth and development of the great majority of plants. No one of them can be replaced by anything else, not even by an increased amount of some other of them. All must be supplied together; in the absence of any one, the rest, however abundant, are wholly incapable of supporting vegetation, and deficiency of any one limits the effect of the remainder.

However, the relative proportions of the several materials of plant-food requisite for vegetation are not absolutely constant for all plants: on the contrary, they vary to some extent in different plants, or families of plants: some plants drawing more largely upon air-food than others; some requiring a greater proportion of ash-constituents.

Among the former, some produce the nitrogenous constituents in larger proportion than others; while some produce chiefly the corresponding non-nitrogenous constituents. Among the latter, some require alkalis, some phosphoric acid in preponderating amount, others require chiefly lime, silica, &c.

The special conditions under which plants grow also exercise a considerable influence in modifying their requirements as regards the several food-materials, and in determining the size of particular organs, as well as the relative proportion of the nitrogenous and non-nitrogenous constituents produced. Many plants become, under cultivation, totally different, both in structure and composition, from what they are in a state of natural vegetation; but the extent to which this influence is, or may be exerted, is far from being sufficiently known, nor are the conditions which determine it fully ascertained. Climate and season, the physical condition of the soil, the greater or less facility with which some or all of the food-materials may be obtainable by plants in particular cases, and the copious or scanty supply of certain food-materials, are all doubtless influential in this respect, and this subject still offers a wide field for observation and research.

Among those conditions of vegetation which are neither chemical nor climatic, the physical characters and state of land exercise great influence upon the amount of produce. Soils differ naturally, in this respect, according to the relative proportions of clay, sand, gravel, &c., which they contain, and they differ, perhaps still more widely, in regard to the texture they possess, or are capable of acquiring by tillage. (See SOILS, and BOUSSINGAULT, 1845, *Rural Economy*, pp. 258-308.)

The essentially chemical conditions of vegetation consist then, in a supply of food-materials: they comprise the existence in the soil of the requisite ash-constituents in a state fit for assimilation by plants, and a supply of the requisite air-food. Wherever these conditions obtain in due proportion, together with the conditions of climate, &c., required by particular plants—whether perennial or annual—those plants will grow, attain maturity, and perfect development.

So far then as relates to the purely chemical conditions of vegetation, other conditions being the same, the quantity of plant-substance produced within a given time on a given area of land—the amount of produce—will be determined, within certain limits, by the quantity of plant-food supplied; and it will be limited by the available quantity of that constituent of the food which is supplied meanwhile, in least amount, relatively to the general requirements of the particular plant growing.

Since the very striking differences recognisable in vegetation at different places, or on different land, and manifested in the unequal amount of produce, cannot be ascribed to the atmospheric supply of air-food, which is always constant, and everywhere the same, it becomes necessary to seek in the soil for the chemical cause of these differences in the degree of fertility as represented by the amount of produce. The soil being the only source of the ash-constituents of plant-food, the capability of performing its share in the chemical conditions of vegetation must necessarily depend upon its containing the requisite ash-constituents, in sufficient amount, and in such a state, as to be available in the growth of plants.

When it is considered that soils have been formed by the mechanical and chemical alteration of rocks possessing the most varied composition, that they consist of the disintegrated debris of granite, basalt, clay-slate, limestone, sandstone, chalk, &c., it is evident that their chemical constituents must vary very considerably according to the particular rocks from which they have originated, just in the same manner as they differ in being sandy, calcareous, loamy, or argillaceous.

The total amount of the ash-constituents concerned in vegetation will therefore be very different in different soils. Moreover, the different chemical nature of the minerals constituting the rocks from which soils have originated, and the unequal susceptibility of those minerals to decomposition under atmospheric influences, give rise to wide differences between soils in regard to the chemical condition the ash-constituents they contain. Both these circumstances may influence the fertility of land.

The mechanical operations of tillage, besides communicating to soils that texture which is necessary to admit of the free development of the roots, are also conducive to the chemical alteration of minerals in the land, by facilitating the access of atmospheric air, and the consequent decomposition of insoluble alkaline silicates. The fertilising influence of tillage upon land, especially when it contains a large proportion of clay, has long been known, and it was at one time believed to be a substitute for manuring. TULL, *Horse-hoeing Husbandry*.—SMITH, *A Word in Season: Let Us Weedon Husbandry*.

The analysis of soils, from which so much advantage was at one time anticipated, has not been found so useful as had been supposed in regard to agriculture. Indeed, capable of affording any trustworthy indication as to the composition of soils, or their defects; but the following statement of the most prominent features of a series of analyses of soils, made by several chemists under the direction of MAGNUS, will serve to

give some idea of the variation affecting the most important constituents, phosphoric acid and potash, &c., existing in such states as to be soluble and insoluble in dilute hydrochloric acid. (Magnus, 1846, *Ann. der Landwirthschaft*, xiv. 2: Bericht über Versuche betreffend die Erschöpfung des Bodens, welche das Königliche Landes Oekonomie-Kollegium veranlasst hat.)

	Percentage amount of ash-constituents in soils.					Quantity per acre at a depth of one foot. Soluble in acid. Average.
	Soluble in dilute acid.			Insoluble in acid.		
	Average.	Maximum.	Minimum.	Maximum.	Minimum.	
Lime	0.896	35,794 lbs.
Magnesia . .	0.260	10,180
Potash . . .	0.221	0.530	trace	3.406	trace	8,983

Silica	0.448	17,920
Phosphoric acid .	0.172	0.651	trace	7,581
Sulphuric acid .	0.154	
Ammonia	8.4

The extent of the resources of land in ash-constituents is still further illustrated by the following table calculated from the results of experiments conducted by Lawes and Gilbert at Rothamsted, in which wheat was grown every year on the same land without any manure for 20 years. The land was a heavy loam, resting upon chalk. The average amount of produce in the neighbourhood at the time when the experiments were commenced was under 22 bushels per acre, and wheat was grown only once in five years. When the experiments were commenced in 1843, the land was in such a condition that, according to the ordinary routine, it required to be again manured with farm-yard manure: for since the previous application of manure, four crops had been removed from it, viz. barley, peas, wheat, oats. See Lawes and Gilbert—1847—*op. cit.* viii.—Agricultural Chemistry—1864—*Ibid.* xxv.—Report of Experiments on the Growth of Wheat—1857—*Chem. Soc. Qu. J. x.* 1.—On some Points in the Composition of Wheat Grain; its Products in the Mill and Bread.)

The soils in which the fertilising effects of tillage are most marked, are generally of a clayey nature, and are therefore capable of furnishing a larger supply of ash-constituents under the influence of atmospheric decomposition. But there is another characteristic which such soils possess in a high degree, viz., the capability of absorbing ammonia from the atmosphere. (See Faraday—1826—*Quarterly Journ. of Science*, xix. 16 *et seq.*) By reason of this capability, they store up, during the period of fallow, the ammonia conveyed to them from the atmosphere by rain and otherwise, and thus provide an increased supply of this air-food to plants requiring it. (See Lawes and Gilbert, *Op. cit.* xvii. 293 *et seq.*)

The absorptive power of soils is not limited to ammonia, but extends likewise to most of the important ash-constituents of plant-food which are soluble in water. This fact was first observed by Thompson (1850, *Journ. Roy. Agric. Soc. of England*, xi. 68), and was afterwards investigated by Way (*Ibid.* xi. 313; xiii. 123). It is

highly probable that the condition in which substances are thus retained by soils, so as to be gradually supplied to the roots of plants by the medium of carbonic acid and water, is of great importance in regard to the nutrition of plants, and to the relative fertility of land. (See SOILS; Way and Voelcker, *Op. cit.*; Liebig, *The Natural Laws of Husbandry*, p. 66 *et seq.*)

In considering the chemical conditions which determine the relative fertility of land, it will be convenient to examine, in the first place, how far this is determined by the ash-constituents. So far as these alone are concerned, the degree of fertility of land—its capability of contributing to the growth of a greater or less amount of produce—would be, in a strictly chemical sense, proportionate to the available amount of ash-constituents it was capable of furnishing within the period of growth; but the amount of produce would not vary in the same ratio, because the ash-constituents of land cannot be useful in vegetation, except in so far as they can co-operate with a due proportion of air-food.

If the sources of air-food, available during the period of growth, were limited to the constant atmospheric supply, the amount of produce would be proportionate to the capability of assimilation by the plant, under the other prevailing conditions of climate, season, &c.

But if other sources of air-food were available within the period of growth, in addition to the atmospheric supply, and together with an abundant supply of ash-constituents by the land, the amount of produce would be largely augmented under conditions otherwise the same.

Thus plants growing upon land affording only a scanty supply of available ash-constituents might be, on that account, incapable of assimilating air-food to the full extent of the atmospheric supply, and the amount of produce in such case would be small. By the death and decay of these plants, their ash-constituents would be restored to the land, so as to become capable of serving for a succeeding growth of plants, and the production of humus, at the same time, would provide in the soil itself a further source of air-food in addition to the atmospheric supply. Still the amount of produce from the succeeding growth would be small, if the available supply of ash-constituents remained as scanty as before. In this way vegetation might continue indefinitely without alteration, affording sustenance to numerous animals, as in the steppes of Central Asia, the prairies and pampas of America.

But if a larger amount of ash-constituents became available, in the interval between the successive growths, by the decomposition of minerals in the land, the conditions might become such as to ensure assimilation of air-food not only to the full extent of the atmospheric supply during the period of growth, but also from the further supply provided by the gradual decomposition of humus in the soil; and in such case the amount of produce would be proportionally increased.

The greater or less amount of available ash-constituents is, therefore, not the only condition upon which the amount of produce or the fertility of land depends, even in a strictly chemical sense; another essential condition is the amount of air-food capable of being supplied from within the soil, during the period of growth. Land, however rich in available ash-constituents—however well adapted in all other respects for prolific vegetation, would still afford but scanty produce without an ample supply of air-food during the period of growth. The increased supply of air-food provided by the decomposition of humus in the soil may be regarded, in this respect, as the accumulated atmospheric supply of several successive periods of growth; and the capability of land to furnish such a supply is, in a chemical sense, as much an element of its fertility as the available amount of ash-constituents it contains.

The requirements of different plants for such an augmented supply of air-food, in regard to the amount of produce, differ very widely, and the capability of different plants to assimilate the air-food thus stored up is also very different. The adaptation of the capability of one plant, in this respect, to provide for the requirements of another, and the development with that view of particular habits and conditions of growth in regard to certain crops, constitute the basis of the modern system of agriculture.

Having thus far described the general features of the chemistry of vegetation, in its simplest form, they must now be considered in their relation to agriculture; and it will be desirable first to examine the conditions affecting the supply of ash-constituents, as well as their influence under different circumstances.

In the cultivation of plants as a source of food for animals, and for other purposes, the ash-constituents requisite for vegetation are removed from the land in the produce; and since they are not replaced in the same manner as the atmospheric supply of air-food, the successive growth of a particular plant, year after year, would in process of time so far exhaust the land of available ash-constituents, as to render it incapable of supporting further growth, or of yielding such an amount of produce as would be

worth the trouble and cost of cultivation. Hence arises the necessity of periodically returning to land under cultivation the ash-constituents thus withdrawn from it. Hence the practice, intuitively adopted in the rudest state of agriculture, of applying to land the excreta of animals fed upon its produce and the decaying refuse of the plants grown upon it. Such a system of cultivation would be sufficient to prevent any decrease in the annual produce of the land, inasmuch as the materials applied to it as manure, would restore whatever had been removed in the plants serving as food for animals, or for other purposes, and thus render the land capable of continuing—with the aid of the atmospheric sources of plant-food—to support vegetation. (See Kirwan, *Op. cit.* p. 160.)

If there were absolutely no export of produce, in such a case the restoration of the ash-constituents would be complete, and the capability of production would continue undiminished, so far as relates to the ash-constituents only. It would, in fact, increase year by year, so far as ash-constituents were concerned; for the available amount of them would be gradually increased by tillage, and by the consequent decomposition of minerals in the land. The improvement of the land by tillage is doubtless referable in some degree to such an unlocking of its natural resources, and the increase of what may be regarded as its floating capital in ash-constituents.

Where the population of a country is small and thinly distributed, and where land is of little value, as in many remote and uncivilised localities, all requirements may be fulfilled by such a system of relying upon the natural produce, without the need of any effort to increase it. But, even in such circumstances, it is seldom that the natural conditions of fertility are relied upon exclusively, or that the means adopted for maintaining the amount of produce are limited to the internal economy of the farm. Whatever fertilising materials can be obtained from external sources, at a cost commensurate with their capability of augmenting the produce, are generally employed as manure even in the rudest practice of agriculture. Guano has long been used for that purpose by the natives of South America (Humboldt, Fourcroy, and Vauquelin, 1803, *Ann. Chim.* lvi. 258–268). Fish, seaweed, &c., have been used from time immemorial as manure by the peasantry of seaboard districts; and wood-ashes, soot, &c., have been applied to the same purpose inland. Most of these materials would add to the amount of available ash-constituents in the land, and would in so far increase its capability of production.

Where, on the contrary, the population of a country was chiefly concentrated in centres, and a portion of the corn grown was annually removed from the land for the supply of food to towns at a distance, or under circumstances not admitting of the corresponding excreta being returned to the land as manure, the soil would be gradually deprived of ash-constituents, in a degree proportionate to the export of food. The internal economy of the farm would then no longer ensure the full restoration to the land of all the ash-constituents of its produce; it would no longer ensure the maintenance of the degree of fertility obtaining before the export of the produce commenced, or the capability of production corresponding to the amount of ash-constituents originally contained in the land. On the contrary, as the yearly export continued, and the abstraction of ash-constituents from the land progressed, the quantitative relation between them and the atmospheric conditions of vegetation at any place would be progressively changed; for while the atmospheric supply of air-food remained constant, the quantity of ash-constituents in the soil would diminish from year to year, until, eventually, vegetation might be no longer possible, in consequence of the deficiency of one of its essential conditions.

Even before that time, a point would be reached when the amount of produce would be no longer limited by the supply of air-food available from the atmosphere within the period of growth; when, on the contrary, the assimilation of air-food would be limited by the available amount of ash-constituents in the land, and when the amount of produce would be so small as not to be worth cultivation.

This exhaustion of land, or reduction of the degree of fertility, by the growth of successive corn-crops, and by the export of the produce, without any supply of manure from extraneous sources, would take place sooner or later, according to the nature of the land and the extent of its natural resources; sooner in the sandy or chalky soils, known as light land, than in the loamy or clay soils, known as heavy land. So far as the ash-constituents were concerned, the exhaustion of land might be retarded, under such circumstances, or the capability of production revived, by allowing it to remain at intervals without growing a crop on it for one or more years—a practice adopted under the name of bare-fallow. (See Kirwan, *Op. cit.* p. 160.)

During the interval of rest, a fresh supply of available ash-constituents would be provided for a future crop of corn by the decomposition of minerals in the land, thus compensating, either wholly or in part, for the abstraction resulting from export of produce. The amount of produce obtained, when a corn crop was grown, might in this way remain constant, or suffer but inappreciable diminution during long periods.

especially in the case of rich soils. The rate at which the restoration of the ratio—previously existing between the supplies of available ash-constituents from the soil and of air-food from the atmosphere—took place, would depend upon the nature of the land and its tillage, and would determine the interval to elapse between the growth of two crops of corn.

The same result might be attained by a rotation of crops, or the alternate growth of different plants, occupying different ranges in the soil during their growth, or requiring different ash-constituents, such as corn and grass, or potatoes; so that, in either case, the ash-constituents contained in the land might be distributed among the different plants, and thus rendered available during a longer period. If the crops grown in the intervals between the corn-crops were consumed on the farm in feeding cattle, they would contribute to the production of manure; and, even if some of the cattle were exported, the greater part of the ash-constituents of the fallow-crops on which they had been fed, would remain upon the farm, and be returned to the land in the manure. However, the ultimate result of exhaustion would still be the same; and it has been long regarded as an established fact, that “the export of grain from a country, unless some articles capable of becoming manure are introduced in compensation, must ultimately tend to exhaust the soil. Some of the spots now desert sands in Northern Africa and Asia Minor were anciently fertile. Sicily was the granary of Italy; and the quantity of corn carried off from it by the Romans is probably the chief cause of its present sterility. In this island our commercial system at present has the effect of affording substances which in their use and decomposition must enrich the land.” (Davy, *Op. cit.* viii. 78.—See Kirwan, *Op. cit.* p. 160.—Liebig, *Einleitung in die Naturgeschichte des Feldbaues*, pp. 106–109.)

For the successful practice of agriculture, therefore, it is as necessary to maintain fertility, as it is to obtain a sufficient amount of produce. Land from which corn is exported requires, in most cases, a constant supply of manure from extraneous sources, capable of replacing the ash-constituents which may have been rendered deficient in amount.

An idea may be formed of the extent of the exhaustion of land from which corn is exported, by assuming that, in the countries which are the chief sources of corn, the amount of produce is at the rate of 16 bushels per acre, and that a corn-crop is grown every other year. The quantity of ash-constituents removed from the land per acre in the crop, would be about as shown the following table:—

Ash-constituents of Wheat, Barley, Oats.

	Total produce.	Corn.	Straw.
Amount of produce per acre . . .	2260 lbs.	16 bushels	1333 lbs.
Total ash-constituents . . .	92	15 lbs.	77
Comprising { Phosphoric acid . . .	11	8	3
Potash . . .	14	4	10
Lime and magnesia . . .	8	2	6
Silica . . .	51	0	51

The greater part of these being contained in the straw, would be returned to the land in the farmyard manure; and if the whole of the corn were exported, without any supply of ash-constituents from without, there would be a permanent abstraction of them at the rate of 4 lbs. phosphoric acid and 2 lbs. of potash annually per acre. These being the substances which are least abundant in land, it is necessary that they should be restored again in some way.

But in order merely to maintain the degree of fertility, the supply from without does not require to be equal to the quantity removed in the exported produce; for land always possesses, in addition to its immediately available resources in ash-constituents, other resources which are latent—resources from which fresh supplies of them are only gradually developed, and rendered available by the operations of tillage in the manner already described. (See *ante*, p. 831, and *Soils*.)

Consequently, the exhaustion of soils, in regard to ash-constituents, though conceivable under such circumstances as those above referred to, is almost inconceivable, even in regard to ordinary land, under circumstances admitting of a proper supply of manure from extraneous sources, in addition to that produced upon the farm.

So far as the ash-constituents of land determine its share in the general conditions of fertility, it may be regarded as practically inexhaustible under any system of agricultural practice considered to be good merely from an empirical point of view, and having no higher recommendation than success.

The fertilising influence of manure is not, however, limited to the restoration of

ash-constituents to land. It is also due to its capability of furnishing a larger supply of air-food to future crops, during their period of growth, than they could obtain directly from the atmosphere. This is one of the chief advantages resulting from rotation and the growth of fallow-crops for feeding cattle. The advantage of bare-fallow is also, to some extent, due to the accumulation of air-food in the soil, in virtue of its absorptive power. (See *ante*, p. 831, and SOILS.)

Since the available ash-constituents of land can be effective in determining an increased amount of produce, only in so far as they can co-operate with a proportionate supply of air-food, during the period of growth, it is evident that the supply of this condition of fertility, by manure, must be of especial importance when it is necessary to obtain a large amount of produce.

The total resources of the generality of land in ash-constituents, preponderate so largely over the constant chemical conditions of fertility at any time available in the atmosphere, within the period of growth of ordinary crops—the latent resources of the land so easily admit of the liberation, from time to time, of fresh supplies of ash-constituents by the operations of tillage, that, under a good system of farming, the probability is rather in favour of the ash-constituents available at any particular time, being in excess of the supply of air-food directly available from atmospheric sources within the period of growth, and of that provided by manure resulting from the internal economy of the farm.

In some cases, the gradual unlocking of the latent resources of the soil by tillage, &c. may far exceed the yearly abstraction of ash-constituents. This chemical condition of fertility in land may increase from year to year, and, instead of retaining a constant proportion to the supplies of air-food from the atmosphere and from manure, it may preponderate over them; so that the amount of produce of the land in corn, might be increased, if the other chemical conditions of fertility were accessible in the same proportion within the period of growth. But though tillage, in such a case, would increase the fertility of the land, so far as the ash-constituents were concerned, it would not be attended with an increase in the amount of produce, unless it were accompanied by an increased supply of air-food during that period of the rotation when the crop, for which the liberated ash-constituents were most required, was growing.

The extent to which the accumulation of available ash-constituents in relative excess, may take place, is well illustrated by the experiments made at Rothamsted, on the growth of wheat, upon land which had been reduced to such a condition, in the ordinary routine, as to yield only half the average amount of produce in wheat. By the use of manure containing only the ash-constituents of wheat, on a plot of this land, the amount of produce obtained in 1844 was not greater than on the unmanured land. In the following year, the application of 336 lbs. per acre of mixed ammoniacal sulphate and chloride was attended with an increased amount of produce, amounting to double that obtained in the previous year from the unmanured land, or from that supplied with ash-constituents only. By continuing to grow wheat upon this plot of land for nineteen consecutive years with ammonia-salts only as manure meanwhile, the amount of produce obtained in each year continued to exceed that from the unmanured land; and the average amount of produce thus obtained, during the whole period, was only one-fourth less than it was in the first year, notwithstanding the very exceptional and continued drain on the ash-constituents of the land. (See Lawes and Gilbert—1847-64. *Op. cit.* viii. 226 xxv.)

Manure.	Amount of Produce per Acre.				Ash in Produce per Acre.

1845—1863							

In these results the influence of season in favouring or impeding the growth of wheat, was manifested by a certain variation in the amount and quality of produce under conditions otherwise similar; but this was not sufficient to obscure the differences referable to other causes.

The quantity of ash-constituents removed from the land during this period, without any such return as would have been made in ordinary practice, by the supply of farm-yard manure, affords still further evidence of the immense resources of the land in this particular, additional to that already referred to in the case of the unmanured land. (See *ante*, p. 831.)

Moreover, the absence of any increase in the amount of produce obtained in 1844 by applying to the exhausted land manure consisting only of ash-constituents of wheat, and the increase in the amount of produce obtained in the following year by using only ammonia, as compared with that on the unmanured land in 1845, are together most conclusive proof that, although in 1844 the chemical conditions of fertility were collectively insufficient for the growth of a full crop of wheat, still there was no deficiency in that element of those conditions which appertains exclusively to the soil—viz., the available amount of ash-constituents. Those results also prove, on the contrary, that in 1844 the available amount of ash-constituents in the unmanured land was far in excess of the other chemical conditions requisite for the growth of wheat—viz., the amount of air-food supplied, by the atmosphere and by the soil, during the period of growth. Consequently, the system of cultivation under which the land had become exhausted in regard to this crop, had admitted of a large accumulation of surplus ash-constituents, which would have remained useless in the land without a corresponding supply of air-food during the period of growth. The exhaustion consisted in the relative deficiency of air-food capable of being supplied from within the soil; and, therefore, increase in the amount of produce could only be effected by an artificial supply of air-food, additional to that furnished by the manure of the farm.

The practice of agriculture in many localities does not require that the amount of produce obtained should be very large: the only thing necessary, in many instances, is to maintain the degree of fertility, and the natural amount of produce is quite sufficient to be remunerative, as in those countries which are the chief sources of the supply of corn. In such cases, the manure produced by the internal economy of the farm may suffice to provide an adequate supply of air-food from within the soil.

In countries, however, where the population is dense, and land is of high value, agriculture assumes a very different character. Its object then is not merely to maintain a certain degree of fertility, but to produce, year by year, in the most profitable manner, and on a given area of land, the largest possible quantity of the materials of food for man and animals; to increase, by artificial means, the amount of produce upon an area incapable of yielding as much under natural conditions. (See Liebig—1843—*Chemistry in its Applications to Agriculture and Physiology*, 3rd edit. p. 112; Lawes and Gilbert—1847—*Journal of the Royal Agricultural Society of England*, viii. 227, xii., xvi. &c.)

Hence arose the idea of employing artificial manures—of augmenting artificially the chemical conditions of fertility. For the practice of agriculture under these circumstances, so utterly distinct from those of agriculture conducted only with a view to the produce of natural vegetation, the problem to be solved by the chemist for the guidance of the farmer is, what substances to supply as plant-food from extraneous sources, in order to obtain, year by year, a remunerative produce.

The question is mainly one as to manure: its solution, however, involves the consideration of conditions and requirements other than those obtained in natural vegetation, not differing in kind, but quantitatively different. Still, the knowledge of the general phenomena of plant-nutrition must be the guide in the endeavour to solve this problem. Since it is established that the various materials of plant-food must bear a certain proportion to each other in order to be in the highest degree effective, and since the amount of produce is known to be limited by the quantity of that food-material which is present in least available amount, relatively to the requirements of any particular crop, the desideratum, in regard to the artificial means of increasing the amount of produce, is to ascertain what food-material becomes deficient, relatively to others, under the circumstances attending the growth of that crop. The deficiency may lie in the source of carbon or of nitrogen, in the supply of water or of available ash-constituents, or of some one of them; but whichever it be, the amount of produce will be limited by the deficiency.

The determination of that point will indicate, therefore, what food-material it is most necessary to supply artificially, in order to render effective in the highest degree those food-materials which are available in greatest abundance, relatively to the requirements of the crop in question. The food-materials least available abundantly in the same relation would be, in that particular case, the manure to be supplied artificially in order to obtain an increased produce. This is the fundamental principle of "high

farming," which really consists in augmenting the acreage-produce—obtaining, year by year, crops larger than could be obtained under natural conditions—by rendering more effective the existing natural conditions of fertility.

This object may be attained in part by the right selection of artificial manure, so as to accumulate on the farm the materials of plant-food which are naturally most deficient, in regard to the whole of the crops grown in a series of years; and by adapting the method of cultivation so as to store up, during part of the rotation, the materials of plant-food which are relatively most deficient as regards a particular crop, grown at intervals, and to make that accumulation serviceable for increasing the amount of produce of that crop.

It is not by substituting for the manure produced by the internal economy of the farm, some one or other of its constituents, that this object is to be attained; but by supplementing it with what is most wanting, either naturally, or as the consequence of that branch of industry which is the business of the farmer—the manufacture of food.

Practically there is a limit to the increase of produce, besides that natural limitation which is due to climate and to season; it is the necessity that the degree of fertility produced and maintained should be remunerative. This purely commercial necessity introduces into the subject an important complication, involving the consideration of a number of circumstances which cannot be entered upon here, but which will readily suggest themselves to the reader.

In order to obtain such an amount of produce in corn as to be remunerative in this case, it is necessary to supply during the period of growth a larger quantity of nitrogenous air-food than would be furnished during that period by the atmosphere alone, or provided, in addition to that, by the internal economy of the farm, when no other crop but meadow-grass was grown besides corn.

This might be effected by the use of ammonia-salts as manure; but this source of ammonia is too limited to be alone sufficient in agriculture. Recourse is therefore had to the accumulation of ammonia from the atmosphere, by the growth of plants which possess the capability, under certain conditions, of appropriating nitrogen from that source, to a much larger extent than either wheat, barley, or oats, and which can be employed as food for cattle so as to produce meat—a marketable commodity equivalent to corn—and, at the same time, a larger supply of manure than could be obtained if the land remained in bare fallow, or were converted at intervals into meadow-land.

The manure so produced by the internal economy of the farm would contain the greater part of the nitrogen collected from the atmosphere by the crop intervening between the corn-crops, and used in feeding cattle, and would serve during the growth of corn to furnish the augmented supply of nitrogenous air-food necessary for obtaining a large crop of corn.

The plants which are cultivated mainly with this object may be represented by the turnip, since it presents a striking contrast to corn-crops, in regard to the conditions most favourable to increase in the amount of produce, as well as in regard to its capabilities and requirements, though it is inferior to leguminous plants in the power of assimilating nitrogen from the atmosphere.

The amount of produce obtained under the system of agriculture generally practised in this country is considerably higher with regard to all crops than it is in many other countries; and though there is a difference in this respect as to particular localities, the accompanying table may be taken to represent a fair average statement of the quantities of the several constituents of the different crops grown alternately in what is termed a "four-course rotation," when a crop of turnips, beans, or clover intervenes between two crops of corn.

The growth of the turnip as an agricultural crop, so as to obtain a large amount of produce, is far more liable to be influenced by differences of season than is the case with wheat. In the absence of rain, at a particular stage of growth, the greater number of the plants may die, and the acreage-produce become very small; but if the conditions of season be favourable, the amount of produce obtained may be as high as 20 or 30 tons per acre.

It has been supposed that the influence exercised by the cultivation of the turnip as a fallow-crop, in restoring and augmenting the fertility of land, and in conducing to the increase of the wheat-crop, was referable to its comparatively greater capability of appropriating, by means of its large leaf-surface, the atmospheric supply of air-food, during its period of growth, and to its requiring but a very small supply of food-materials from the soil. (See Davy, *Op. cit.* viii. 76, 77.)

That this is not the case, is evident from the amount of ash-constituents contained in the turnip, as shown in the table just referred to; and it is rendered still further apparent by the following results of experiments by Lawes and Gilbert (p. 840), showing the amount of produce obtained by growing turnips for three years consecutively on the same plot of land without manure.

Composition of the Acreage Produce of Different Crops.

Crop Amount of produce . .		Corn Crops.			Root Crops.			Leguminous.	
		Wheat. 30 bush.	Barley. 40 bush.	Oats. 44 bush.	Turnips. 10 tons.	Swedes. 13 tons.	Mangel. 16 tons.	Beans. 34 bush.	Clover- hay. 5,400 lbs.

	Straw or leaf	101	75	68	2	1	2	5	
	Total produce	102	88	90	3	3	11	6	11

The immediate object of the cultivation of the turnip being the production of food for cattle, it is not required to reach maturity, as is the case with wheat; and it is desirable to obtain the utmost possible development of the fleshy root, so as to afford a food-material containing both nitrogenous and non-nitrogenous substances in fitting proportion for that purpose. During the early stage of growth, the young leaves of the turnip are liable to be attacked by insects, and it is therefore necessary to forward their development as rapidly as possible until the plants become sufficiently strong to resist this destructive influence. The number of plants per acre is therefore an important indication of the efficacy of the manures used.

The land selected for the experiments was a rather heavy loam, not of the best character for the growth of turnips; and three crops—wheat, clover, and wheat—had

been grown upon it since it was manured. The variety of turnip grown was that known as Norfolk white. To ascertain the capability of appropriating the atmospheric food, and the relation which the turnip bore to the soil which was exhausted for wheat, a plot was left each year unmanured. On this plot the amount of produce was very small even in the first year, and in the third year the bulbs did not weigh more than two ounces each; so that in regard to the growth of the turnip, the resources of the soil are soon exhausted, and some supply of manure is evidently requisite for the growth of the turnip as a fallow-crop. (See Lawes and Gilbert—1847—*Op. cit.* viii. 38.)

Effect of various Manures on Growth of Turnips.

Plot.	Quantities of Manure per acre.	Number of plants per acre.	Average weight of bulb. lbs.	Amount of produce.		Dry substance.

With farmyard manure, which may be considered as supplying all the constituents of a large crop of turnips, the number of plants in each year represents the influence of season during the early stage of the growth; and the average weights of the bulbs represent the influence of season during the stage of bulb-formation.

Ammoniacal salts operated in most instances prejudicially during the earlier stage of growth, especially when placed near the seed; when used with farmyard or other carbonaceous manure, the development of bulb was in some instances considerable, and the development of leaf was much increased; but the amount of dry substance in these bulbs was generally less than in others, and the amount of nitrogen in the substance was greater—just the opposite of what happens in the growth of wheat.

With a considerable supply of ammonia, the vigorous growth of the plants was accompanied by a less rapid advance towards maturity in the bulb, and a condition less favourable for providing a supply of root-food than for the production of seed by further growth. In this respect the influence of artificial supply of ammonia upon the amount of produce of the turnip-root and of wheat, presents a striking contrast; and it is evident that in the cultivation of the turnip for feeding purposes, and as a fallow-crop for obtaining a supply of manure, it is capable of appropriating nitrogen from the atmospheric supply during its period of growth, or from within the soil, to such an extent as not to require any considerable supply artificially by means of manure.

The influence of soluble phosphates in promoting the early growth of the plants is well indicated in each year by the number of plants, both when used alone and with other manures; but it is only during that stage of the growth that they contribute to increase the amount of produce in bulbs, as will be seen by the small average weight of the bulbs grown with phosphates only supplied as manure.

In the plots supplied with manure capable of furnishing a considerable amount of carbonaceous air-food, the development of the bulbs, indicated by their average weight,

was much more considerable than in any other case, except where soluble phosphate was used in the first year, and where the exceptional result was probably referable to carbonaceous substances in the soil. The influence of a supply of air-food from within the soil, upon the development of bulb, is still more strikingly illustrated by the contrast between the second and third year's results. Though with soluble phosphates alone or with other manure, the number of plants was always considerably greater than in their absence, the average weight of bulbs was very small; while on the plots where phosphates were used together with a carbonaceous manure, the average weight of the bulbs indicates a much larger bulb-development. That, together with a greater number of plants, gave consequently the largest amount of produce.

The necessity for the presence of carbonaceous substances capable of supplying food-material from within the soil, is rendered more strikingly evident by the results of the second year; for although the season was, on the whole, more favourable than that of the preceding year, and though the number of plants was greater, the amount of produce was generally less, in consequence of the slower rate of growth and bulb-formation. In the third year, also, the deficient bulb-development within the period of growth, on those plots where phosphates alone were used, as compared with the results obtained where carbonaceous manures were also supplied, shows the importance of providing that source of plant-food in order to insure rapid growth, and to obtain a large amount of produce.

The influence exercised upon the composition of the bulb by the ratio existing between the supply of carbonaceous and nitrogenous air-food from within the soil, is well indicated by the differences in the amount of nitrogen in the dry substance of the turnips grown with farmyard manure and rape-cake alone, and with addition of ammonia, and in those grown without manure and with top-dressings containing different proportions of carbon- and nitrogen-yielding materials.

Carbonaceous manures, however, are serviceable only in the later stage of growth by affording a supply of food-material for the development of bulk; and in the earlier stage of growth they may even be prejudicial if placed near the seed, as indicated by the smaller number of plants in the first two years when these manures were drilled with the seed. They should, therefore, be placed so as to be only within reach of the young plant when it has developed its accumulative organs under the influence of the phosphate, which should be placed as near as possible to the seed. The advantage of doing so is illustrated by the greater number of plants in the third year, when these manures were applied as a top-dressing to the land.

Comparing these results with the quantity of phosphoric acid contained in the turnip, it will be seen that the influence of phosphates on the growth of this plant cannot altogether be referred to the mere supply of material serving for the production of plant-substance by becoming a constituent of it. Though the amount of phosphoric acid in the turnip-crop is not larger than that in the wheat-crop, a direct supply of soluble phosphate appears, from very general experience, to be much more influential in regard to the development of the turnip than in the growth of wheat. Hence it is scarcely possible to avoid the conclusion that it exercises some important and essential function in that particular mode of development requisite in the cultivation of the turnip as a fallow- and feeding-crop, other than that which is represented by the amount of phosphoric acid contained in the plants.

In these experiments the supply of potash as a constituent of manure was not found to exercise any favourable influence, either upon the mode of development of the turnip-plant, or upon the amount of produce; nor was it to be expected that this land, which was capable of growing wheat without manure for several consecutive years, should be at all deficient in supply of potash for the growth of a turnip-crop, although the quantity of potash required by it is so much larger than that needed for wheat.

The quantity of potash removed from the land in the turnip-crop does not cause exhaustion of the ash-constituents to any sensible extent; for, excepting a small portion exported in the meat produced by the use of the turnip in feeding live-stock, they are again returned to the land in the manure; and if artificial phosphate-manures be employed in the cultivation of turnips, the abstraction of this constituent from the land by the export of corn will be to a great extent compensated, if not covered.

The facts already described will serve to show that the cultivation of the turnip is a part of the economy of the farm, by means of which nitrogen is stored up as part of the floating capital of the land, and, after having served intermediate purposes, is made to contribute to the important result of increasing the amount of produce in corn. It is by this means that concentration of the atmospheric supply of nitrogenous plant-food is effected, so as to furnish the corn-crops, during their period of growth, with twice as much as they could otherwise obtain directly from that source by their own unaided capability of appropriation.

Though the turnip has here been referred to as a plant presenting, in the circumstances of its cultivation, a strong contrast to corn-crops, it is chiefly by the growth of leguminous crops—such as clover, beans, and tares—that nitrogen is directly appropriated from the atmosphere. In the cultivation of the turnip as a fallow-crop an artificial supply of nitrogen over and above that provided by the farm manure is not generally requisite; but it draws largely upon the supplies of nitrogen from within the soil; and in this respect it tends to render an artificial supply of nitrogenous manure more necessary for the succeeding corn-crop (Lawes and Gilbert, *Op. cit.* xviii. 454; *Journ. Chem. Soc.* [2] i. 100). Leguminous crops, on the contrary, appear to render land richer in nitrogenous supply, and thus to augment its capability of yielding large crops of corn. The influence of clover in this respect has long been known. (See Kirwan, *Op. cit.*, p. 166.)

In the cultivation of land under such circumstances, supposing the amount of produce sold during 4 years to be 30 bushels wheat, 35 bushels barley, and the live-weight produced from 10 tons turnips and 5,000 lbs. clover-hay, or 1,500 lbs. beans, without imported food, the quantity of ash-constituents removed from the land would be, at the utmost, as shown in the following table:—

Quantities of Ash-constituents per Acre abstracted from Land, in Produce sold off the Farm during Four Years.

Amount of produce.	1st Year.	2nd Year.	3rd Year.		4th Year.	Average Quantity per Acre, in Four Years. per Annum.	
	Live-Weight from Turnips. 10 tons.	Barley. 35 bushels.	Live-weight from Clover-hay or Beans. 5,000 lbs. 1,500 lbs.		Wheat. 30 bushels.		
Fresh produce .	22,400	1,820	5,000	1,500	1,800		
Dry produce .	2,464	1,529	4,200	1,260	1,530		
Nitrogen .	.	30	.	.	32		
Total ash .	2.46	40.5	3.13	1.58	31	76	19
Phosphoric acid	0.98	13.4	1.05	0.63	15	30	7.6
Potash .	.	9.75	0.16	0.09	9	19	4.8
Silica .	.	11.4	.	.	0.6	12	3

It now only remains to consider the means of maintaining the supply of carbonaceous material requisite as one of the conditions of the production of the full amount of produce in turnips. In the feeding of animals there is a loss of carbon, due to respiration, amounting to nearly one-half of that contained in the food. It is therefore necessary to increase as far as possible the quantity of manure produced by the internal economy of the farm, by the use of imported food-materials in feeding cattle. This is at once a profitable mode of converting those materials into a more valuable commodity, and of obtaining a larger quantity of manure for the cultivation of crops; thus maintaining, or even increasing, the fertility of the land, by bringing upon the farm ash-constituents—which compensate for the export of corn—and materials containing nitrogen and carbon in a form capable of becoming available in the cultivation of crops as supplies of air-food, auxiliary to those furnished by the atmosphere and by the farm-yard-manure resulting from the crops grown.

On a farm cultivated under such a system, the exhaustion of the land is altogether precluded; and although the existing system of disposing of town-refuse involves a total loss of the phosphates and potash contained in the exported produce, it is probable that, as regards the extent of land at present under cultivation, there may be sufficient available sources of those substances in the mineral kingdom, to counterbalance such a loss for a long time to come. Still, the disposition of town-refuse in such a manner as to be available in fertilising land, and to be useful rather than a source of injury and annoyance, is a requirement which is every day more urgently demanding attention.

Having thus considered the nature of the differences obtaining, on the one hand, between spontaneous vegetation altogether unaided by art, and natural vegetation assisted by tillage—on the other, between agriculture conducted only with a view to obtaining the natural amount of produce, and agriculture involving an increased produce by artificial means, it is now necessary to consider what applications have been made of the general knowledge of the chemistry of vegetation, or of the views which have been entertained with regard to it.

Lietig, in applying to agriculture the theory of plant-nutrition which he constructed from the materials furnished by Saussure, Davy, Sprengel, and Bous-singault, adopted the fundamental proposition, that plant-food consists solely of carbonic acid, water, ammonia, and the ash-constituents. In endeavouring to ascertain the causes of the efficacy of manure; the mode in which it acts; the circumstances upon which different methods of culture depend; and to establish rules for a rational system of agriculture,—he addressed himself first to the questions, "What does the soil contain? What do the materials called manure contain?" as questions whose determination constituted the starting-point of rational agriculture (*Chemistry, &c.*, 1st edit. p. 139). In this enquiry his attention was mainly directed to the ash-constituents of plants, and to the comparison of these with the constituents of soils and of manure. Observing that all cultivated plants contained potash, phosphoric acid, and other ash-constituents; that the presence of these substances was constant in particular plants, and parts of plants; that every productive soil contained the same substances; that the repeated successive growth of a particular crop on the same land rendered it less capable of producing that crop until an interval of some years had been allowed to elapse without growing it,—he came to the conclusion, that the capability of land to produce crops, was due to the presence in it of the ash-constituents of plants; that the assimilation of carbon and nitrogen was dependent upon the presence of the ash-constituents in the soil, and limited by the available amount of them: consequently, that the amount of produce was proportionate to the available amount of ash-constituents in the soil (*Op. cit.* 3rd edit. pp. 113–123). From the same data he concluded that the decrease of produce observed when a particular crop is raised year after year on the same land, was due to the abstraction of ash-constituents from the soil. (*Op. cit.* pp. 118, 164.)

Observing, further, that animal excreta and the plant-remains in farmyard manure contained the same ash-constituents as the plants which had been consumed as food; that this manure exercised a fertilising influence upon land naturally unproductive, or exhausted by the cultivation of crops,—he concluded that the efficacy of this manure, which might be regarded as the ashes of the food burnt in the bodies of animals, was due to the ash-constituents it contained; that its peculiar action consisted in and was limited to the supply or restoration of the ash-constituents, which the land was either destitute of or had been deprived of by previous crops. (*Op. cit.* pp. 176–187; *Address to the Agriculturists of Great Britain*, pp. 7–12.)

From the well-known facts that the produce of land could be increased by manure, and that in many cases the crop is directly proportionate to the quantity of manure used, he concluded that this effect was referable to the amount of ash-constituents supplied to the land; that if the supply of those constituents were greater than the quantity taken away in the previous crop, the amount of produce would be increased; that if the supply of them were less than that, the produce would be reduced; and that if it were just equal to the quantity removed, the produce would remain constant. (*Address*, pp. 7–12.)

Adopting these conclusions as axioms to be observed in practical agriculture, Liebig also taught that the production of the organic constituents of plants from carbonic acid, water, and ammonia was determined by the presence of the ash-constituents proper to the plants cultivated (*Chemistry, &c.*, pp. 196, 204); that its extent was limited by the available amount of them in the soil (*Op. cit.* p. 203); that the efficacy of humus in augmenting the amount of produce, by furnishing a supply of carbonic acid additional to that afforded by the atmosphere, was subject to the same limitation (*Op. cit.* p. 197); that the amount of produce was so entirely independent of the artificial supply of ammonia, that if only the ashes of solid and liquid excreta were supplied as manure, the crops cultivated would derive their carbon and nitrogen from the atmosphere (*Op. cit.* pp. 181, 203–204); that the ammonia of the atmosphere, exceeding the requirements of wild plants, was fully sufficient for all the objects of agriculture, even for that most important one, the production of nitrogenous constituents of plants to serve as food for man and animals. (*Op. cit.* pp. 54, 211.)

The production of these substances was represented by Liebig as depending upon the presence, in the soil, of phosphates, which enabled plants to derive the requisite nitrogen from the atmosphere—a source where the abstraction of that element was spontaneously compensated by the ammonia resulting from the decay of animals and plants, and perhaps from other sources (*Op. cit.* pp. 147, 212). He also insisted that it was of the greatest importance for agriculture, to know with certainty that the artificial supply of ammonia was unnecessary and superfluous for the growth of most cultivated plants, and that the value of manure could not be estimated, according to the rule recognised in France and Germany, by the amount of nitrogenous substances it contained. (*Op. cit.* p. 213.)

To give still greater prominence to his opinion as to the superfluity of nitrogenous

manure, Liebig instanced the large quantity of nitrogenous substances produced—as hay, milk, and flesh—on grass-land without any supply of nitrogenous manure, and contrasted that fact with the smaller produce of nitrogenous constituents produced, within the same period—as corn and roots—on land to which nitrogen had been supplied as manure in greater quantity than was contained in the produce. He also referred to the export from Egypt of ammonia, obtained by burning animal excreta; to the proverbial fertility of that country, where only the ashes of excreta, and the Nile mud, containing little nitrogen, had been used as manure for ages; to the export of cheese from Holland and Switzerland,—as rendering it perfectly certain that the production of nitrogenous constituents of plants was not proportionate to the quantity of nitrogen supplied to the land in the manure: that the export of nitrogenous produce was not exhaustive; because it was not the soil, but the atmosphere, which yielded nitrogen to plants: that it was impossible to augment the produce of land by the supply of highly nitrogenous manure, or of ammonia-salts alone; but that, on the contrary, the capability of land to produce crops increased or diminished in direct proportion to the ash-constituents supplied to it in the manure. (*Op. cit.* pp. 210, 211.)

The logical consequence of the opinions thus formed, was to regard the ash-constituents as the essentially, if not the only, effective portion of manure (*Op. cit.* p. 202). It was insisted upon as a point of especial importance for the practical farmer not to deceive himself concerning the cause of the efficacy of manures (*Op. cit.* p. 187). In this respect the ash-constituents were compared by Liebig to the quinine of cinchona-bark, the iodine of burnt sponge, or the active principles of opium (*Op. cit.* p. 187). Consequently, the ash-constituents of manure were the materials which, according to his view, it was essential for the farmer to supply to land artificially, in order to increase the amount of produce. (*Op. cit.* p. 203, 211.)

The fundamental principle of rational culture, according to that view, was the perfect restoration of the ash-constituents removed from the land; and whether that restitution were made by applying excreta, or ashes, or bones, was regarded as a matter of indifference (*Op. cit.* p. 187). The particular kind of ash-constituents to be used as manure, was to depend upon the kind of produce required; alkalis for the production of substances analogous to starch; phosphates for the production of nitrogenous substances (*Op. cit.* pp. 193, 142, 144, 148). By the exact determination of the amount of ash in cultivated plants, and by the analysis of the ashes, the quantities of these substances removed from land by crops was to be ascertained. Thus the farmer was to be enabled to keep a debtor and creditor account, for each of his fields, of the several ash-constituents removed from the land, year by year; and to determine, according to the kind and quantity of the crops raised upon it, what substances and what quantities of them were to be returned to the land, in order to restore its original condition of fertility, or to be able to express exactly how many pounds of one or other constituent was to be supplied to the land in order to augment the amount of produce. (*Op. cit.* pp. 213, 214.)

Extending this view of the chemistry of plant-nutrition to the explanation of the various operations of the farm, the practices of rotation, fallow, &c., Liebig, still concentrating his attention upon that particular aspect of the chemistry of agriculture in which the ash-constituents of plants, soils, and manure are concerned, ascribed the influence of fallow in rendering land again capable of supporting the growth of corn, solely to the liberation of the ash-constituents requisite for that crop, by the decomposition of alkaline silicates in the land during the interval of fallow (*Op. cit.* pp. 118, 130–133). The similar influence of burnt lime and burnt clay on some soils, was ascribed to the same cause (p. 136). He represented the advantages of rotation of crops as being, to some extent, due to the production of humus in the soil, but chiefly to the unequal requirements of the different alternating crops for particular ash-constituents, and to the consequent accumulation, during the greater part of the period of rotation, of those ash-constituents present in least available amount in the soil, and requisite for the growth of one crop in larger amount than for the growth of the intervening crops. (*Op. cit.* pp. 150–161, 169, 172; Berzelius—1844—*Jahresbericht*, xxiv. 333.)

This theory of the chemistry of agriculture was applied by Liebig in the production of artificial manure; and a patent was obtained by Muspratt for the method of manufacture, as a communication from Liebig (*Improvements in the Manufacture of Manure*, 1846, Specification No. 10,616). These artificial manures were intended to supply to the land exactly what was wanting for the growth of any particular crop, and thus to effect an economy which would be impossible while manure was applied indiscriminately—the useful and the unnecessary constituents together. But the chief advantages which these artificial manures were to secure, were to render the rotation of crops and fallowing unnecessary and superfluous, and to admit of one and the same kind of crop being grown, year after year, upon the same field—of a perennial wheat-crop without the necessity either of fallow or of a rotation of crops, which was regarded by

Liebig as a restriction excluding all that science might be able to teach (*Principles*, p. 47). These manures, which were intended to effect such an entire revolution in agricultural practice, consisted chiefly of compounds of potassium-carbonate, with calcium-carbonate or phosphate, potassium-silicate, gypsum, bone-earth, and salt, and about 4 per cent. ammonio-magnesian phosphate, equivalent to rather less than 0.25 per cent. ammonia in the manures. The following table contains analyses of these manures, as manufactured by Messrs. Pfeiffer, Schwarzenberg, & Co. in Cassel (Pabst—1849—*Landwirthschaftliche Erfahrungen von Hohenheim*, p. 13). For the sake of comparison, the calculated composition of the manures, according to the directions of the specification, is added:—

Composition of Liebig's Artificial Manures.

	For Cereals.		For Leguminous Crops.		For Root-Crops.		For Timber-Crops.
	Calculated		Calculated		Calculated		
Soluble in hydrochloric acid.

	100.04	100.00	98.01	100.00	98.76	100.00	99.12

The proper composition of manures for other plants, was to be ascertained by burning the plants, and analysing the ashes, and then combining the manure according to the analysis (*"Specif."* p. 4, line 27). In the *Address to Agriculturists*, explaining the principles of artificial manuring, Liebig stated his view that "the exhaustion of the soil by subsequent crops—its decrease in fertility—is produced by the gradual removal of the mineral elements, in a soluble state, which are necessary for the development of our cultivated plants. By a supply of manure they are again restored to the state suited to serve as nourishment to a new vegetation. If the supply of the removed elements of the soil, by means of manure, be sufficient, if the quantity taken away be restored, the original fertility reappears; if the supply be greater, the produce increases; a defective supply gives a smaller produce" (p. 12); or, in other words, the amount of produce was directly proportionate to the available quantity of ash-constituents, or mineral substances which, "as such, are indestructible by fire, and consequently remain as ashes after the incineration of the plants, or of their parts." (p. 8.)

Consequently, the agriculturist was to confine himself to supplying these substances to his land, and giving it the proper physical condition, so as to render possible, and to increase, the assimilation of carbonic acid and ammonia from the atmosphere.

This theory of agriculture, or of manures—known as the mineral theory—was received with enthusiasm in England and America, and the estimation in which it was held is well represented by the following comments, published shortly after the introduction of the new manures:—"Since the organic food-materials are universally supplied to plants in constant amount, the great difference of vegetation cannot be sought in them, and, consequently, must be due to the inorganic constituents; so that, in putting farm-manure upon land, it would be essentially quite the same if it were first burnt, and only the ashes strowed upon the land, since its efficacy can only be due to its ash-constituents. It is easy to perceive that this principle, applied to agriculture, suddenly sheds a new light upon all phenomena whose explanation has hitherto been sought for in vain. Now, it is easy to conceive why irrigated meadow-land can yield annually great quantities of hay without manure when the necessary quantities of salts are conveyed to it in the water. It becomes clear how the Peruvian is able to obtain luxuriant crops of maize upon the most arid sand-drifts, if only a tiny rill from the snow-peaks of the Andes conveys to them the requisite soluble earths. Hundreds of similar phenomena are elucidated by this ingenious idea of Liebig's; but hundreds of new ideas are also suggested fruitful in development and improvement for that

simplification and security of agriculture which will be the inheritance of posterity; and we begin to find it natural that in England—where, according to the standard hitherto known, agriculture stands so high—Liebig should be celebrated as the founder of a rational system, in opposition to the previous purely empirical one; and that he should be overwhelmed with laudatory demonstrations and marks of honour, in such a way as scarcely any one, and certainly no foreigner, has ever experienced there.”—Schleiden, *The Plant*, pp. 173-174.

Under the auspices of the Royal Agricultural Society of England, an elaborate investigation of plant-ashes was undertaken by Way and Ogston, with the view of obtaining data for the preparation of artificial manures according to Liebig's mineral theory of agriculture (*Journ. Roy. Agric. Soc.*).

Experience did not realise the expectations which had been entertained as to the results to be obtained by the use of manure prepared according to the principles of the mineral theory.” Among other places, the wheat-manure was tried at Rothamsted, and the following results were obtained. (See Lawes and Gilbert, *op. cit.* viii. xxv.)

		Dressed corn per acre.	Weight per bushel.	Total corn.	Straw.	Total produce.
		bushels.		lbs.	lbs.	lbs.
1843-44						
3	Unmanured	15	58.5	923	1,120	2,043

	Unmanured	17½	63.8	1,216	1,455	2,671

Comparing the amount of produce obtained by the use of farmyard manure, with that obtained where only the ash of an equal quantity of the same manure was used, it is evident that the use of this manure effects something more than the mere restoration of ash-constituents to the land: and this result alone is sufficient to show the value of the mineral theory of agriculture.”

It has already been shown that the land, though exhausted in regard to the growth of wheat under the ordinary system of cultivation, was still rich in available ash-constituents (see *ante*, p. 837): consequently, the application of these only as manure, was not attended with any increase of produce over that obtained without any manure, which may be regarded as the measure of the extent to which the natural supply of air-food by the atmosphere and soil was available for the growth of wheat. But, wherever ammonia was supplied as manure, the produce was always much increased, even in those exceptional instances where it was used alone. These results, then, are in direct opposition to Liebig's mineral theory of agriculture.

In the case of wheat, the capability of production does not increase or diminish in exact proportion to the ash-constituents supplied to land in manure, but the amount of produce is proportionate to the supply of nitrogen in the manure; the capability of production may be increased by manure rich in nitrogen, and even by ammonia-salts alone. (See Chatterley—1843—*Phil. Mag.* xxii. 470: Report of some experiments with saline manures, containing nitrogen.)

It is, therefore, the relative deficiency of the supply of nitrogenous food which must be regarded as constituting the principal feature of that exhaustion of land, in regard to the growth of wheat, which takes place in the ordinary routine of agricultural practice.

Similar experiments to those above described have been made on the light land of Norfolk and in Kent, and the same general results have been arrived at. (See Lawes and Gilbert, *Op. cit.* xvi. 207. xxiii. 31.)

These facts at once furnish a clue to the function of farmyard manure in the growth of wheat, over and above the mere restitution of ash-constituents, and they illustrate the importance of the accumulation of available nitrogen upon the farm by the cultivation of fallow-crops. Moreover, they are conclusive proof that, so far as relates to increase of produce in wheat, the value of this manure is more essentially dependent upon the supply of nitrogenous material which it provides, than upon the restoration of ash-constituents removed by former crops; though this latter is a necessary condition of the maintenance of fertility in regard to long periods of time, and one which obtains under a good system of farming.

The striking contrast presented by wheat and turnips in regard to amount of produce when grown year after year on the same land without manure, clearly indicates that in the cultivation of the turnip, by which the exhaustion of land, by previous crops, is compensated for in ordinary practice, a supply of air-food from within the soil ~~is~~ must be provided by manure. Though the produce of wheat—allowing for the influence of season—was tolerably constant during twenty consecutive years, the produce of turnips was reduced in three years to almost nothing. Consequently, the capability of this plant to appropriate the food-materials furnished by the atmosphere during its period of growth, is not so great as has been supposed, and is, indeed, inferior to that of wheat.

The different value of manure in regard to these crops respectively, is also shown by the results obtained with phosphates, with ammonia-salts, and with farmyard manure. Superphosphates applied to wheat afforded no increase in the amount of produce over that obtained without manure; but with turnips it always increased the amount of produce, especially when there was an abundant supply of carbonaceous air-food provided, in addition to that furnished by the atmosphere within the period of growth. Ammonia-salts applied to turnips, either with or without other ingredients of manure, and with abundant supplies of ash-constituents in the land, did not increase the produce, or promote a favourable mode of growth; but with wheat, under the same conditions, they often doubled the amount of produce. Farmyard manure—containing both phosphates and ammonia, or its equivalent, together with a large amount of carbonaceous material—applied to wheat did not increase the amount of produce more than 50 per cent. over that obtained without manure; but with turnips its use was attended with large increase in the average weight of the bulbs; and when soluble phosphates were also used, there was a very considerable increase in the amount of produce per acre. The difference in these cases is chiefly referable to difference in the requirements of these plants as they are cultivated; a comparatively more abundant supply of carbonaceous food and of phosphates being necessary for the turnip, while wheat requires a comparatively more abundant supply of nitrogenous food.

The amount of produce obtained with Liebig's wheat-manure, in the third year, was little above that obtained without any manure, and much less than that obtained with farm-yard manure; but when ammonia-salts were used with Liebig's manure, the amount of produce was increased nearly in proportion to the amount of nitrogenous material supplied either as ammonia-salts or rape-cake.

Experiments made before 1845 by Liebig himself, with these manures consisting only of ash-constituents, did not furnish any indications of their efficacy; and in subsequent trials upon poor uncultivated land at Giessen, the effect produced where they were used alone was very slight, compared with that where forest-earth or stable-manure were used (Liebig, *Principles*, pp. 40-45). By cultivation, the fertility of the soil gradually increased; but as no data have been given as to the composition of the soil, the amount of produce, &c., by which an opinion could be formed as to what were the latent resources of the land—how much of the result may be due to the influence of tillage, or to the manure produced as the result of cultivation only, and how little of that result may be due to the supply of ash-constituents to the land in the first year—it is impossible to regard the results of these experiments as constituting any exception to the observations made elsewhere as to the effect of manure consisting wholly of ash-constituents of plants.

The failure of Liebig's wheat-manure, and the inefficacy of the ash of farm-yard manure have been ascribed to their deficient solubility. (See Liebig, *Einführung in die Naturgesetze des Feldbaues*, pp. 70 et seq.; International Exhibition, 1862, *Reports by the Juries*, p. 151.) This opinion may be urged as an excuse in those instances, but it has no applicability to the other instances in which the constituents of the wheat-manure and of the ashes were used in a very soluble condition, and were nevertheless equally inefficient in augmenting the produce beyond that obtained without manure. The state of exhaustion could not, therefore, consist in deficiency of ash-constituents; and the results obtained by the use of ammonia, even alone, or with those manures,

clearly prove that the relative deficiency of nitrogenous supply within the period of growth, was the main feature of the exhaustion, the determining cause of the small amount of produce on the unmanured land, and of the inefficacy of the soluble ash-constituents, if not also of the farmyard manure ash and of Liebig's manure.

These results, therefore, show that all hope of obtaining annual crops of corn, or of increasing the amount of produce of crops generally, by means of manures consisting only of the ash-constituents of the plants grown, must be entirely abandoned; and that, as regards agricultural practice, precisely the opposite course must be adopted, of supplying air-food by artificial means, in order to render the available resources of the land fully effective. The artificial supply of nitrogenous air-food is the only means by which a full agricultural crop of corn can be obtained year after year from ordinary land. But since the sources of ammonia-salts at present available are inadequate for that purpose, it is evident that a rotation of crops is an indispensable feature of a system of agriculture where the production of corn is the chief object, and where it is necessary to obtain a large amount of produce. The increased supply of nitrogen stored up from atmospheric sources by the cultivation of fallow-crops, and made available by cattle-feeding for the production of corn, must at the same time be supplemented by the purchase, from extraneous sources, of nitrogenous manures, and cattle-food, as far as may be practicable and profitable in particular instances. In the case of land rich in ash-constituents, the artificial supply of nitrogenous manure may be, to some extent, substituted for rotation, and cattle-feeding, so as to obtain larger and more frequent corn-crops.

It appears, therefore, that instead of reforming agriculture by his manures, Liebig caused them to demonstrate the incorrectness of his mineral theory of agriculture; and the failure of those manures, from the application of which farmers had been induced to anticipate such wonderful results, naturally produced a revulsion of opinion which was sometimes expressed in a manner not altogether free from exaggerated opposition to the views put forward by Liebig. Thus the President of the Royal Agricultural Society of England, after remarking, in his annual address, that "the mineral theory, hastily adopted by Liebig, had broken down; and that the doctrine of the increase or diminution of crops being exactly proportionate to the increase or diminution in the quantity of ash-constituents supplied to them in manure, had received its death-blow from the experiments at Rothamsted," went on to state, that of the active principles of manure, ammonia was specially suited for corn, phosphates for turnips. (Pusey—1850—*Jour. Roy. Agric. Soc.* xxii. 383-392.)

This expression of opinion by a practical farmer must be regarded as applying chiefly to the artificial supplies of manure required for different cultivated plants, and not by any means indicative of the idea that, in regard to the nutrition of plants considered apart from agriculture, any one or other constituent of plant-food possessed a special value independent of others. The erroneous estimate Liebig has formed of the opinions held in this country respecting manure, has no other basis than the supposition that such an idea has been entertained, or else the want of a due comprehension of the farmer's strictly technical view of this subject being limited to the consideration of materials to be provided over and above those supplies which are furnished by ordinary practice, either from extraneous sources or by modifications of that practice.

That erroneous estimate has also given rise to much of the controversial opposition which Liebig has manifested towards the conclusions arrived at by the researches of Lawes and Gilbert, though virtually adopting those conclusions, and materially modifying his own views in accordance with them. It has also led him to imagine that the general doctrine of plant-nutrition has been called in question. But that is not the case, nor has this general doctrine ever been disputed, except in so far as relates to that extreme form of it, adopted by Liebig, according to which carbonic acid, water, and ammonia are held to be the only sources of the organic constituents of plants. (Saussure—1841—"Sur la Nutrition des Végétaux."—*Bibl. univ.* xxxvi. 340.—Berzelius—1842—*Jahresbericht*, xxii. 220.—Mulder, *op. cit.*—Mohl, *op. cit.* p. 78.) The originality of that extreme view, was, indeed, disputed by Dumas, by whom it was also put forward about the same time. (Dumas—1841—"Sur le Rôle que joue l'air atmosphérique dans la nature, et sur l'action qu'il exerce sur tous les êtres organisés." *Rev. scient. indust.* vi. 228, and *Chemical and Physiological Balance of Organic Nature.*) Berzelius, in criticising that doctrine, remarked that, while it was not supported by any experimental evidence, it was so opposed to general agricultural experience, that it could not even be regarded as probable; though it manifested many errors of inspiration, and had been propounded with the art peculiar to Dumas. It was, however, by soundness of argument, to overcome the doubts of those acquainted with the subject, than to impress others, less cognisant of it, by striking manner and popular expression—the most efficient means of making precipitate scientific conclusions popular. (*Jahresbericht*, xxii. 220.) In reference to Liebig's views on the chemistry of agriculture, he also remarked that the mode in which he had sought to decide questions of the highest importance for that art, had met with greater recognition, as being perfectly

trustworthy, than was consistent with the state of knowledge at that time. Of Boussingault, on the contrary, who had followed "the difficult and laborious course of deciding every question by experiment," he remarked, that "his answers, though not so rapid, were mostly trustworthy." (*Jahresbericht*, xxi. 236, 238.)

The difference thus early recognised by Berzelius between Liebig's mineral theory of agriculture, and Boussingault's views on the same subject, has been fully confirmed by the results of experience. The former may be looked upon as a thing of the past, the error of which has been demonstrated by the entire failure of the attempts to carry into practice its fundamental principle as to fertility and manure. The latter, though modified in some particulars by their development, and by the progress of research, have been found in the main correct, and are supported by the extended results obtained by Lawes and Gilbert, in the series of experiments they have conducted upon a working scale, during the last twenty years, with a strict regard to actual practice in the field, and in the laboratory, with all the refinement of modern methods of research.

The difference between Liebig's doctrine and the conclusions arrived at by Lawes and Gilbert, as the result of their experimental researches, does not relate to the abstract theory of plant-nutrition; but it relates solely to the ordinary system of agricultural practice, and chiefly to that branch of the "mineral theory" of agriculture propounded by Liebig, which comprises the principles of manuring. Liebig ascribed fertility and the efficacy of manure, solely to the amount of available ash-constituents in land, and the advantages of rotation, mainly to the unequal requirements of different plants for those substances.

Lawes and Gilbert, on the contrary, have shown that fertility is not proportionate to the amount of available ash-constituents in land; that the efficacy of manure is not proportionate to the amount of ash-constituents it contains; that the exhaustion of land, in the ordinary practice of agriculture, consists chiefly in a deficiency of nitrogenous food-material; that the advantage of rotation consists more in the accumulation of nitrogenous and carbonaceous food-materials in the farmyard manure, than in the difference between the ash-constituents taken from land by corn and fallow-crops; and that the requirements of cultivated plants cannot be measured merely by the results of their analyses.

The sterling value of the results thus obtained is not overrated by the opinion expressed in the annual address of the President of the Royal Agricultural Society of England, that "during the last twenty-five years, there has not been any addition made to our knowledge, which approaches, in importance, to the insight into the true principles of cropping and manuring, obtained on the experimental farm at Rothamsted." (Thompson—1864—*Journ. Roy. Agric. Soc.* xxv. 4.)

The particular conclusions and general views which have been arrived at by these researches have been vehemently disputed by Liebig, who has sought to maintain that they are at once totally erroneous, and perfectly confirmatory of his "mineral theory of agriculture." (Liebig—1851—*Letters on Chemistry*, 3rd edit.; 1855—*Principles of Agric. Chemistry*; 1863—*Natural Laws of Husbandry, Einkultung*, &c.—Hofmann, *Op. cit.* p. 160.)

This paradoxical position has been arrived at by a singular process.

It is contended that the "mineral theory" of agriculture comprised ammonia and its salts, among the mineral substances which were considered to determine the fertility of land and the efficacy of manure, and which it was, consequently, necessary to return or supply to land, in order to maintain or increase fertility. (Liebig—1855—*Principles of Agric. Chemistry*, p. 90.)

This claim, however, is quite inconsistent with Liebig's original exposition of his views, and with the pointed antithesis constantly maintained in all his writings, between the atmospheric food of plants, carbonic acid, water, and ammonia, whether furnished directly by the atmosphere, or indirectly from within the soil; and those materials derived exclusively from the soil, which "are mineral substances, and as such are indestructible by fire, and consequently, remain as ashes after the incineration of the plants, or of their parts." It is also inconsistent with the general interpretation of his "mineral theory" by other writers on the subject. (See Horsford—1840—*Genesis Farmer*, Aug. 1855.—Weissenborn—1847—*Farmer's Magazine*.—Schultze—1848, *American Farmer's Office Report*, 1849.—Johnston—1848—*Jour. Roy. Agric. Soc. Eng.*, ix. 244.—1844—*Traité des Amendments*, pp. 423, 623, 624, 627, 632.—Boussingault—1844—*Economie Rurale*, ii. 81.—*North British Agriculturist*, Nov. 7, 1855.) It is also inconsistent with the fact, that, in the specification of the patent which was the embodiment of Liebig's "mineral theory" in relation to practical agriculture, neither ammonia nor its salts were included* among the mineral substances mentioned in the recipes and

* The quantity of ammonia, amounting to less than 0.5 per cent., corresponding to the ammonio-magnesian phosphate in the manure, is of course considered as unimportant.

directions given by him for the preparation of manures (see p. 845). In the "Address" also, though ammonia was stated to have been added to the manure in the first year, still the prospect of being able to exclude it altogether was spoken of as probable; and in the third edition of the *Letters on Chemistry*, 1851, (p. 602), a whole letter was devoted to the argument, that an artificial supply of nitrogen was quite a matter of indifference (p. 515); for though such a supply would exercise a favourable effect on vegetation, still, if it were not given, all the requisite nitrogen would be obtained from the atmosphere. (p. 518. See also *Allgemeine Zeitung*—1857—No. 157.)

In the criticism of Lawes' and Gilbert's experiments and conclusions, Liebig has assumed that they have regarded certain substances as having a specific value as materials of plant-food in an abstract point of view; but this assumption is unfounded. Their experiments have only led them to consider that in a practical point of view, and in relation to the existing practice of agriculture, in this country especially, those materials of plant-food acquire a preponderating value as manure, which, like ammonia in the case of corn, become relatively deficient; or which are capable of determining a particular mode of growth, like phosphoric acid in the case of root-crops; that they are the materials to be supplied artificially, not with the object of wasting the available resources of land, but in order to prevent these from lying idle.

Herein lies a difference which Liebig has either failed to perceive, or studiously disregarded; and it is a difference of the highest importance. The practical farmer accepts, in its full significance, the abstract theory of plant-nutrition, so far as it concerns him: he also looks for its application to the art in which he is engaged, and for rules by which his practice may be improved. There is probably no art in which suggestions for improvement have been more eagerly accepted during the past twenty or thirty years than in agriculture; but when such suggestions are tested and found wanting, the practical nature of agriculture demands their abandonment.

So it has proved with Liebig's application of his theory of plant-nutrition to agriculture. Looking only to the ash-constituents of plants, of soils, and of manure, he has laid down rules for agricultural practice—he has prescribed manures, and written elaborate expositions of the various operations of culture, which in every single instance fail to bear the test of experience.

But where the enquiry into this subject has been conducted in a more catholic spirit, and by a method at once more philosophical and more directly relating to the ruling conditions of practical agriculture, as in the experiments of Boussingault, and of Lawes and Gilbert, the results obtained are calculated to afford materials for a legitimate induction, by which principles of real value in relation to the practice of the art may be arrived at.

The customary routine of agricultural practice, however defective it may be in particular cases, has become established by observation and experience, and by the exercise of the same mental functions which are employed in scientific research. Though their exercise may be limited by the practical object in view, there can be no doubt that, in reality, agricultural customs represent natural facts to a greater extent than science is yet competent to explain. To those who do not, like Liebig, consider the farmer to be "destitute of all understanding," the prejudices characteristic even of the rudest practice will, therefore, appear as the exponents of those peculiarities of climate, soil, and other circumstances, which lie at the root of the practice adopted. However vague and unintelligible such prejudices and empirical rules may appear, it is from the consideration of them, that a clue may be obtained to the scientific elucidation and improvement of agriculture. The science, which is to be of value in agriculture, and whose value will be recognised by farmers, must grow out of the practice of the art, and the patient examination of its various details, and not be a mere speculative grafting upon it. The accumulated data of ordinary experience must furnish the basis for its construction, and its doctrines must rest upon evidence of reality, not upon mere probability. It may be a slow growth, but it must be a sure one.

Meanwhile, it is no reproach to the farmer if he adheres to the system which he knows by experience to have brought him certain results, or that he refuses to adopt another system until he has sufficient proof of its being more advantageous than that with which he is familiar. This natural conservative tendency has been strengthened by the failures attending the premature application of scientific doctrines. This is really the reason why farmers are in many cases averse to the adoption of improvements suggested by science. It is not because they are "destitute of all understanding," or because they pretend to deny the existence of any connection between scientific doctrines and the phenomena concerned in agriculture, but because it is still questionable whether those doctrines really furnish the means of improvement. For this reason they prefer to be guided by tradition and experience, rather than by untried precepts of scientific speculation. If there be an established and invariable connection between the practice of rotation with cattle-feeding, and the profitable result of farming—

between the use of superphosphates and the production of a large root-crop—between the use of nitrogenous manure and the increase of corn-crops—those practices will continue to be adopted, and they will constitute the scientific practice of agriculture, quite independent of the questions whether superphosphate or ammonia have any special value as materials of plant-food, or what becomes of those portions of them which are supplied as manure and are not obtained in the crop. These are abstract scientific questions of high interest for the chemist, and of possible importance to the future of agriculture; but they do not concern the farmer, whose business is to produce food with such means as are at his disposal. It would be a very illogical conclusion that the facts observed as to the influence of artificial supplies of ammonia and superphosphates upon the growth of corn- and root-crops should be disregarded because science is unable to explain the precise functions of those substances in vegetation; and it is equally irrational to denounce, as a folly and an error, the application of those facts so far as present knowledge will admit.

B. H. P.

MARASMOLITE. Syn. with BLENDER. (See ZINC, SULPHIDE OF.)

MARBLE. See LIMESTONE (p. 697).—Church (Chem. Soc. J. xvii. 379) has lately examined the colouring matter of the Blue Forest Marble, and has shown that the colouring material of the dark bands which occupy the central portion of the various-sized slabs into which the stone has naturally divided, consists of iron pyrites, while the paler yellow, brown, or buff tint of the outer parts of the slabs is due to ferric oxide resulting from the oxidation of the pyrites. It appears probable that the colouring of other blue and grey clays, rocks, and soils may also be due to the presence of iron pyrites; and hence, perhaps, may be explained the injurious influence which these blue and grey matters exert on vegetation.

MARCASITE. White iron pyrites. (See IRON, SULPHIDES OF, p. 402.)

MARCELIN. A name applied to an impure variety of braunite (manganic oxide); also used as a synonym of rhodonite (silicate of manganese).

MARCYLITE. A mineral having the aspect of tenorite cupric oxide), from the southern part of Red River, in the neighbourhood of Mount Wichita. Hardness = 3. Specific gravity = 4.0 to 4.1. In the flame of a candle it melts, and acquires a bluish green colour. On charcoal it gives off vapours of chloride of copper, and ultimately leaves pure copper. In the pulverised state, it dissolves completely in ammonia. Contains 54.3 per cent. copper, 36.2 chlorine and oxygen, and 9.5 water. (C. U. Shepard, Sill. Am. J. [2] xxi. 206.)

MARCANITE. Syn. with PEARLSTONE.

MARGARIC ACID. $C^{18}H^{32}O_2 = \begin{matrix} C^{18}H^{30}O \\ H \end{matrix} \} O.$ (Heintz, Pogg. Ann. cii. 272).—

This term was formerly applied to an acid intermediate between stearic and palmitic acids, supposed to be produced, together with others, by the saponification of solid natural fats; but it is now restricted, for reasons presently to be mentioned, to an artificially prepared fatty acid of the series $C^mH^{2m}O_2$, resulting from a definite reaction.

a. *Artificial Margaric acid.*—This acid is produced by the action of potash on cyanide of cetyl (margaronitrile):

Cyanide of cetyl (oily, see i. 841) is continuously boiled with alcoholic potash, till ammonia is no longer given off, and the residue has become solid; this residue is then decomposed by boiling dilute hydrochloric acid; the separated fatty acid is shaken up with aqueous ammonia; and the turbid solution is precipitated by chloride of barium. The precipitate, after being washed with water and with alcohol, and repeatedly boiled with ether, yields to this solvent an oil, which solidifies in the cold, melts below 40°, and has the composition of a mixture of cetylic ether and cetylic aldehyde. The undissolved barium-salt is decomposed by agitation with hydrochloric acid and ether; and by pipetting off the ethereal liquid, and distilling off the ether, crude yellowish margaric acid is obtained, melting at 56.6°, and solidifying in scales and fine needles. This acid may be resolved, by several crystallisations from alcohol, repeated partial precipitation from the solution of its sodium-salt by acetate of magnesium, and subsequent recrystallisation of the portions of acid again separated (somewhat in the manner described on page 474) into margaric acid, and an acid containing a larger proportion of carbon ($C^{18}H^{32}O_2$, formed from cyanide of *stearyl*, $C^{18}H^{34}N$, contained in the cyanide of cetyl employed), which occurs chiefly in the portions first precipitated by acetate of magnesium. (Heintz.)

The portions last precipitated by acetate of magnesium yield margaric acid, which, after its melting-point has been raised by repeated crystallisation to 59.9°, exhibits the characteristics of a pure fatty acid mentioned below, and cannot in any way be resolved into acids differing in melting-point. This is the only way in which pure margaric

acid can be obtained. The acids formerly so called, obtained by the saponification of natural fats, were mixtures of stearic acid with palmitic acid, or other acids of lower melting-point.

Margaric acid forms white crystals, melting at 59.9° , and solidifying in crystalline scales on cooling. It contains, according to the mean of Heintz's analyses, 75.46 to 75.55 per cent. carbon, and 12.44 to 12.57 hydrogen; the formula requiring 75.56 carbon, 12.59 hydrogen, and 12.85 oxygen.

But few of the margarates have been prepared. The barium-salt, $C^{18}H^{34}BaO^4$, obtained by precipitating the sodium-salt with nitrate of barium, and washing with water, is a white amorphous powder yielding, by analysis, 60.39 per cent. C, 9.80 H, and 22.40 BaO; the formula requiring 60.44 C, 9.78 H, and 22.67 BaO.

The silver-salt, $C^{18}H^{34}AgO^2$, obtained in like manner by precipitation, dries up to a loose, white, amorphous powder, containing 63.67 per cent. C, 8.74 H, and 28.85 Ag (calc. 54.11 C, 8.75 H, 28.65 Ag, and 8.74 O).

The sodium-salt is prepared by adding a boiling aqueous solution of pure sodic carbonate to a boiling alcoholic solution of margaric acid, evaporating to dryness over the water-bath, exhausting the residue with boiling alcohol, and filtering hot. The filtrate, which solidifies to a jelly on cooling, is liquefied by heat and mixed with water in the proportion of one-eighth of the volume of the alcohol employed, whereby a mother-liquid is formed which takes up any foreign salts present. On again solidifying, the salt is collected on linen and strongly pressed.

B. The so-called margaric acid obtained by saponification of natural fats.—Chevreul in 1820 distinguished the solid acids resulting from the saponification of fats, as margaric acid and margarous, afterwards stearic acid; the former melting at 60° , the latter at 75° , and solidifying at 70° . He did not consider the difference between the two acids to be fully established, but suggested that margaric acid might be a mixture of stearic acid with another acid more fusible and richer in oxygen.

The fatty acid melting at 60° was, however, afterwards examined by several chemists (see Gerhardt, *Traité*, ii. 835), and regarded as a separate acid, having the composition $C^{18}H^{34}O^2$, and this view of its nature continued to prevail, till Heintz, in a series of researches published in 1852 and subsequent years, showed that it was not a distinct acid, but could be separated, by certain processes, into stearic acid and other fatty acids of lower melting-point. The leading points established by Heintz in this series of researches (for the references to which see *Gmelin's Handbook*, xvi. 343, 344), are the following:

1. All the acids obtained in the saponification of fats contain an even number of carbon-atoms ($C = 12$).
2. The margaric acid of most chemists is separable into palmitic and stearic acids.
3. Fatty acids may be mixtures, and not definite compounds, even though neither their composition nor their melting-point can be altered by recrystallisation.
4. Such mixtures may, however, be separated by partial precipitation (p. 474).
5. They differ from pure acids as regards their melting-point and their mode of solidifying.

Heintz has, moreover, determined with accuracy the melting-point, composition, and many other properties of the fatty acids, and has also drawn up tables, hereafter to be given, of mixtures of fatty acids of known composition (see MYRISTIC, PALMITIC, and STEARIC ACIDS). From these, and the investigations of other chemists subsequently published, it appears that the nature of the bodies described as margaric acid is probably as follows:

a. *Margaric acid of Chevreul*.—This, according to Heintz, is to be regarded as a mixture of about 90 per cent. palmitic acid and 10 per cent. stearic acid, which is probable from the circumstance that it crystallises in needles on cooling. Of similar nature are doubtless the margaric acid of Varrentrapp (*Ann. Ch. Pharm.* xxxv. 84), obtained from human fat; that from goose-fat by Gottlieb (*ibid.* lvii. 56); from sheep-butter by Thomson and Wood (*J. pr. Chem.* xlvii. 237), and many others.

b. *Margaric acid of Bromeis*.—The acid obtained by oxidation of stearic acid is undecomposed stearic acid, which owes its lower melting-point to association with volatile acids (see STEARIC ACID).—Respecting the margaric acid which Bromeis (*Ann. Ch. Pharm.* xxxv. 93) obtained from impure oleic acid by the action of nitric acid, see OLEIC ACID.

c. *Margaric acid of Redtenbacher and Varrentrapp*.—That of Redtenbacher is obtained by the dry distillation of stearic acid, when, according to Heintz, most of the stearic acid passes over unchanged. That of Varrentrapp (*Ann. Ch. Pharm.* xxxv. 86), obtained by the dry distillation of beef-suet, hog's-lard, olive-oil, or crude oleic acid, doubtless varies in composition according to the kind of fat employed.

d. *Anderson's Margaric acid* (*Ann. Ch. Pharm.* lxiii. 376) is obtained, together with sulphuric acid, odmyl, and other products, by the dry distillation of almond-oil

with sulphur. It contains, on the average, 75.34 per cent. C, 12.58 H; in the silver salt, 28.62 per cent. silver; in the ethylic ether, 78.33 per cent. C, 12.73 H, and 10.97 O. It appears to be palmitic acid formed by the decomposition of oleic acid.

c. Margaric acid of Poleck, Lewy, and others, obtained by the dry distillation or saponification of wax, is doubtless palmitic acid, more or less pure.

MARGARIC ETHERS. No compounds of the alcohol-radicles with pure margaric acid (Heintz's), have yet been obtained. The compounds to which the name has generally been applied were probably mixtures of stearic and palmitic ethers. A similar remark applies to Chevreul's *margarin*.

MARGARITE. *Perlglimmer, Emeryllite, Corundellite, and Uingmannite.*—A silicate of calcium and aluminium, occurring in trimetric hemihedral crystals, with a monoclinic aspect, like muscovite; tabular from predominance of the form *oP*. Angle $\infty P : \infty P = 119^\circ$ to 120° . Lateral planes longitudinally striated. Cleavage basal, eminent. Usually in intersecting or aggregated laminae, sometimes compact, massive, with a somewhat scaly structure. Hardness = 3.5 to 4.5. Specific gravity = 3.032 to 2.99; the latter for margarite (Hermann), 2.995 for emeryllite (Silliman, jun.). Lustre of base pearly, laterally vitreous. Colour greyish, reddish, or yellowish. Translucent to subtranslucent. Laminae rather brittle.

Analyses.—*a.* From Sterzing, in the Tyrol (Smith and Brush, Sill. Am. J. ii. xv. 209). *b.* From the corundum mines of Gumuchdagh, in Asia Minor. *c.* From the island of Nicaria, in the Grecian Archipelago. *d.* From Naxos. *e.* From Katharinenburg, in the Ural (J. L. Smith, *ibid.* xi. 59 and xv. 208). *f.* From Village Green, Chester county, Pennsylvania (Craw, *ibid.* viii. 379). *g.* From Buncombe county, North Carolina (B. Silliman, *ibid.* viii. 1). *A.* From Unionville, Pennsylvania (Craw, *loc. cit.* :

	<i>a.</i>	<i>b.</i>	<i>c.</i>	<i>d.</i>	<i>e.</i>	<i>f.</i>	<i>g.</i>	<i>A.</i>
Silica	28.55	30.83	30.04	29.68	28.50	31.20	29.17	29.99
Alumina	50.24	49.30	49.08	49.38	51.02	50.86	48.40	50.54
Ferric oxide	1.65	2.08	1.48	1.26	1.78			
Lime	11.88	10.83	11.20	11.18	12.05	10.25	9.87	11.51
Magnesia	0.69	0.50	trace			0.45	1.24	0.83
Soda and potash	1.87	1.90	2.68	1.25	?	2.29	6.15	0.83
Water	4.88	3.88	4.72	5.05	5.04	4.83	3.99	
Fluorine							2.00	
	99.76	99.27	99.10	97.80	98.39	99.88	100.82	100.10

These analyses lead to the formula $\text{CaO} \cdot 2\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2 \cdot \text{H}_2\text{O}$ (the calcium being partly replaced by potassium and sodium, and the aluminium by ferricium).

Corundellite is margarite from Unionville, Chester county, Pennsylvania. *Uingmannite* is the same mineral from Buncombe county, North Carolina.

Diphenite (ii. 430) is also a variety of margarite. (Dana, ii. 300. Rammelsberg's *Mineralchemie*, p. 843.)

MARGARODITE. A variety of muscovite or biaxial mica, apparently formed from this mineral by assumption of water, and loss of alkalis and ferric oxide. A specimen from Monroe, Connecticut, analysed by Smith and Brush (Sill. Am. J. [2] xvi. 48), gave by analysis 46.50 per cent. silica, 33.91 alumina, 2.69 ferric oxide, 0.90 magnesia, 2.70 soda, 7.32 potash, and 4.63 water, with 0.82 fluorine and 0.31 chlorine.

MARGARONE. The acetone of margaric acid: it has not been prepared from the pure acid.

MARGALITE. Syn. with HAUYNE (p. 14).

MARGARITE. A hydrous carbonate of zinc, containing 73.26 per cent. ZnO , 15.01 CO_2 , and 11.61 water, found in Marion county, Arkansas (Elderhorst, Sill. Am. J. [2] xiii. 383). A mineral of the same composition occurs at Cumillas, near Santaspe, in Spain. Its composition is expressed nearly by the formula:

(Petersen and Voit, Jahrb. 1858, p. 734.)

MARINE METAL. An alloy introduced by Wetterstedt in 1636, for the sheathing of ships. It consists of 94.4 per cent. lead, 4.3 antimony, and 1.3 arsenic; has a specific gravity of 11.1, is very malleable, but harder than lead. It is said to be attacked by water or hydrochloric acid, and to be twice as cheap as copper. It does not appear, however, to have been practically used.

MARIOTTE'S LAW. The law which expresses the inverse proportionality of the volume of a gas, to the pressure to which it is subjected at a given temperature. (See ii. 370, 819.)

MARJORAM, OIL OF. The volatile oil obtained by distilling sweet marjoram (*Marjorana hortensis* or *Origanum marjorana*) with water is lighter than water, and

contains a considerable quantity of camphor or steareptene. When freed from the latter by rectification, it boils at about 161° , and appears to have the composition of oil of turpentine, containing, according to Kane (Ann. Ch. Pharm. xxxii. 285), 86.7 to 86.1 per cent. carbon, 11.1 to 11.4 hydrogen, and about 2 per cent. oxygen, probably arising from a small quantity of the camphor not completely separated.

The camphor of marjoram is hard, colourless, inodorous, heavier than water, melts when heated, and sublimates without residue. It is soluble in boiling water, in ether, nitric acid, and sulphuric acid, the last colouring it red. It contains, according to Mulder (Ann. Ch. Pharm. xxxi. 69), 60.0 per cent. carbon, and 10.7 hydrogen.

MARL. See LIMESTONE (p. 698).

MARMATITE. A black ferruginous variety of blende, found at Marmato, near Popayan, South America. (See ZINC, SULPHIDE OF.)

MARMOLITE. Syn. with SERPENTINE.

MARRUBIIN. (Kromayer, Arch. Pharm. [2] cviii. 257.)—The bitter principle of white horehound (*Marrubium vulgare*). To prepare it, the dried herb is repeatedly exhausted with hot water; the united and concentrated extracts are treated with recently-ignited animal charcoal; and the charcoal, after washing with water, is well boiled with alcohol, whereby a bitter solution is obtained, which, when freed from the greater part of the alcohol by distillation, and then left to evaporate, deposits crude marrubiin as a brown bitter balsam. For purification, it is dissolved in alcohol; the solution is mixed with water till it begins to show turbidity, then with acetate of lead; and the filtered liquid, after being freed from lead by sulphuric acid, is left to evaporate. The marrubiin then separates in light brownish-yellow oily drops, which, when separated from the mother-liquid, solidify in crystalline masses. Only a part of the marrubiin, however, assumes the crystalline form; the rest, which in other respects, resembles the crystallised substance, solidifying in the amorphous state. In preparing marrubiin also from fresh horehound, the greater part of the product is obtained in the amorphous state.

Marrubiin crystallises from ether in colourless rhombic plates, or thick four-sided twin-crystals; from alcohol in needles. It is nearly insoluble in cold water (whence the bitter taste of horehound becomes perceptible after some time only); somewhat more soluble in hot water. Alcohol and ether dissolve it readily, forming perfectly neutral solutions. Marrubiin melts at 160° , and solidifies crystalline on cooling; at higher temperatures, it gives off white, very irritating vapours. When heated in a test-tube, it distils in oily drops, giving off pungent vapours smelling like oil of mustard. Strong sulphuric acid dissolves it with brown-yellow colour; strong hydrochloric acid does not act upon it even when heated; strong nitric acid does not act on it in the cold, but dissolves it with yellow colour when heated. It is not perceptibly altered by alkalis, or by metallic salts, and produces but a slight reduction in ammoniacal nitrate of silver; neither is it precipitated by tannic acid.

MARSH-GAS.—Light carburetted hydrogen, *Hydride of Methyl*, CH^4 . This hydrocarbon gas is very abundant in nature. The bubbles of gas which are so often seen on the surface of stagnant water consist of it, mixed with nitrogen and carbonic acid. From its occurrence in this way in marshy districts it takes its name. Great quantities of it are given off by many of the coal-beds, so that it often accumulates in coal pits, where it is known as the *fire-damp* of the miners, and is the cause of the explosions which occur in those places. It is, moreover, found escaping from the earth in many parts of Italy, Persia, China, and America.

Besides being one of the usual products of the decay of organic substances, and also of their destructive distillation, especially when this operation is performed at elevated temperatures, and in general of the imperfect combustion of fuel, it constitutes a large proportion of common illuminating gas. Bunsen's analysis of Manchester coal gas gives 84 vols. of marsh-gas in every 100 vols. of the gas.

In the laboratory—if we except this production of it by the imperfect combustion or destructive distillation of organic substances—it is comparatively a rare product. The following other reactions which are known to yield it are:—

(1) The action of nascent hydrogen on tetrachloride of carbon (the nascent hydrogen being generated by the action of potassium-amalgam on water.) (Regnault.)

(2) The action of zinc-methyl on water, and certain analogous actions of the same kind. (Schindler.)

From this reaction it derives its name, hydride of methyl.

(3) The action of sodium on iodide of methyl in presence of ether (Wasklynski).

Buckeisen), which, instead of yielding pure methyl, gives a large quantity of hydride of methyl.

(4) The action of sulphide of carbon upon sulphuretted hydrogen and copper, or iron at a red heat; also the action of sulphide of carbon on phosphoretted hydrogen and copper. (Berthelot.)

There is also some reason for believing that it is produced by the direct action of hydrogen on carbonic anhydride at a red heat, since when marble is heated in a current of hydrogen, more water is generated than corresponds to the simple reduction of the carbonic acid to carbonic oxide. (Wanklyn and Frank.)

Preparation.—The readiest way of preparing large quantities of marsh-gas in a state of tolerable purity is by the destructive distillation of a mixture of an alkaline acetate with a hydrated alkali.

It is recommended to employ 2 parts of crystallised acetate of sodium, 2 parts of caustic potash, and 3 parts of powdered quicklime (Dumas, Ann. Ch. Phys. [2] lxxiii. 92). The object of using the quicklime is to save the retort, which might otherwise be perforated by the caustic potash. In conducting the operation, a little caution is requisite; no trace of gas comes off until the temperature is very high, and then there is a sudden rush of gas.

The reaction between the alkali and the acetate is tolerably precise:

With the exception of Bunsen's destructive distillation of cacodyl,

it is the only destructive distillation which yields marsh-gas by a precise reaction.

Marsh-gas prepared as just described from the acetate is, however, liable to certain small quantities of impurity. It is easy to see how small quantities of acetone-vapour are almost inevitable: for destructive distillation of an acetate alone gives acetone.

If marsh-gas of a high degree of purity be required, it may be obtained by decomposing zinc-methyl with water.

Of all known compounds, marsh-gas is the richest in hydrogen, containing as much as 25 per cent. Next to hydrogen itself it is the lightest gas (specific gravity 0.5576), and is thence not inappropriately named *light carburetted hydrogen*. In general character it bears a great resemblance to hydrogen. It is incondensable, colourless, without taste or smell; neutral to test-paper, and very neutral altogether. It is distinguishable from all other hydrocarbons by the low luminosity of its flame. In water and in alcohol it is very sparingly soluble. 100 vols. of water at 0° C. dissolve 5.449 vols. of marsh-gas; 100 vols. of alcohol at 0° C. dissolve 52.259 vols. (Bunsen). The sparing solubility of marsh-gas in alcohol affords a method of separating it from some other hydrocarbon gases, such as ethyl, which dissolve in alcohol to a much greater extent. By means of sulphuric acid or bromine (neither of which attacks it), the olefines may be removed from a gaseous mixture containing marsh-gas and olefines. It is not absorbed by potash, and indeed there is no reagent which absorbs it. From acetylene it is easily separated by means of an ammoniacal solution of cuprous chloride. The same reagent, or the hydrochloric solution of cuprous chloride, might be employed to remove carbonic oxide (see ANALYSIS OF GASES, I. 283). According to Dumas it is not attacked by chloride of sulphur, nor by pentachloride of phosphorus, nor by pentachloride of antimony. According to Kolbe, a hot and concentrated mixture of sulphuric and nitric acids does not affect it. In the dark, dry chlorine is without action upon it. A mixture of 2 vols. of chlorine with 1 vol. of marsh-gas is not at first visibly affected by sunlight, but after a while it explodes. The passage of an electric spark also determines an explosion. If the gaseous mixture be diluted with carbonic anhydride, and then exposed to sunlight, a quiet chlorination takes place; and if excess of chlorine be there, chloroform and tetrachloride of carbon are produced (Dumas). Equal volumes of dry chlorine and marsh-gas exposed to diffused daylight, give a chlorinated product, having the formula CH_2Cl . It appears that this compound, CH_2Cl , if not identical with chloride of methyl, is very readily converted into it: for Berthelot has succeeded in obtaining methyl-compounds from it by double decomposition.

If moisture be present, chlorine converts marsh-gas into hydrochloric acid, carbonic acid, and carbonic oxide.

At a white heat, marsh-gas is resolved into carbon and hydrogen. The same change

is effected by the transmission of electric sparks, but the decomposition is never complete.

Carbon being a tetratomic element, marsh-gas is the normal hydride of carbon, and the type of a numerous class of compounds which are produced by replacement of more or less hydrogen by other radicles. Thus chloride of methyl is monochlorinated marsh-gas: Methyl-alcohol is marsh-gas wherein hydrogen has been replaced by peroxide of hydrogen: Formic acid is marsh-gas wherein some of the hydrogen has been replaced by oxygen and some by peroxide of hydrogen, *c. g.*—

When carbon makes a partial saturation of itself, as polyatomic elements occasionally do, and as carbon of all polyatomic elements is especially liable to do, there result complex carbon-groups requiring very various amounts of hydrogen for their saturation. When the carbon has adhered to itself with the least possible expenditure of saturating power, and when the complex carbon-group so resulting is fully saturated with hydrogen, there result certain hydrocarbons which form a very well characterised family—the marsh-gas family. The marsh-gases—homologues of marsh-gas—are characterised by their great neutrality, and present a uniformity of character which is most remarkable. J. A. W.

MARSH'S TEST FOR ARSENIC. See ARSENIC (i. 362).

MARTINSITE. A variety of common salt from Stassfurth, containing 10 pts. chloride of sodium to 1 pt. sulphate of magnesium. (Karsten, J. pr. Chem. xxxvi. 127.)

MARTITE. The octahedral form of native ferric oxide, found on the Puy de Dome; at Traumont; in Monroe County, New York; in Peru; and in Brazil. The crystals are regular octahedrons, often flattened, and having the octahedral faces striated parallel to the edges. Cleavage indistinct. Hardness = 6. Specific gravity = 4.82, Brazil; 4.65, Puy de Dome; 3.80, Peru (Breithaupt); 5.33, Monroe (Hunt). Lustre submetallic. Colour iron-black, sometimes with a bronze tarnish. Streak brown, or purplish-brown. Fracture conchoidal. Not magnetic.

MARTYLAMINE. Syn. with XENYLAMINE.

MARUM-CAMPHOR. A camphor or stearoptene existing in all parts of catthyme (*Thaenium Marum*). It is extracted by distilling the dry herb with water, and repeatedly cohobating the distillate over fresh quantities of the green herb. It is a white, crystalline, transparent, brittle mass, consisting of thin laminae, heavier than water, having an unpleasant odour and aromatic taste. (Bley, N. Trommsd. xiv. 2 and 87.)

MASCAGNINE. A sulphate of ammonium, $(\text{NH}_4)_2\text{SO}_4 \cdot 2\text{H}_2\text{O}$, occurring about volcanoes; it was discovered by Mascagni in the fissures of the lava at Etna, Vesuvius, and the Lipari Isles. It sometimes forms trimetric crystals in which $a : b : c = 0.731 : 1 : 1.129$. Angle $\infty P = \infty P = 107^\circ 40'$; $oP : P\infty = 122^\circ 56'$. Cleavage, perfect parallel to $\infty P\infty$; imperfect parallel to oP . Usually in mealy crusts and stalactitic forms. Hardness = 2.25. Specific gravity = 1.72 to 1.73. Lustre when crystallised vitreous. Colour yellowish-grey to lemon-yellow. Translucent. Tastes pungent and bitter. (Dana, ii. 379.)

MASOPIN. $\text{C}^{18}\text{H}^{18}\text{O}^2$. (Genth, Ann. Ch. Pharm. xli. 124.)—A resinous substance obtained from a material used in Mexico for chewing. This latter substance, which is said to be derived from a tree called *Dschilte*, growing abundantly in Mexico, forms crude porous lumps having a dull aspect, but presenting a bright surface when cut; it softens between the fingers, has little or no taste when chewed, but a distinct odour like that of rotten cheese. To extract the masopin, the dried juice is comminuted and exhausted by boiling with water; and the soft ropy residue is digested with absolute alcohol, which on cooling deposits masopin in crystalline flocks, a further quantity separating on addition of water. The portion of the juice insoluble in alcohol consists of caoutchouc.

Masopin is a snow-white, light, pulverulent substance, which becomes adhesive when passed between the fingers, has neither smell nor taste, is insoluble in water, but easily soluble in alcohol and in ether, and crystallises from the ethereal solution in white silky needles or frequently in tufts of small prisms. The crystals melt at 155° , emitting an agreeable odour, and the melted mass solidifies on cooling to a glassy,

brittle, yellow substance, having a conchoidal fracture, and melting again at 69° or 70° .

Masopin yields by distillation a brown viscid oily mass, having an acid reaction. If the acid be removed by digestion with ammoniacal water, and the remainder then rectified over slaked lime, a light-yellow mobile oil is obtained, having an agreeable odour of ginger, and containing 88.02 per cent. carbon, and 11.49 hydrogen. The acid which unites with the ammonia separates, on addition of hydrochloric acid, in nacereous crystals like boracic acid: it may be further purified by precipitation from solution in potash. It forms a dazzling-white silver-salt, which burns with an odour of cinnamon, and contains 45.49 per cent. silver oxide.

Masopin dissolves gradually in nitric acid, and the solution leaves on evaporation a viscid mass like melted sugar, which is soluble in water, ammonia, and potash, and when combined with the latter, forms dingy yellow precipitates with most metallic salts.

MASSICOT. Protoxide of lead prepared without fusion. See LEAD, OXIDES OF (p. 549).

MASOY-CAMPHOR AND OIL. Massey-bark, obtained from New Guinea, and said to be the bark of *Laurus Burmanni*, or of *Cinnamomum Kiamis* (Nees), contains a camphor or stearoptene, and two volatile oils. The camphor is heavier than water, soluble in alcohol, ether, and acetic acid, and coloured yellow by nitric acid. The heavier of the two oils sinks in water, becomes pasty at 10° , has a pungent taste, and is coloured deep red by nitric acid. The lighter oil is more volatile, has a stronger odour like that of sassafras, is lighter than water, dissolves easily in alcohol, ether, and acetic acid, and is coloured cherry-red by nitric acid. The two oils and the camphor are obtained from the bark by distillation with water. (Bonastre, J. Pharm. xv. 204.)

MASTERWORT, OIL OF. (Wackenroder, Br. Arch. xxxvii. 341.—Hirzel, J. pr. Chem. xlvii. 202.)—The root of masterwort (*Imperatoria Ostruthiana*) contains a volatile oil, which may be extracted by distilling the comminuted root with water. Part of it floats on the watery distillate; the rest may be obtained by agitation with ether and evaporation, and the whole purified by rectification with a small quantity of water and dehydration over chloride of calcium. The yield of oil is from 0.78 to 0.78 per cent.

This oil is transparent and colourless (Hirzel), pale yellow (Wackenroder), mobile (the portion which distils between 200° and 220° is more viscid). It boils between 170° and 220° ; has an aromatic odour (some what empyreumatic, between 200° and 220° according to Hirzel); penetrating (Wackenroder); its taste is strongly heating (Hirzel); camphorous like that of poppy-oil (Wackenroder). It burns with a bright fuliginous flame.

The portion which distils between 170° and 180° contains, according to Hirzel, 85.57 per cent. carbon, 11.45 hydrogen, and 2.98 oxygen; that which distils between 200° and 220° contains 81.43 carbon, 11.32 hydrogen, and 7.25 oxygen. The oil appears to be a mixture of several hydrates of a hydrocarbon isomeric with oil of turpentine, corresponding with the formula $4C^{10}H^{16}.H^2O$ and $3C^{10}H^{16}.2H^2O$. (Hirzel.)

It absorbs chlorine, with rise of temperature and evolution of hydrochloric acid gas, being thereby converted into a yellow viscid oil, which sinks in water, has a peculiar odour, and a biting taste. It is decomposed in like manner by bromine, with evolution of hydrobromic acid. By distillation with phosphoric anhydride it yields a transparent colourless oil, which has an odour of rosemary and an aromatic taste, and is isomeric with oil of turpentine. This latter oil absorbs hydrochloric acid gas, assuming a reddish-yellow colour, and forming, after complete saturation, rectification with water, and dehydration with chloride of calcium, an oil which has an agreeable odour, an aromatic taste, and a composition (74.98 C, 10.86 H, 13.28 Cl) agreeing with the formula $3C^{10}H^{16}.HCl$. (Hirzel.)

MASTIC. A resin obtained by incisions in the bark of the stem and branches of *Pistacia Lentiscus*, a tree growing in the islands of the Grecian Archipelago, especially in Chios. It forms small round transparent grains, having a faint agreeable odour, which becomes very distinct when the resin is thrown on red-hot coals. It softens when masticated, and is said to strengthen the gums. It is also used in fumigations, and in the composition of varnishes. Specific gravity = 1.074. According to Schrötter, its composition is $C^{10}H^{12}O^2$.

Aqueous alcohol dissolves the greater part of the resin, leaving masticin undissolved. The more soluble portion, which, according to Johnston, has the composition $C^{10}H^{12}O^2$, is precipitated from its solution by chlorine as a viscid mass. When heated for some time to 145° in the dry state, it is said to be resolved into two other resins, one containing a larger, the other a smaller proportion of oxygen.

MASTIC CEMENT. A building cement composed of finely-ground oolitic

limestone mixed with sand and litharge, and made into a loosely coherent paste with linseed-oil. (See CEMENTS, i. 820.)

MASTICIN. $C^{40}H^{51}O^2$, according to Johnston.—The constituent of mastic resin which is the least soluble in alcohol, amounting to $\frac{1}{12}$ — $\frac{1}{5}$ of the whole. It is white, soft at ordinary temperatures, but by prolonged drying and fusion becomes transparent, yellowish, and friable, and is said to be then more soluble in alcohol.

MATICIN. A bitter substance of unknown composition obtained from the leaves of the matico (*Piper asperifolium*), a plant growing in Peru. The leaves, which have a strongly aromatic and slightly astringent taste, are noted in Peru for their medicinal properties, and especially for their styptic power. When boiled with water, they yield a somewhat considerable quantity of a heavy volatile oil, while the maticin dissolves in the water, together with several other substances, from which it may be partly freed by precipitation with acetate of lead. The maticin then remains dissolved in the water, and may be obtained, by evaporation to a syrup, solution in alcohol, and evaporation of the alcoholic solution, as a yellow-brown extractive matter, having a disagreeable odour and extremely bitter taste. It is soluble in alcohol and in water, insoluble in ether. The aqueous solution is not precipitated by platine chloride, but forms a yellow precipitate with potash, and with ammonia. (Hodges, Phil. Mag. [3] xxv. 204; Mem. Chem. Soc. i. 123.)

MATICO, OIL OF. To obtain this oil, the leaves of *Piper asperifolium* are distilled with water, and the oil which slowly sinks to the bottom of the milky distillate is collected. Pale green, thickish; has a strong and persistent odour, and a persistent camphorous taste. By keeping, it becomes thicker and ultimately crystalline; by nitric acid, it is coloured amber-yellow and resinised. It dissolves in oil of vitriol, forming a carmine-coloured liquid which becomes milky on addition of water. It dissolves readily in alcohol and ether, not in aqueous potash or ammonia. (Hodges, loc. cit.)

MATLOCKITE. Oxychloride of lead, Pb^2Cl^2O , found at Matlock in Derbyshire (p. 335).

MATRICARIA CHAMOMILLA. *Wild chamomile.*—The flowers of this plant distilled with water, yield a volatile oil of a dark blue colour, and nearly opaque, with a strong odour of chamomile, and an aromatic burning taste. It is fluid at 12° , but thickens when cooled below 0° . (Gmelin's Handbook, xiv. 365.)

MATRICARIA PARTHENIUM. *Feverfew.*—This plant, while in the flowering state, yields by distillation with water a greenish oil, which begins to pass over between 165° and 220° , the largest portion, however, distilling between 205° and 220° . The oil consists of a hydrocarbon containing about 86 per cent. carbon and 11 hydrogen, a camphor having the same composition as that of the lauraceae, but possessing levorotatory power (see CAMPHOR, i. 729), and an oxygenated oil containing more oxygen than camphor. (Dessaignes and Chautard, J. Pharm. xiii. 251.—Chautard, Compt. rend. xxxvii. 166.)

MAULITE. Syn. with LARRADORITE (p. 450).

MAYNAS RESIN. *Calaba or Galba of the Antilles* (Lewy, Ann. Ch. Phys. [3] x. 380). A resin extracted by incision from *Calophyllum Calaba*, Jacq., a tree growing on the plains of San Martino and of the Oronoco. It possesses the usual external characters of resins, but when purified by solution in alcohol, it crystallises in small transparent prisms, and is obtained by slow crystallisation in very beautiful crystals of a fine yellow colour. According to Probst, they are monoclinic, exhibiting the combination ∞P . $\infty P\infty$. [$\infty P\infty$]. ∞P . + P . $P\infty$. [$P\infty$]. Angle ∞P : [$\infty P\infty$] = 119° ; ∞P : ∞P = $101^\circ 7'$; ∞P : [$P\infty$] = $143^\circ 15'$; ∞P : [$P\infty$] = about $98^\circ 45'$; $\infty P\infty$: $P\infty$ = $139^\circ 35'$; $\infty P\infty$: ∞P = $150^\circ 30'$. Ratio of axes a : b : c = 1.769 : 1 : 1.347. Angle of axes b and c = $78^\circ 43'$.

Maynas resin has the characters of an acid, dissolving readily, even at common temperatures, in potash, soda, and ammonia. It is insoluble in water, very soluble in alcohol, ether, and oils both fixed and volatile. Specific gravity = 1.12. It melts at about 105° to a transparent glass, and when once melted, remains liquid for a long time, not solidifying till cooled to about 90° . By dry distillation it yields empyreumatic oils, and leaves a carbonaceous residue. It contains, according to the mean of Lewy's analyses, 67.52 per cent. carbon and 7.30 hydrogen, whence Lewy deduces the formula $C^{67}H^{11}O^4$ (calc. 67.2 C, 7.2 H, and 25.6 O).

The resin dissolves in cold acetic acid, also in sulphuric acid, forming a solution of a fine red colour, from which it is precipitated by water in its original state. It is strongly acted upon by fuming nitric acid, yielding a non-crystallisable nitro-acid. With ordinary nitric acid it forms a volatile acid exhibiting the characters of butyric acid; the solution yields, by concentration, crystals of oxalic acid, as well as a liquid

acid, the nature of which has not been determined. The resin heated with a mixture of *acid chromate of potassium* and *sulphuric acid*, gives off carbonic anhydride and formic acid. Chlorine and bromine act upon it, but without yielding definite products.

MEADOW SAFFRON. *Gratiola officinalis* (ii. 942).

MEADOW-SWEET. See SPIRÆA.

MECHLOIC ACID. A crystalline acid produced, together with a chlorinated resin, by the action of chlorine on meconin. It contains 48.72 per cent. carbon, 4.07 hydrogen, no chlorine; crystallises in fine prismatic needles; is soluble in potash, sparingly soluble in cold, easily in boiling water.

MECONAMIC ACID. See MECONIC ACID, AMIDES OF.

MECONIC ACID. $C^H^4O^4 = \begin{matrix} C^H^4O^4 \\ H^4 \end{matrix} \} O^2$. *Mohnsäure. Opiumsäure.*—This acid, which is one of the constituents of opium, was discovered by Sertürner in 1805 (Gillb. Ann. lv. 72; lvii. 183; lxiv. 65), but the more exact investigation of it has been made chiefly by Robiquet (Ann. Ch. Phys. v. 282; li. 236; liii. 425), and Liebig (Ann. Ch. Pharm. vii. 37; xxvi. 113, 147).

The best method of preparing it is that of Robiquet, modified by Gregory (Ann. Ch. Pharm. xxiv. 43). Opium is exhausted with water at 38°; the extract is neutralised with coarsely pounded marble, evaporated to a syrup, and mixed with a concentrated solution of chloride of calcium, whereby the meconate of calcium is more completely separated in proportion as the liquids are more concentrated; and the precipitate is washed with water and pressed. [The mother-liquor serves for the preparation of morphine.]—1 pt. of the precipitated meconate of calcium is now suspended in a mixture of 3 pts. commercial hydrochloric acid and 20 pts. boiling water; the mixture is kept at a temperature short of 100°, and frequently shaken, till the whole is dissolved; and the acid meconate of calcium which separates on cooling is collected on linen, washed with a small quantity of water, and redissolved, after pressure, in a mixture of 3 pts. of hydrochloric acid and 20 pts. of hot water, avoiding ebullition. The liquid then yields, on cooling, crystals of meconic acid nearly free from lime, while the mother-liquor, in consequence of the excess of hydrochloric acid, contains scarcely any meconic acid. The still coloured crystals, after being washed and pressed, are dissolved in 16 pts. of hot water; the liquid is strained through linen; and the filtrate is mixed with two-thirds of the original quantity of hydrochloric acid; on cooling it yields crystals of meconic acid, free from lime, but still coloured. These crystals are suspended in cold water, neutralised with carbonate of potassium, and heated to 100° with gradual addition of water in quantity just sufficient to dissolve them; the solution, which solidifies on cooling, is well pressed (the liquid which runs off yields impure meconic acid when treated with excess of hydrochloric acid); the expressed mass, which is not yet quite white, is redissolved in the smallest possible quantity of boiling water; the solid mass obtained on cooling is again pressed; and this treatment is repeated till a pure white product is obtained. Lastly, this pure meconate of potassium is dissolved in 16 to 20 pts. of hot water; the acid meconate of potassium which separates on cooling is mixed on linen with a small quantity of cold water, pressed, and redissolved in 16 pts. of hot water; the solution is mixed with 2 or 3 pts. of hydrochloric acid; and the crystals of pure meconic acid which form on cooling are washed with cold water, and recrystallised from solution in the smallest possible quantity of boiling water. The mother-liquor expressed from the potassium-salt still yields a quantity of impure meconic acid when treated with hydrochloric acid. Paper-filters [probably on account of the iron contained in them] cannot be used in any part of the process.

How (Ann. Ch. Pharm. lxxxiii. 350) heats the crude acid free from lime with twice its weight of water, till the whole dissolves on addition of ammonia. The solution on cooling solidifies in a crystalline mass, which may be freed by pressure from the black mother-liquor, and recrystallised two or three times from the smallest possible quantity of boiling water. From the solution in hot water, the meconic acid separates, on addition of excess of hydrochloric acid, in colourless laminae, which are washed with cold water, and once recrystallised from boiling water.

The aqueous extract of opium might also be treated in the first instance with ammonia to precipitate the morphine, and the meconic acid afterwards precipitated by chloride of calcium; but ammonia always precipitates a certain quantity of meconic acid from the aqueous solution in the form of a calcium-salt: hence the process is attended with loss.

Meconic acid crystallises in micaceous scales or small rhombic prisms, containing 3 at. water ($C^H^4O^4.3H^2O$), which it gives off at 100°, leaving a white, opaque, effloresced mass. It has a sour taste, and reddens litmus strongly. It dissolves readily in water and alcohol, less easily in ether.

Meconic acid is resolved, under various circumstances, into carbonic anhydride and comenic acid:

the latter frequently undergoing further transformation:—1. When dry meconic acid is *heated* to about 120°, carbonic anhydride is given off and comenic acid remains behind; at higher temperatures, the comenic acid is further resolved, partly into carbonic anhydride and pyromeconic acid, $\text{C}^6\text{H}^4\text{O}^4$, partly into water, acetic acid, empyreumatic oil, and charcoal.—2. When meconic acid is boiled with *water*, or with *hydrochloric acid*, a brown colouring matter being also produced in the former case.—3. By the action of *chlorine* or *bromine*, in presence of water, the products being carbonic anhydride and chloro- or bromo-comenic acid.—4. By boiling with excess of *ammonia*, the comenic acid being then converted into comenamic acid.—5. By heating with *iodide of ethyl*, whereby carbonic anhydride is given off, and ethyl-comenic acid produced.

Meconic acid is easily oxidised by *nitric acid*, yielding a large quantity of oxalic acid.—By boiling with strong caustic *potash* also, it yields oxalic acid, together with carbonic anhydride and a brown substance.—By *chloride* or *bromide of iodine*, it is converted into iodomeconic, $\text{C}^6\text{H}^4\text{I}^2\text{O}^2$. [? impure iodoform; see p. 312.]

The aqueous solution of meconic acid is coloured deep red by *ferric chloride*, the colour not being destroyed by boiling, or by the action of dilute acids.

Meconates.—Meconic acid is tribasic, and forms three series of salts:

The dimetallic meconates are neutral to vegetable colours.

Meconates of Ammonium.—The *tri-ammoniac salt* is unknown. The *di-ammoniac salt*, $\text{C}^6\text{H}^4(\text{NH}^1)^2\text{O}^7$, crystallises in slender needles. On passing chlorine through its solution, the *mono-ammoniac salt*, $\text{C}^6\text{H}^4(\text{NH}^1)\text{O}^7 \cdot \text{H}^2\text{O}$, separates in granular crystals, sparingly soluble in cold water.

Meconates of Barium.—The *dibarytic salt* is sparingly soluble in water. Chloride of barium forms, with solutions of the alkaline meconates, white flakes soluble in acetic acid. Aqueous meconic acid forms with baryta-water a bulky yellow precipitate, probably consisting of *tribarytic meconate*.

Meconates of Calcium.—The *monocalcic salt*, $\text{C}^6\text{H}^4\text{Ca}^1\text{O}^7 \cdot 2\text{H}^2\text{O}$, is precipitated by chloride of calcium from aqueous meconic acid, and from the solutions of acid, and even of neutral meconates.—The *dicalcic salt*, $\text{C}^6\text{H}^4\text{Ca}^2\text{O}^7 \cdot \text{H}^2\text{O}$, is obtained as a yellow gelatinous precipitate, on adding chloride of calcium to the solution of a meconate saturated with ammonia.

Meconates of Copper.—The *monocupric salt* is obtained as a yellowish-green precipitate on adding meconic acid to a solution of cupric acetate. By dry distillation it yields a large quantity of pyromeconic acid. Meconate of potassium forms an emerald-green precipitate with cupric acetate.

Meconates of Iron.—*a*. The *ferrous salt* is very soluble, colourless, turns red on exposure to the air, and more quickly when mixed with *nitric acid*.

b. *Ferric salt*. Soluble meconates added to ferric salts produce, for the most part, a deep blood-red liquid, without precipitation, even *when* the solutions are concentrated; but when neutral ferric sulphate is treated with meconate of ammonium, a cinnabar-coloured pulverulent precipitate is formed after a while, which is sparingly soluble in cold water and in alcohol, easily in boiling water and in dilute acids. On mixing its aqueous solution with potash, ferric oxide is precipitated, ammonia is given off, and the red colour disappears; if hydrochloric acid be then added, sufficient to saturate the alkali, the red colour reappears, but is again destroyed by excess of acid. The red precipitate, if previously dried in the air at ordinary temperatures, undergoes no alteration at 100°. Stenhouse found in five samples of it, dried at 100°, from 30.4 to 31.1 per cent. carbon, 2.1 to 2.5 hydrogen, 3.4 to 3.5 nitrogen, and 22.6 to 24.3 ferric oxide. On mixing solutions of meconic acid and ferric chloride in anhydrous ether, red-brown flocks very soluble in cold water are precipitated. Stenhouse found in three preparations (at 100°) from 25.3 to 25.9 per cent. carbon, 1.7 to 1.9 hydrogen, and 30.3 to 31.2 ferric oxide.

Meconates of Lead.—The *neutral salt*, $\text{C}^6\text{H}^4\text{Pb}^1\text{O}^7 \cdot 2\text{H}^2\text{O}$, is produced by precipitating neutral acetate of lead with meconic acid, even in excess; it forms white flocks, insoluble even in boiling water.

Basic salts, containing from 68·4 to 78·4 per cent. lead-oxide, are obtained by precipitating basic acetate of lead with alkaline meconates.

Magnesium-salts.—The *dimagnesian salt* is sparingly, the monomagnesian salt easily soluble in water; the latter crystallises in shining, transparent, flattened needles, having an acid and bitter taste.

Meconates of Mercury.—Both the mercurous and mercuric salt are pale yellow flocculent precipitates, insoluble in water, soluble in nitric acid.

Meconates of Potassium.—The *acid salts* are crystallisable, the *neutral salt* uncrystallisable.

Meconates of Silver.—Aqueous meconic acid forms with nitrate of silver a white precipitate of the *di-argentic salt*, $C^2H^2Ag^2O^2$, which, by prolonged boiling with water, is converted into the *tri-argentic salt*, $C^2HAg^3O^2$. The latter is also formed, as a yellow precipitate, on mixing a solution of meconic acid, exactly saturated with ammonia (the di-ammoniac salt) with nitrate of silver.

Meconates of Sodium.—The *monosodic salt* forms hard grains, but slightly soluble in water. The *disodic salt*, obtained by digesting meconate of barium with aqueous sulphate of sodium, crystallises in slender needles, soluble in 5 pts. of water, and containing a large quantity of water of crystallisation. The *trisodic salt* is crystallisable, very soluble in water, and efflorescent.

Meconates of Tin.—The *stannous salt* is a white precipitate, very soluble in excess of the stannous solution. The *stannic salt* is also a white precipitate, sparingly soluble in acetic, easily in nitric acid.

Meconate of Yttrium.—Sparingly soluble in water; yttrium-salts, however, give no precipitate with meconic acid.

MECONIC ACID, AMIDES OF. By acting on ethyl-meconic acid and diethyl-meconic acid with ammonia, How has obtained two acids, which may be regarded as mono-ammoniac meconate *minus* water, viz.:

Neither of these acids has, however, been obtained in the crystalline form, and their formulae are somewhat doubtful. To the former How assigned the somewhat improbable formula $C^2H^2N^2O^6$; the formula above given was proposed by Gerhardt. (*Traité*, ii. 180.)

MECONIC ETHERS. Meconic acid, being tribasic, should form three ethers containing ethyl or other alcohol-radicles. Only the two acid ethyl-meconates are, however, at present known.

ETHYL-MECONIC ACID, $C^2H^2(C^2H^2)O^2$, is obtained by passing dry hydrochloric acid gas through a solution of meconic acid in absolute alcohol, till the liquid emits fumes. It then, if left at rest, deposits the ethylated acid in needle-shaped crystals, which may be purified by recrystallisation from hot water.

The acid forms small needles very soluble in boiling water, soluble in ether and in alcohol of ordinary strength, less soluble in absolute alcohol. The crystals are anhydrous, melt at 158°, and sublime in brilliant rhombs.

Ethyl-meconic acid is dibasic, forming two series of very stable salts, viz. *neutral salts*, $C^2HM^2(C^2H^2)O^2$, and *acid salts*, $C^2H^2M(C^2H^2)O^2$. They crystallise readily. (How, *Ann. Ch. Pharm.* lxxxiii. 350.)

DITHYL-MECONIC ACID, $C^2H^2(C^2H^2)^2O^2$, is contained in the mother-liquor from which ethyl-meconic acid has separated, and may be obtained by evaporating this liquid till it gives off acid vapours. The residue is a thick oil which solidifies on cooling, and may be purified by recrystallisation.

It forms flattened colourless prisms, melting at about 110°; it melts in boiling water before dissolving, and dissolves very easily in alcohol. Its aqueous solution has a strong acid reaction, decomposes carbonates, and rapidly coagulates albumin. It colours ferric salts red.

The acid is monobasic, the formula of its salts being $C^2HM(C^2H^2)O^2$. The *ammonium-salt* crystallises in yellow needles, and is very soluble in cold water. It is most easily prepared by passing gaseous ammonia into an alcoholic solution of the acid. The *barium-salt* is a yellow semi-gelatinous precipitate, insoluble in boiling water, but very soluble in excess of chloride of barium. The *strontium-* and *calcium-salts* resemble the barium-salt. The *magnesium-salt* is a crystalline precipitate. The *copper-salt* is green and gelatinous. The *lead-salt* is a yellowish-white precipitate. The *silver-salt* is yellow, gelatinous, insoluble in boiling water. (How, *loc. cit.*)

MECONIN. *Opianyl*. $C^2H^2O^2$.—A neutral substance existing in opium. It was first observed by Dublanc (*Ann. Ch. Phys.* [2] xlix. 17); afterwards prepared in the pure state, and examined by Couerbe (*ibid.* xlix. 11; l. 337; lix. 148).

It is produced from narcotine, together with teropiammone, cotarnine, opianic acid, and hemipinic acid, by the action of warm dilute nitric acid (Anderson, Ed. Phil. Trans. xx. 347; xxi. 204), and from opianic acid by the action of caustic alkalis, or of nascent hydrogen, evolved either by the action of sodium-amalgam on water, or of zinc on dilute sulphuric acid. (Matthiessen and Foster, Chem. Soc. J. xvi. 349.)

a. Action of alkalis:

B. Action of nascent hydrogen:

Preparation. a. *From Opium.*—1. Finely cut Smyrna opium is exhausted with cold water; the filtrate is evaporated to 8° Bm., and the morphine and narcotine are precipitated by dilute ammonia. The filtrate evaporated to a syrup, and then left for several weeks in a cool place, deposits brown crystals, which must be pressed and then dried at a gentle heat. The brown crystalline mass contains meconin, meconates, and other substances. It is exhausted with boiling alcohol of 36°, and the extracts are concentrated to one-third by distilling off the alcohol; the liquid then on cooling deposits crystals, which are purified by recrystallisation from boiling water, with addition of animal charcoal, then from hot ether. The mother-liquor from which the crystals have separated, yields an additional quantity of meconin by concentration. (Couverbe.)

2. The aqueous extract of opium is precipitated by chloride of calcium; the precipitated meconate of calcium is filtered; the filtrate evaporated to the crystallising point, and separated from the deposited hydrochlorate of morphine; and the dark mother-liquor is diluted with water, filtered from the flocks which separate, and treated with ammonia, which precipitates narcotine, thebaine, and a large quantity of resin. The filtrate is mixed with acetate of lead; the excess of lead is removed from the filtered liquid by dilute sulphuric acid; and the filtrate is neutralised with ammonia, and evaporated to the crystallising point at a moderate heat, whereupon narceine separates out, and then sal-ammoniac by further concentration. The mother-liquor is repeatedly digested with $\frac{1}{2}$ vol. ether at 26°, and the ether is distilled off from the extracts, a brown syrup then remaining. On treating this syrup with dilute hydrochloric acid, papaverine dissolves, and meconin remains in the form of a dark grey crystalline powder, which, to free it from resin and purify it completely, must be several times crystallised from boiling water, with addition of animal charcoal. (Anderson.)

b. *From Narcotine.*—Narcotine is heated in the water-bath to 49° with 2·8 pts. of nitric acid of specific gravity 1·4, and 8 pts. water, whereupon it melts into a yellowish mass, dissolves slowly without evolution of gas, if constantly stirred, and then gradually deposits crystalline teropiammone. The liquid is filtered through asbestos; the filtrate saturated with potash-ley; the solution again filtered from precipitated cotarnine, and concentrated to a small bulk; crystallised nitre is removed, and the mother-liquor freed from carbonate of potassium by precipitation with alcohol; the alcohol is distilled off; and the cooled residue treated with hydrochloric acid, which precipitates opianic acid, hemipinic acid, and meconin. If this precipitate be dissolved in a large quantity of boiling water, meconin crystallises out on cooling (mixed with a little opianic acid, if the quantity of water added was insufficient), and may be purified by recrystallisation from water or alcohol. (Anderson.)

c. *From Opianic acid.*—1. By the action of strong caustic potash. This mode of preparation is described under HEMIPINIC ACID (p. 142).—2. By the action of nascent hydrogen. Sodium-amalgam is warmed for several hours in an aqueous solution of opianic acid; and the meconin is precipitated from the solution by hydrochloric acid. The formation of the meconin in this case is not due to the action of the caustic soda formed from the sodium-amalgam: for it takes place in a dilute solution, and at a temperature very much below that at which opianic acid is decomposed under the influence of alkali; the quantity of meconin formed is also considerably greater than that which is produced under the latter circumstances, 5 grms. opianic acid decomposed by sodium-amalgam having yielded 3·65 grms. of pure meconin, whereas, according to the first of the two equations above given, it should, when decomposed by alkalis, yield only 2·3 grms. meconin. Moreover, opianic acid is similarly converted into meconin by the action of zinc and dilute sulphuric acid. (Matthiessen and Foster.)

Properties.—Meconin crystallises in hexagonal prisms with dihedral summits. It is perfectly colourless; has no smell; and appears tasteless at first, but exhibits a very acid taste as it dissolves in the mouth.

It melts at 90° (Couverbe); between 98° and 99° (M. and F.) to a colourless liquid, which retains its fluidity till cooled to 75°. At a higher temperature, it boils and distils without alteration, solidifying to a fatty mass on cooling.

A hydrate of meconin was once obtained by Anderson, in decomposing meconin

with nitric acid: it resembled the anhydrous compound, but was lighter, and did not melt below 96° .

Meconin dissolves in 265.7 pts. of cold, and 18.5 pts. of boiling water; in alcohol and ether it is still more soluble. It is dissolved by the fixed alkalis, but is nearly insoluble in ammonia. When heated to 100° with aqueous ammonia, it yields a solution which may be evaporated over sulphuric acid at ordinary temperatures, but from which meconin is precipitated on addition of water (Matthiessen and Foster).—Its aqueous solution precipitates basic acetate of lead, but not the neutral acetate.

Meconin dissolves without alteration in dilute sulphuric acid, forming a colourless solution which becomes dark green when evaporated: if alcohol be then added, the liquid acquires a rose colour; but as the alcohol evaporates, the green tint returns. The green solution deposits brown flocks when mixed with water (Couterbe). With strong sulphuric acid, meconin forms a colourless solution which becomes purple when heated, and brown on addition of water, depositing at the same time a brown precipitate, which dissolves with rose colour in alkalis. Nitric acid, either dilute or concentrated, converts meconin into nitromeconin, with evolution of red vapours. With peroxide of lead and dilute sulphuric acid, it gives off carbonic anhydride, and forms an amorphous substance which remains dissolved.

With chlorine, meconin forms chloromeconin (Anderson). According to Couterbe, chlorine acts but slightly on meconin at common temperatures, but is rapidly absorbed by melting meconin, forming a red and then a dark brown mass, which melts at a higher temperature than meconin, and forms on cooling a crystalline mass containing mecloic acid (p. 859), meconin-resin, and 25.5 per cent. chlorine. Meconin is not altered by iodine, but when heated with chloride of iodine, it forms iodomeconin. With bromine-water, it forms bromomeconin.

Meconin dissolves without alteration in cold hydrochloric acid; but when heated with three times its weight of strong hydrochloric acid to 100° in a sealed tube, it is decomposed, with formation of an acid containing $C^8H^8O^4$, and separation of chloride of methyl, which quickly volatilises when the tube is opened: $C^8H^8O^4 + HCl = C^8H^8O^4 + CH^3Cl$ (Matthiessen and Foster, unpublished experiments). A similar decomposition is produced by hydriodic acid. From these results Matthiessen and Foster conclude that meconin is a methylated compound; and although the proportion of methyl contained in it has not been experimentally determined, they infer, from the analogy of other derivatives of narcotine (q. v.) that its rational formula is $\left\{ \begin{array}{l} (C^8H^8O)^{''''} \\ (CH^3)^2 \end{array} \right\} O^2$; that is to say, that it is the dimethylated derivative of a compound, $\left\{ \begin{array}{l} (C^8H^8O)^{''''} \\ H^2 \end{array} \right\} O^2$, not yet isolated, which may be called normal meconin.

Substitution Derivatives of Meconin.

Bromomeconin. $C^8H^8BrO^4$.—When bromine-water is gradually added to aqueous meconin, crystals of bromomeconin separate out, and may be purified by recrystallisation from boiling alcohol. It forms colourless needles, which melt at 167° , and behave in other respects like chloromeconin. It dissolves sparingly in water, more readily in alcohol and ether. (Anderson, Ann. Ch. Pharm. xcviii. 48.)

Chloromeconin. $C^8H^8ClO^4$. When chlorine-gas is passed into a cold saturated aqueous solution of meconin, an abundant crop of crystals quickly separates, consisting of chloromeconin, which may be purified by recrystallisation from alcohol. It is likewise produced when dry chlorine-gas is passed over melted meconin. It crystallises in colourless needles, which melt at 175° , and sublime undecomposed at higher temperatures. It dissolves sparingly in cold, somewhat more freely in boiling water; in alkalis to about the same amount as in water, and without decomposition. It is soluble in alcohol and in ether.

It dissolves in cold sulphuric acid, assumes a greenish-blue colour when heated therewith, and on subsequent addition of water, deposits brown flocks which dissolve with red colour in alkalis. It dissolves with red colour in nitric acid, and is decomposed when heated therewith. (Anderson, Ann. Ch. Pharm. xcviii. 47.)

Iodomeconin. $C^8H^8IO^4$.—When chloride of iodine is added to aqueous meconin, and the mixture left to itself for several days in a warm place, long crystals form in it, contaminated by free iodine. They are purified by recrystallisation from boiling alcohol.

Iodomeconin forms colourless needles, which melt at 112° to a colourless liquid. It is nearly insoluble in water, more soluble in alcohol and ether. It melts at a temperature above 100° to a brown liquid, which decomposes at a stronger heat with volatilisation of iodine. It dissolves in sulphuric acid, forming a dark-coloured liquid when heated; and is decomposed by nitric acid, with separation of iodine. (Anderson, loc. cit.)

Nitromeconin. $C^8H^8NO^6 = C^8H^8(NO_2)O^4$. Meconin dissolves abundantly in

cold concentrated nitric acid, the solution giving off red fumes when heated. On diluting with water, bulky crystals separate, which may be obtained pure by washing and recrystallisation from boiling alcohol.

Nitromeconin forms white needles and prisms, melting at 160° to a transparent liquid, which solidifies in the crystalline form on cooling. It is neutral, dissolves sparingly in cold, somewhat more freely in boiling water; it is insoluble in *hydrochloric acid*, but dissolves in cold strong *nitric acid*, separating in flocks when the solution is diluted. In cold *ammonia* and *potash*, it is not more soluble than in water. It is not precipitated by metallic salts. It dissolves in boiling *alcohol* and *ether*.

Heated in small quantities on platinum-foil, it volatilises almost without decomposition, leaving only a small quantity of charcoal; but, if heated in a test-tube, it decomposes suddenly, and leaves a large quantity of porous charcoal. Boiled with *ammonia* or *potash*, it forms, without decomposition, a yellow solution which does not deposit anything on cooling or on addition of acids.

MECONIUM. A substance occurring in the intestinal canal of the fœtus, and voided soon after birth: it consists, in fact, of the bile of the fœtus, which is gradually poured into the intestines, and has there undergone a certain amount of alteration. It is a pitchy substance, of a dark brown-yellow colour, and the consistence of honey. Its odour is for the most part faint, and only occasionally unpleasant; taste mawkish, and slightly sweet. It stains linen permanently yellow. In water it swells up to a bulky mass, in which the microscope shows epithelium-cells, small round bodies, probably consisting of decolorised blood-corpuscles, and a considerable number of rhombic tablets of cholesterin. According to Simon, dried meconium contains 16 pts. cholesterin, 10.4 extractive matter and bile-resin, 34 casein, 6 pieromel, 4 biliverdin, 26 cells, mucus, and perhaps albumin (= 96.4). The cholesterin is extracted by ether, the extractive matter and bile-resin by alcohol. Aqueous alcohol takes up the casein together with pieromel; the biliverdin may be dissolved out by alcohol acidulated with sulphuric acid.

According to John Davy, meconium contains 72.7 pts. of water, 23.6 mucus and epithelium-cells, 7.0 cholesterin and margarin, and 3.0 olein and biliary colouring matters.

When burnt, it leaves an ash consisting chiefly of ferric oxide and magnesia, with traces of calcic phosphate and sodic chloride. According to Payen, it contains common salt, alkaline carbonate and calcic phosphate. (Handw. d. Chem. v. 143.)

MEDICAGO SATIVA. *Lucern*.—The composition of the ash of this plant, as determined by Way and Ogston, is given under FODDER (ii. 680).

MEDICINER, OIL OF. This oil, obtained by expression from the seeds of *Jatropha Curcas*, is white, scentless, has a density of 0.91 at 19° , and solidifies to a buttery mass at -8° . It is nearly insoluble in alcohol, has a sweet taste, and alters but very little on exposure to the air. It is not easily saponified by potash, but soda easily converts it into a hard white soap, containing oleic and isocetic acids. Nitric acid converts the oil into suberic acid: pernitric oxide does not solidify it completely. When heated with ammonia, in a sealed tube, it is converted into isocetamide.

MEDJIDITE. Calcio-uranic sulphate, occurring near Adrianople. (See SULPHATES.)

MEDULLIC ACID. $C^{21}H^{42}O^2$.—A fatty acid produced, together with oleic and palmitic acids, by the saponification of beef-marrow. It forms 10 per cent. of the acid mixture thus obtained. Melting point 72.5° . (Eylert's Arch. Pharm. [2] civ. 129.)

MEDULLIN. A name applied by Braconnot to cellulose obtained from the pith or medulla of certain plants.

MEERSCHAUM. (*Sea-foam*: from its apparent lightness and whitish colour.) A hydrated silicate of magnesium, $2MgO \cdot 3SiO_2 \cdot 2H_2O$, or $Mg_2Si_3O_8 \cdot 2H_2O$, occurring in stratified earthy or alluvial deposits on the plains of Eskihi-sheer, in Asia Minor; also in Greece, at Hrubtschitz in Moravia, and in Morocco. It is compact, smooth to the touch, and of fine earthy texture. Hardness = 2 to 2.5; impressible by the nail. It is opaque and white, sometimes with a greyish, yellowish, or reddish tinge. When heated in a tube, it gives off water, blackens, and emits a burnt smell. Before the blowpipe on charcoal it burns white, and melts on the thinnest edges. It dissolves readily in borax to a transparent glass, and exhibits a lilac colour with cobalt-solution. Hydrochloric acid dissolves it, with separation of silica.

Analyses.—1. by Lychenell (Kongl. Vetensk. Acad. Föreläsningar, 1826, p. 175); 2. By Damour (Ann. Ch. Phys. [3] vii. 316):

	SiO ^a	MgO	H ² O	F ² O ³	Al ² O ³	CaO	K ² O	Sand	
1. Asia Minor	60.87	27.80	11.29	0.09					= 100.05
2. Morocco	55.00	28.00	10.35	1.40	1.20	1.01	0.52	1.50	= 98.98

The formula above given requires 60.9 silica, 26.1 magnesia, and 12.0 water. In these analyses, the mineral was first dried over sulphuric acid to expel hygroscopic water (of which, being porous, it contains a considerable quantity), and the combined water was then driven off by heat. The mineral is often mixed with more or less carbonate of magnesium, by the decomposition of which it appears to have been produced. (J. L. Smith, *Sill. Am. J.* [2] vii. 286.)

MEILER. The German name for the heaps or stacks of timber piled up for burning into charcoal. (See *CARRON*, i. 760.)

MEIN. A body obtained by Reinsch from *Athamanta Meum*. The root, after exhaustion with hot water, is treated with alcohol of 70 per cent.; the alcohol is removed by distillation, and subsequent spontaneous evaporation; and the residue is digested with ether, which extracts the mein. On evaporating the ether, the mein remains as a thick, yellow, inodorous, combustible oil, having a burning taste, and not volatile without decomposition. (*Handwörterbuch*.)

MEGABROMITE. A variety of chlorobromide of silver from Chile, crystallised in cubes and octahedrons containing $\text{Ag}^*\text{Br}^*\text{Cl}^*$, or $4\text{AgCl} \cdot 5\text{AgBr}$. (See *SILVER*.)

MEIONITE. A calcio-aluminic silicate from Somma, where it occurs in small dimetric crystals, in geodes, usually in limestone blocks. Ratio of the principal to the secondary axes = 1 : 0.439. Angle P : P in the terminal edges = $136^\circ 11'$; in the lateral edges = $63^\circ 40'$; these angles are nearly the same as those of scapolite (*q. n.*). Observed combination $\infty\text{P} \infty$. $\infty\text{P} \cdot \text{P}$. $\infty\text{P}3$. $\text{P} \infty$. $3\text{P}3$. oP Sometimes hemihedral in the planes $3\text{P}3$, the alternate ones being wanting. Cleavage parallel to $\infty\text{P} \infty$ and ∞P , rather perfect, but often interrupted.

Hardness = 5.5 to 6. Specific gravity = 2.5 to 2.74. Lustre vitreous. Colourless to white. Transparent to translucent; often cracked within. Before the blowpipe it melts to a colourless glass; forms also a clear glass with soda. According to v. Rath, the mineral when pure, dissolves completely in moderately strong hydrochloric acid; but on heating or evaporating the solution, the silica separates in the pulverulent form. According to L. Gmelin and Kobell, it gelatinises with hydrochloric acid.

Analyses: a. L. Gmelin (*Schw. J.* xxv. 36; xxxv. 345).—b. Stromeyer (*Untersuchungen*, p. 378).—c. Wolff (*De compositione Ekebergitæ, Scapolithi et Meionitis, Dissertatio*, Berolini, 1843).—d. Rath (*Pogg. Ann.* lxxxii. 288).

	SiO_2	Al_2O_3	Fe_2O_3	FeO	CaO	MgO	Na_2O^*	K_2O	Loss by ignition.
a.	43.80	32.85	. .	1.07	20.64	. .	2.57	. .	= 100.93
b.	40.53	32.73	. .	0.18	24.24	. .	1.81	. .	= 99.19
c.	42.07	31.71	22.43	. .	0.45	0.31	= 97.28
d.	42.55	30.89	0.41	. .	21.41	0.83	1.25	0.93	0.19 = 98.46

* With some lithia.

These analyses lead to the formula $3(2\text{CaO} \cdot \text{SiO}_2) + 2(2\text{Al}_2\text{O}_3 \cdot 3\text{SiO}_2)$, or $\text{Ca}^*\text{Al}^*\text{Si}^*\text{O}^*$, which, substituting $\text{al} = \frac{1}{3}\text{Al}$, may be reduced to an orthosilicate, R^*SiO_4 . (Dana, ii. 200. —*Rammelsberg's Mineralchemie*, p. 714.)

MELACONITE. Native cupric oxide, found at Copper Harbour, Keweenaw Point, Lake Superior (ii. 68).

MELAIN. This name is given by Bizio to the black substance which is deposited, together with the carbonates of calcium and magnesium, when the dried residue of the so-called ink of cuttle-fish is stirred up with water. It is contained in a peculiar bladder which the animals eject on the approach of their enemies, to render the water opaque. It may be obtained pure by boiling the above-mentioned residue with water, then with alcohol, lastly with hydrochloric acid, and washing with water containing a little carbonate of ammonium. It is insoluble in water, alcohol, and ether, but remains suspended in water for a long time. It dissolves in strong nitric and sulphuric acids, not in hydrochloric or acetic acid. Strong caustic potash dissolves it, forming a dark brown liquid, which is precipitated by sulphuric and hydrochloric acids. It is not dissolved by alkaline carbonates. These characters are very similar to those of the black pigment of the eye. (*Handw. d. Chem.* v. 160.)

MELALEUCA LEUCODENDRON. The tree which yields cajuput-oil (i. 710.)

MELAM. $\text{C}^*\text{N}^*\text{H}^*$ or $\text{C}^*\text{N}^*\text{H}^*?$ (Liebig, *Ann. Ch. Pharm.* x. 10; liii. 240.—Knapp, *ibid.* xxi. 242.—Völkcl, *Pogg. Ann.* lxi. 367; lxxiii. 90.—Gerh. i. 464.)—A compound obtained as a residue when sulphocyanate of ammonium is heated. This salt decomposes at a temperature a little above the boiling-point of water, first giving

off ammonia, then sulphide of carbon in considerable quantity, and sulphide of ammonium, and leaving a residue which Liebig calls *rule melam*. On boiling this product with moderately strong potash-ley, till the greater part is dissolved, and leaving the filtered liquid to cool, melam is deposited in the form of a white granular powder. Instead of sulphocyanate of ammonium, Liebig finds it preferable to heat a mixture of equal parts sal-ammoniac and sulphocyanate of potassium, stirring constantly till no more vapours of sulphocyanate of ammonium are evolved, and sal-ammoniac begins to sublime. The mass is then exhausted with cold water, and the residue is dried and gently ignited.

Völckel prepares melam by heating sulphocyanate of ammonium in a retort, exhausting the residue with cold water, and then with boiling water. The first decoctions deposit a bulky matter; the last, on cooling, yield melam in the form of a white powder.

Melam is a white granular powder insoluble in cold water, also in alcohol and in ether. It yields by analysis the following numbers:

	Liebig.	Völckel.
Carbon	30.49	28.37
Hydrogen	3.94	4.77
Nitrogen	65.57	66.86
	100.00	100.00

Liebig deduces from his own analysis the formula $C^3N^4H^5$ (calc. 30.63 carbon and 3.8 hydrogen); according to which, melam may be regarded as hexcyanopentamide, $C^3N^3\{NH\}N^3$, or as a compound of 2 at. tricyanimide with 3 at. ammonia = $2C^3N^3\cdot 3H^3N$. Gerhardt, on the other hand, prefers the formula $C^3N^6H^4$, which agrees better with Völckel's analysis (calc. 28.57 carbon, 4.76 hydrogen, and 66.67), and represents melam as isomeric or polymeric with melamine or cyanuro-triamide, $Cy^3\{N^3\}$.

By prolonged boiling with caustic alkalis, melam is converted into melamine, which separates on evaporation or as the liquid cools. The mother-liquor contains ammeline, which may be precipitated by acids, together with ammelide; and the latter, by the continued action of the alkali, is ultimately resolved into ammonia and cyanuric acid. These changes may be represented by the following equations:

If Gerhardt's formula of melam be admitted, the formation of melamine is a case of mere polymeric transformation: according to Liebig's formula, on the other hand, the melamine is produced by assumption of ammonia eliminated in the formation of the other products above mentioned:

Melam is resolved by *heat* into ammonia and mellone or hydromellone (perhaps thus: $C^3N^4H^5 = 2NH^3 + C^3N^3H^4$). When boiled with dilute hydrochloric or sulphuric acid, or when treated with nitric acid, it yields ammeline; with concentrated sulphuric acid, the same, together with ammelide. By boiling with strong nitric acid, it is converted into cyanuric acid; and by fusion with hydrate of potassium, it forms cyanate of potassium.

According to Völckel, melam absorbs hydrochloric acid gas, forming the compound $C^3N^6H^4.HCl$.

MELAMINE. $C^3N^3H^4$.—Syn. with CYANURAMIDE (ii. 287).

MELAMPYRIN or **MELAMPYRITE.** Syn. with DULCITE (ii. 346).

MELANASPHALT. A kind of bituminous coal found in Nova Scotia.

MELANCHLOR. A blackish-green phosphate of iron from Rabenstein, containing in 100 pts. 38.9 per cent. ferric and 3.87 ferrous oxide, besides manganous oxide and 9 to 10 per cent. water. (Fuchs, J. pr. Chem. xvii. 171.)

MELANGLANCE. Native sulphide of silver. (See SILVER.)

MELANHYDRITE. A mineral found in the greywacke formed from decom-

posed basalt in the Schmelzerthal, near Honnef on the Rhine. It is deposited in the rock in amorphous nodular particles, of conchoidal fracture; opaque, with velvet-black, sometimes brownish-black colour, and blackish-brown streak; small lumps adhere to the tongue; it does not fall to pieces in water. Specific gravity = 1.820. Rammelsberg found in it:

SiO ²	Al ² O ³	Fe ² O ³	FeO	MnO	MgO	CaO	H ² O
41.63	18.72	2.36	7.83	2.51	5.23	1.67	30.71 = 100.66;

whence the formula $3\text{M}^{\circ}\text{O}.2\text{R}^{\circ}\text{O}^{\circ}.6\text{SiO}^{\circ}.12\text{H}^{\circ}\text{O}$, showing that the mineral is related in composition to palagonite. (Krantz, Jahresb. 1859, p. 795.)

MELANIC ACID. $\text{C}^{\circ}\text{H}^{\circ}\text{O}^{\circ}$. (Piria, Ann. Ch. Phys. [2] lxi. 281.)—A black substance produced, together with acetate of potassium, by the oxidation of salicylide of potassium. This compound, when exposed in a slightly moist state to the air, becomes covered with spots, which are green at first, but ultimately become quite black. This change does not take place in an atmosphere free from oxygen; but if the experiment be made under a bell-jar filled with oxygen, the whole of that gas is gradually absorbed, and no other gas is evolved.

The reaction may be represented by the following equation:

When the transformation is complete, a carbonaceous mass remains, from which water extracts acetate of potassium, while melanic acid remains undissolved in the form of a powder resembling lamp-black. It is tasteless, insoluble in water, very soluble in alcohol, ether, and alkaline liquids, and precipitated from the latter by acids. It decomposes alkaline carbonates.

Melanic acid gives by analysis 56.26 and 56.56 per cent. carbon, and 4.01 hydrogen: the formula $\text{C}^{\circ}\text{H}^{\circ}\text{O}^{\circ}$ requires 59.69 carbon, 3.84 hydrogen, and 38.47 oxygen.

A black substance having nearly the same composition is obtained by the action of alkalis on quinone.

Melanate of ammonium is obtained by digesting melanic acid with ammonia. *Melanate of silver* is a black precipitate containing 27.27 per cent. carbon, 1.95 hydrogen, and 48.00 silver.

MELANILINE. See ANILINE, DERIVATIVES OF, under PHENYLAMINES.

MELANIN. The black pigment of the eye (ii. 615).

MELANITE. A black calcio-ferrie garnet (ii. 772), found chiefly near Albano and Frascati, in the neighbourhood of Rome.

MELANOCARBIMIDE. $\text{C}^{\circ}\text{H}^{\circ}\text{N}^{\circ}\text{O}^{\circ}$.—A substance probably formed by the decomposition of melanoximide (q. v.).

MELANOCHIN. A doubtful product, formed, according to Brandes and Leber (Arch. Pharm. xv. 259), together with several others, by the action of ammonia and chlorine upon quinine (q. v.).

MELANOCHROITE. A basic chromate of lead, $\text{PbO}.4\text{PbCrO}^{\circ}$, found at Bereasof in the Ural (i. 934).

MELANOGLALLIC ACID. Syn. with METAGALLIC ACID.

MELANOLITE. A mineral having the aspect of chlorite, from Milk Row Quarry, near Charlestown, Massachusetts. It is black and opaque, with a striated surface, and somewhat columnar structure. Streak dark olive-green. Hardness = 2. Specific gravity = 2.69. According to H. Wurtz, it contains 30.86 per cent. silica, 3.92 alumina, 20.25 ferric oxide, 21.97 ferrous oxide, 1.62 soda, and 8.04 water, with 12.77 carbonate of calcium = 100.33. This composition, deducting the calcic carbonate, may be represented by the formula $2(\text{MO.SiO}^{\circ}).\text{R}^{\circ}\text{O}^{\circ}.\text{SiO}^{\circ} + 3\text{H}^{\circ}\text{O}$; but the mineral is perhaps not of constant composition (Dana, ii. 288). Rammelsberg (*Mineralchemie*, p. 539) observes that it is near Hisingerite.

MELANOXIMIDE. $\text{C}^{\circ}\text{H}^{\circ}\text{N}^{\circ}\text{O}^{\circ}$.—A product of the decomposition of cyanomelaniline. (See MELANILINE, under PHENYLAMINES.)

MELANTHERITE. Native ferrous sulphate. (See SULPHATES.)

MELANTURENIC ACID. See CYANURIC ACIDS (ii. 287).

MELAPHYRE. The name given by Von Buch to a porphyritic rock, consisting of a black or blackish-grey matrix of labrador and augite, in which are imbedded crystals of the same minerals, and sometimes, as accessory constituents, uniaxial mica, hornblende, and iron pyrites. It sometimes has the structure of almond-stone, with

spherical and almond-shaped nodules of calcespar, zeolites, &c. *Melaphyre* occurs in the Alps, especially in the Fassa valley, and near Klausen, in the Tyrol; also in the Lower Rhine, on the Fichtelgebirge; at Friedrischrode, in the Thüringer Wald; and at Holmestrand, in South Norway.

MELASSIC ACID. A black acid, produced, together with glucic acid (ii. 848), by heating glucose with caustic alkalis. When glucose is melted at 100° , and a hot saturated solution of baryta is added, a very violent action takes place, giving rise in the first instance to the formation of glucic acid; but if the mixture be exposed for some time to a high temperature, it becomes continually darker in colour, in consequence of the formation of melassic acid. On dissolving the residue in water and precipitating by hydrochloric acid, melassic acid is deposited in black flocks insoluble in water, but soluble in alcohol. It contains, according to Peligot's analysis, 61.9 to 61.0 per cent. carbon, and 5.3 to 5.4 hydrogen. The formula $C^{12}H^{10}O^3$, requiring 61.9 carbon, 4.3 hydrogen, and 33.8 oxygen, agrees with these results so far as the carbon is concerned; but the amount of hydrogen found by experiment is too large for it.

MELENE. $C^{10}H^{10}$. *Paraffin of Wax.* (Ettling, Ann. Ch. Pharm. ii. 252.—Lewy, Ann. Ch. Phys. [3] v. 395.—Brodie, Ann. Ch. Pharm. lxxi. 156.)—A substance homologous with ethylene, &c., produced by the dry distillation of hydrate of myricyl and of myricin. It may be prepared by subjecting bees'-wax to dry distillation, treating the product with potash, to saponify the fatty acid formed at the same time; decanting the soap from the mixture of melene and oily hydrocarbons; and distilling this mixture, which then gives off, first, the oily hydrocarbons, and, lastly, the melene, when the heat is considerably increased. The product is purified by pressure and recrystallisation from boiling ether. It is generally necessary, however, before crystallising it, to rectify it over caustic potash, in order to remove a small quantity of an oxygenated substance with which it is still contaminated.

Melene crystallises in perfectly white nacreous scales, inodorous and tasteless, of specific gravity 0.89. It melts at 62° (Brodie), at 33.5° (Ettling), at 47.8° (Lewy), and solidifies in a waxy mass on cooling. Boils between 370° and 380° . Vapour-density, by three experiments, between 10.0 and 11.8: the determinations were, however, rendered inaccurate by partial decomposition. It is insoluble in water and in cold alcohol, but dissolves in boiling alcohol, and easily in ether, and in oils both fixed and volatile.

Melene is not attacked by *potash* or *soda*, even at the boiling heat. *Sulphuric acid* does not attack it at ordinary temperatures; but on applying heat, part of the melene is carbonised, while the rest sublimes. It is but slightly attacked by boiling *nitric acid*. *Chlorine* attacks it, producing, under certain circumstances, a body containing a considerable amount of chlorine.

Related to melene are the several mineral tallowes, distinguished as *fichtelite*, *hartite*, *hutchin*, *ixolyte*, *kœnigite*, *ozokerite*, *schererite*, &c.

MELENE, SULPHIDE OF. This name was applied by Vöckel to a sulphuretted residue obtained, together with others (called respectively *sulphide of alphen*, *zanthene*, *zuthene*, &c.), by the action of heat on persulphocyanic acid. These residues are yellow or brown powders varying in composition according to the degree of heat applied, and are probably mere mixtures. (See Gmelin's *Handbook*, ix. 394.)

MELETIN. This name is given by W. Stein (J. pr. Chem. lxxxv. 351) to the substance produced, together with glucose, by the action of acids on rutin. This substance, according to most authorities, is identical with quercetin, $C^{12}H^{16}O^{10}$; but, according to Stein, it differs from quercetin, and has the composition $C^{12}H^{14}O^9$. It forms yellow crystals which act on polarised light, and reduce potassio-cupric tartrate. (See QUERCETIN and RUTIN.)

MELIN. See RUTIN.

MELINOPHANE. A mineral from the zircon-syenite of Norway, nearly related to leucophane. The crystals are optically uniaxial, but it has not been determined whether they are dimetric or hexagonal. It also occurs massive, with a scaly and sometimes foliated structure; cleavable in one direction. Hardness = 5. Specific gravity = 3.0. Lustre vitreous. Colour, sulphur-, citron-, or honey-yellow. Not phosphorescent. Brittle. It contains, according to an approximate analysis by Richter, 44.8 per cent. silica, 2.2 glucina, 12.4 alumina, 1.4 manganic oxide, 1.1 ferric oxide, 31.5 lime, 0.2 magnesia, 2.6 soda, 2.3 fluorine, and 0.3 nickel-oxide, zirconia, ceric oxide, and yttria.

MELEZITOSE. $C^{12}H^{20}O^{11}$.—A kind of sugar discovered in the manna of Briançon (p. 822) by Bonastre, and further investigated by Berthelot (Ann. Ch. Phys. [3] lv. 282). The extract of this substance prepared with boiling alcohol deposits

melizitose after being evaporated to a syrup, and left to stand for several weeks; the product may be purified by recrystallisation from boiling alcohol.

Melizitose forms very small, short, hard, shining crystals, resembling those of cane-sugar under the microscope, white and mealy when seen in mass; it effloresces readily when exposed to the air, and gives off 4 per cent. of water when heated; melts below 140° without further alteration, and solidifies to a glass on cooling. It is about as sweet as glucose. Dextro-rotatory; for the transition-tint, $[\alpha] = 94.1^{\circ}$ for $C^{12}H^{11}O^{11}$.

It dissolves readily in water, and is precipitated by an ammoniacal solution of neutral acetate of lead. It is nearly insoluble in cold, slightly soluble in boiling alcohol, quite insoluble in ether. Absolute alcohol precipitates it from the aqueous solution.

Melizitose decomposes at about 200° . It is carbonised by cold strong sulphuric acid, quickly turns brown with boiling hydrochloric acid, and forms oxalic acid with nitric acid. By an hour's boiling with dilute sulphuric acid, it is converted into glucose. In contact with yeast, it passes slowly, or sometimes not at all, into vinous fermentation. It is not altered at 100° by aqueous alkalis, and scarcely by potassio-cupric tartrate.

MELILOT-CAMPHOR. See COUMARIN (ii. 93).

MELINUM. Syn. with CADMIUM.

MELISSA, OIL OF. A volatile oil contained in balm (*Melissa officinalis*), most abundantly at the flowering time, and obtained from it by distillation with water. It is colourless or pale-yellow; of specific gravity 0.85 to 0.82; has a peculiar odour; reddens litmus slightly. According to Bizio (Brugn. Giorn. xix. 360), it contains a camphor in solution. It dissolves in 5 to 6 pts. of alcohol of specific gravity 0.856. It dissolves iodine, with great rise of temperature and evolution of vapour, and becomes viscid. With nitric acid, it turns brown, gives off a large quantity of gas when heated, and becomes resinous. (Zeller, *Stud. über äther. Oele*, Landau, 1850.)

MELISSIC ACID. $C^{30}H^{60}O^8 = \frac{C^{30}H^{58}O^8}{H} \} O$. — (Brodie, Ann. Ch. Pharm.

lxxi. 156.)—A fatty acid obtained by treating hydrate of myricyl (melissic alcohol) with potash-lime. It bears considerable resemblance to cerotic acid (i. 836), but melts at a higher temperature, viz. at 88° or 89° . According to Brodie's analysis, it contains 79.19 to 79.97 per cent. carbon, and 13.00 to 13.63 hydrogen (calc. 79.64 carbon, 13.27 hydrogen, and 7.09 oxygen). The silver salt, $C^{30}H^{58}AgO^2$, is a white precipitate containing 19.30 to 19.74 per cent. silver (calc. 19.30).

MELISSIN. Syn. with MELISSIC ALCOHOL, or HYDRATE OF MYRICYL. (See MYRICYL.

MELITOSE. $C^{12}H^{22}O^{11}$.—A kind of sugar obtained from the manna which falls in opaque drops from various species of *Eucalyptus* growing in Tasmania. It was first recognised as a distinct substance by Johnston (Mem. Chem. Soc. i. 159), more fully examined by Berthelot (Ann. Ch. Phys. [3] xlvii. 66, — *Chimie organique*, Par. 1860, ii. 260). It is extracted from the manna by water, and crystallises in extremely thin interlaced needles, having a slightly saccharine taste.

The crystals of melitose are hydrated, containing $C^{12}H^{22}O^{11}.3H^2O$. They give off 2 at. water at 100° , and become anhydrous at 130° . They dissolve in 9 pts. of cold water, very easily in boiling water, and dissolve also in boiling alcohol more freely than mannite. The alcoholic solution yields small but well-developed crystals. The aqueous solution turns the plane of polarisation to the right: for the transition-tint $[\alpha] = +102^{\circ}$.

Melitose heated with dilute sulphuric acid is resolved into a fermentable sugar (probably dextro-glucose), and non-fermentable eucalyn (ii. 601):

Melitose ferments in contact with yeast, but it is resolved, in the first instance, into glucose and eucalyn: consequently, since the latter is unfermentable, the quantities of alcohol and carbonic anhydride obtained from it are only half of those which would be yielded by an equal quantity of glucose. It does not reduce an alkaline cupric solution, and is not altered by boiling with dilute alkalis or with baryta-water. It is oxidised by nitric acid, yielding a certain quantity of mucic acid, together with a large quantity of oxalic acid.

MELLAMIC ACID. Syn. with EUCHROIC ACID (ii. 601).

MELLAN. Syn. with MELLONE.

MELLIC ACID. Syn. with MELLITIC ACID.

MELLILITE.—Humboldtite. Somervillite. Zurlite.—A silicate occurring on

Vesuvius and at Capo di Bove, near Rome, in dimetric crystals, in which the principal is to the secondary axes as 0.6432 : 1. Observed combination $\alpha P : \infty P : \infty P \infty P$. Angle $\alpha P : P \infty = 147^\circ 15'$; $P \infty : P \infty$ (over $\infty P \infty$) = $65^\circ 30'$; $P \infty : P \infty$ (over terminal edge) = $134^\circ 48'$. Cleavage basal, distinct. Hardness = 5. Specific gravity = 2.9 to 3.104. The crystals are brown or yellow, with vitreous lustre, generally translucent, sometimes opaque. Fracture conchoidal to uneven. Before the blowpipe it fuses with difficulty to a yellowish or black glass. Gives, with fluxes, the reactions of iron and silica. Gelatinises with acids.

Analyses.—*a. Humboldtite*, from Somma, by Kobell (Schw. J. lxiv. 293).—*b. The same by Damour* (Ann. Ch. Phys. [3] x. 59).—*c, d. Mellite*, from Cape di Bove, by Damour (*loc. cit.*).

	SiO ²	Al ² O ³	Fe ² O ³	FeO	CaO	MgO	Na ² O	K ² O	
<i>a.</i>	43.96	11.20	.	2.32	31.96	6.10	4.28	0.38	= 100.20
<i>b.</i>	40.60	10.88	4.43	.	31.81	4.54	4.43	0.36	= 98.05
<i>c.</i>	39.27	6.42	10.17	.	32.47	6.44	1.95	1.46	= 98.18
<i>d.</i>	38.34	8.61	10.02	.	32.05	6.71	2.12	1.51	= 99.36

These analyses may be approximately represented by the formula $6(2\text{CaO} \cdot \text{SiO}_2) + 2(\text{Al}_2\text{O}_3 \cdot \text{Fe}_2\text{O}_3) \cdot 3\text{SiO}_2$, which is that of an orthosilicate, the calcium being partly replaced by magnesium, sodium, and potassium.

Massive Gehlenite, which contains, according to Kobell (Kastn. Arch., iv. 313), 39.80 per cent. silica, 12.80 alumina, 2.57 ferric oxide, 37.64 lime, 4.64 magnesia, 0.30 potash, and 2.00 water, may be included in the same general formula.

Sonervillite, occurring on Vesuvius in dull yellow crystals, has the angles of this species. (Desclouzeaux.)

MELLIMIDE. Syn. with MELLITIMIDE.

MELLITAMIC ACID. See MELLITIC ACID, AMIDES OF.

MELLITE, or *Honeystone*.—Native mellitate of aluminium (p. 871).

MELLITIMIDE. See MELLITIC ACID, AMIDES OF.

MELLITIC ACID. $\text{C}^{12}\text{H}^6\text{O}^{12} = \left\{ \begin{matrix} (\text{C}^{12}\text{O}^6)^{+1} \\ \text{H}^6 \end{matrix} \right\} \text{O}^6$. *Mellie acid, Mellithsäure, Honigsteinsäure.* (Gm. x. 1.—Gerh. iii. 822.—Bayer, Ann. Ch. Pharm. Suppl. vi. 1.)—This acid, which was discovered by Klaproth in 1799, occurs as mellitate of aluminium, in honeystone or mellite, which is the only known source of it. There is a statement by Hünefeld (Schw. J., xlix. 215), that it may be produced by treating amber with hot hydrochloric acid; but it has not been confirmed.

To prepare it, powdered honeystone is treated with solution of carbonate of ammonium, the liquid is boiled till the excess of the ammonium-salt is expelled; caustic ammonia is added to precipitate any alumina that may have been dissolved; the liquid is filtered and evaporated till neutral mellitate of ammonium crystallises out; and this salt is purified by recrystallisation from water, a small quantity of ammonia being each time added, to reconvert the acid salt produced by evaporation of the ammonia into the crystallisable neutral salt. The purified ammoniacal salt is finally dissolved in water; the solution precipitated with acetate of lead or nitrate of silver; the washed precipitate decomposed by sulphydric acid if it contains lead, or by hydrochloric acid if it contains silver; and the liquid filtered and evaporated, whereby the excess of hydrochloric acid is expelled. (Wöhler, Ann. Ch. Pharm. xxxvii. 263.)

The lead-precipitate contains ammonia, which is transferred to the separated acid. Either, therefore, the acid must be re-precipitated with acetate of lead; the precipitate, which still contains a small quantity of ammonia, washed and again decomposed with sulphydric acid; and the acid thus liberated precipitated a third time with hydrochloric acid, in order to obtain a precipitate free from ammonia, and thence to separate the pure acid by sulphydric acid;—or the ammonium-salt must be boiled with excess of baryta-water; the resulting barium-salt decomposed by digestion with dilute sulphuric acid; the liquid filtered and evaporated till it crystallises; and the crystals freed from adhering sulphuric acid by recrystallisation. (Erdmann and Marchand.)

To prepare colourless mellitic acid from the brown acid mother-liquor obtained in the preparation of mellitate of ammonium, the colouring matter may be precipitated by chloride of barium; the mellitate of barium thrown down from the filtrate by ammonia, or by boiling with acetate of ammonium, and converted into mellitate of ammonium by digestion with carbonate of ammonium;—or the brown mother-liquor may be precipitated by a strong solution of sulphate of copper, and the crystallised mellitate of copper decomposed by sulphhydrate of ammonium.—In precipitating the purified ammonium-salt by nitrate of silver, it is necessary to drop the former into an excess of the latter; otherwise the precipitate will retain ammonia. (Schwarz.)

Mellitic acid, as obtained by evaporation, is a white powder exhibiting scarcely any appearance of crystalline structure; as crystallised from solution in cold alcohol by spontaneous evaporation, it forms delicate, silky needles, united in stellate groups. It dissolves readily in water and in alcohol. It is fusible by heat, tastes strongly acid, and is permanent in the air. (Wöhler.)

The crystallised acid does not give off water at 100°, but at a higher temperature it sublimes partly unaltered: the greater portion is however decomposed, with separation of charcoal. According to Erdmann (J. pr. Chem. lii. 432), the sublimate obtained by heating mellitic acid consists of pyromellitic acid, $C^{10}H^4O^8$, which melts in the neck of the retort, and solidifies in a radiated crystalline mass. Mellitic acid, when heated in the air, burns with a bright sooty flame, leaving a large quantity of charcoal, which afterwards burns completely away. It is not decomposed by boiling nitric or sulphuric acid, but the latter dissolves it.

Mellitates.—Mellitic acid, formerly regarded as a dibasic acid ($C^6H^4O^4$), has recently been shown by Bayer to be sexbasic. The mellitates are decomposed by heat, yielding a large quantity of charcoal, and a small quantity of products containing hydrogen. When slowly distilled with sulphuric acid, they yield pyromellitic acid, together with carbonic oxide, carbonic anhydride, and, towards the end, sulphurous anhydride.

The mellitates of ammonium, potassium, and sodium dissolve readily in water. The zinc- and manganese-salts dissolve more readily in cold than in hot water. The rest are insoluble or sparingly soluble in water.

Mellitate of Aluminium, $Al^2O^3.C^{12}O^8.18H^2O = C^{12}(Al^2)^4O^{12}.18H^2O$.—This compound occurs native as *mellite* or *honeystone*, in lignite, at Asten in Thuringia, near Bilin in Bohemia, and near Walchau in Moravia, both crystallised and in massive nodules. The crystals are dimetric, exhibiting the combination $P. \infty P. oP. P. \&c.$, the P -faces usually predominating. Length of principal axis = 0.7453. Angle $P : P$ (terminal) = $118^\circ 4'$; $P : \infty P$ (lateral) = $93^\circ 22'$; $P : \infty P = 120^\circ 58'$. Cleavage imperfect, parallel to P . Hardness = 2 to 2.5. Specific gravity 1.55 to 1.642. Lustre resinous, inclining to vitreous. Colour honey-yellow, sometimes reddish or brownish; rarely white. Streak white. Transparent to translucent, and with strong double refraction. Fracture conchoidal. Sectile.

The crystals contain 14.5 per cent. alumina and 44.1 per cent. water of crystallisation, which is driven off at a temperature near the boiling-point of sulphuric acid. Caustic alkalis decompose them, setting the alumina free. They are dissolved by nitric acid, and separate from the solution without change of form or constitution.

Native honeystone contains a small quantity of a yellow resin, to which it owes its colour, and probably also its odour.

Mellitate of potassium, added to a solution of alum, forms a crystalline precipitate containing 9.5 per cent. alumina and 48.0 per cent. water; probably an acid salt. (Wöhler.)

Mellitates of Ammonium.—The neutral salt, $C^{12}(NH^4)^6O^{12}.9H^2O$, forms large shining transparent crystals, having a slight acid reaction. They exhibit two forms, probably with different amounts of water, both belonging to the trimetric system, but differing considerably in the angles.

The crystals α are derived from an octahedron whose axes are to one another as $\sqrt{3} : 290 : \sqrt{7} : 881 : 1$. Observed combination $oP. \infty P. \infty \bar{P} \infty. \bar{P} \infty. \bar{P} \infty$. Angle $oP : \bar{P} \infty = 161^\circ 8'$; $oP : \bar{P} \infty = 160^\circ 24'$; $\infty P : \infty \bar{P} = 144^\circ 16'$; $\infty P : \infty \bar{P} \infty = 122^\circ 0'$. The faces $\infty \bar{P} \infty$ are longitudinally striated. No cleavage parallel to oP .

The crystals β are derived from an octahedron whose axes are to one another as $\sqrt{2} : 676 : \sqrt{7} : 923 : 1$. Observed combination $oP. P. \infty P. \infty \bar{P} \infty$. Angle $oP : P = 144^\circ 44'$; $P : P = 146^\circ 17'$; $P : \infty P = 125^\circ 16'$; $\infty P : \infty P = 119^\circ 41'$; $\infty P : \infty \bar{P} \infty = 120^\circ 9\frac{1}{2}'$. Cleavage parallel to oP .

The crystals give off 24.1 per cent. water (1 at.) at 100°, and at 150° decomposition takes place, with evolution of large quantities of ammonia and water, and formation of paramide and euchroate of ammonium:

Mellitate of ammonium. Paramide.

Mellitate of ammonium. Euchroate of ammonium.

The acid salt, $C^{12}H^2(NH^4)^2O^{12}.4H^2O$, is obtained by decomposing ammonio-cuprie mellitate with sulphydric acid. It crystallises in trimetric prisms, having their lateral edges truncated. Observed combination $oP. \infty P. \infty \bar{P} \infty. \infty \bar{P} \infty$. Angle $oP : \infty \bar{P} \infty = 122^\circ$.

Mellitate of Barium, $C^{12}(Ba^2)^4O^{12}.3H^2O$, obtained by double decomposition, is a white gelatinous precipitate, which after a while crystallises in scales, or, if the solution is Vol. III.

from which it was formed were very dilute, in needles. Mellitic acid added to chloride of barium forms, after a few seconds, a precipitate composed of needle-shaped crystals.

Mellitate of Calcium is obtained on mixing mellitate of ammonium with chloride of calcium, as an amorphous precipitate, which soon becomes crystalline. Mellitic acid added to lime-water throws down white flocks soluble in hydrochloric acid.

Mellitate of Cobalt, $C^{12}(Co'')^3O^{12}.18H^2O$, crystallises from solution in boiling water in microscopic prisms.

Mellitates of Copper.—The neutral salt, $C^{12}(Cu'')^2O^{12}.12H^2O$, is produced as an amorphous precipitate, becoming crystalline after a while, on mixing boiling solutions of mellitic acid and cupric acetate. On mixing cold solutions of mellitic acid and cupric acetate, there is deposited an acid salt, $C^{12}H^2(Cu'')^2O^{12}.12H^2O$, which also becomes crystalline. On adding a solution of cupric sulphate to a salt of mellitate of ammonium, a crystalline precipitate is formed consisting of ammonio-cupric mellitate, $C^{12}(NH^1)^2(Cu'')^2O^{12}.12H^2O$.

Mellitates of Iron.—The ferric salt is a cream-coloured precipitate, soluble in hydrochloric acid.—*Ferrous salts*. Mellitate of ammonium forms with ferrous sulphate a greenish-white precipitate, which redissolves when the liquid is warmed; but on raising the temperature to the boiling point, a basic salt, $3Fe''O.C^{12}(Fe'')^3O^{12}.9H^2O$, is precipitated in microscopic cubo-octahedrons of a lemon-yellow colour; very sparingly soluble in water, easily soluble in hydrochloric acid; assuming an olive-green colour when dry; and giving off all their water of crystallisation at 190° .

Mellitate of Lead. $C^{12}(Pb'')^3O^{12}$ (at 180°).—Bulky white precipitate, soluble in nitric acid; obtained by adding the acid or the ammonium-salt to acetate or nitrate of lead.

Mellitate of Magnesium. $C^{12}(Mg'')^3O^{12}.18H^2O$.—Precipitated on adding carbonate of magnesium to a hot aqueous solution of mellitic acid, as an oil which solidifies to a crystalline mass on cooling.

Mellitate of Manganese. $C^{12}(Mn'')^3O^{12}.18H^2O$.—Obtained in like manner. White powder, composed of microscopic needles; more soluble in cold than in boiling water, which dissolves only $\frac{1}{800}$ of it.

Mellitates of Mercury.—The mercuric salt, $C^{12}(Hg'')^2O^{12}.6H^2O$ (at 100°), is obtained as a white granular mass by triturating mercuric oxide with mellitic acid and a small quantity of water, or by precipitating an alkaline mellitate with mercuric nitrate.

The mercurous salt, $C^{12}(Hg'')^2O^{12}.6H^2O$ (at 100°), is also obtained by precipitation, as a white granular precipitate, very soluble in nitric acid, becoming anhydrous at 190° .

Mellitate of Nickel, $C^{12}(Ni'')^3O^{12}.24H^2O$.—When a hot solution of mellitic acid is saturated with carbonate of nickel, a green semi-fluid mass separates, which hardens and becomes vitreous in contact with the air. This salt is very slightly soluble in water, very freely in dilute hydrochloric and nitric acids. It gives off half its water (4 at.) at 100° , and the rest at 300° .

Mellitates of Palladium.—Mellitic acid is perfectly neutralised by oxide of palladium; but the liquid does not yield any crystals, even when concentrated to a syrup; but on evaporation to dryness, it leaves a brown amorphous residue of palladious mellitate. This salt dissolves in ammonia, forming a colourless liquid, which, on evaporation, deposits colourless rhombic crystals, often maced in twos and threes, and containing $12NH^1.C^{12}(Pd'')^3O^{12}.6H^2O$. The whole of the water is given off at 100° , together with a small quantity of ammonia. (Karmrodt, Ann. Ch. Pharm. lxxxi. 164.)

Mellitate of Palladium and Potassium crystallises from the mixture of the two salts evaporated to a syrup, in nodular groups of indistinct prisms. *Mellitate of palladium and sodium* crystallises in maced triangular pyramids containing 34 per cent. palladium. (Karmrodt.)

Mellitates of Potassium.—The neutral salt, $C^{12}K^3O^{12}.9H^2O$, forms efflorescent trimetric crystals, isomorphous with the neutral ammonium-salt a. Observed combination $\infty P : \infty P : \infty P \infty : P \infty : P \infty$. Angle $\infty P : \infty P = 114^\circ$; $\infty P : P \infty = 151^\circ$; $\infty P : P \infty = 160^\circ$; $\infty P : \infty P \infty = 123^\circ$ nearly.

Acid salt, $C^{12}H^3K^3O^{12}.6H^2O$.—A hot solution of 1 at. of the neutral salt and 1 at. mellitic acid yields this salt on cooling in large transparent right rhomboidal prisms, often truncated on the lateral and terminal edges. It is more soluble in water than the neutral salt.

A compound of acid mellitate and nitrate of potassium, $4C^{12}H^3K^3O^{12}.3NKO^1.9H^2O$, is formed by treating the preceding salt with nitric acid, or by mixing a concentrated solution of neutral potassic mellitate with nitric acid, as long as any precipitate is

formed, and heating the liquid till the precipitate disappears. The double salt then crystallises in six-sided trimetric prisms with dihedral summits, exhibiting the combination $\infty P : \infty P_{\infty} : P_{\infty}$. It has an acid taste, and is but slightly soluble in water.

Another acid mellitate of potassium (perhaps $C^{12}H^{12}K^2O^{12} \cdot C^{12}K^2O^{12} \cdot 18H^2O$) is mentioned by Erdmann and Marchand (J. pr. Chem. xliii. 129) as having been obtained in the form of a crystalline powder on adding mellitic acid to a concentrated solution of the neutral salt. This powder redissolved in water yielded large nacreous crystals containing 20.63 per cent. carbon, 2.74 hydrogen, and 30.49 potash.

Mellitates of Silver.—The *argentic salt*, $C^{12}Ag^2O^{12}$, is obtained on adding mellitic acid or mellitate of ammonium to nitrate or acetate of silver, as a white, crystalline, shining, scaly powder, which the microscope shows to consist of transparent, colourless, square plates, usually having their angles truncated. When heated, it decomposes slightly, but without exhibiting any electric excitement, as the oxalate does under similar circumstances. Heated to 100° in a stream of hydrogen, it blackens and gives off water, and the residue dissolves in water, forming a dark-brown, strongly acid liquid, which gradually deposits a mirror of metallic silver, leaving a solution of argentic mellitate in mellitic acid. The brown or black residue obtained by heating the argentic salt evidently contains *argentic mellitate*. When argentic mellitate previously heated to 280° is heated with iodine, iodide of silver is formed, together with a white crystalline sublimate, strongly acid, and very soluble in water.

Potassio-argentic Mellitate, $C^{12}K^2Ag^2O^{12}$, is deposited from a mixture of the component salts containing nitric acid, in small, transparent rhombic prisms, in which the angle $\infty P : P = 121^{\circ} 30'$; $\infty P : \infty P_{\infty} = 119^{\circ} 11'$.

These crystals, when heated, first give off water and become opaque, then swell up with a kind of explosion, and leave a residue of silver and potassic carbonate.

Mellitate of Sodium, $C^{12}Na^2O^{12}$, crystallises with two different proportions of water. A hot concentrated solution deposits needles containing 32.81 per cent. (12 at.) water, the whole of which is given off at 180° . A solution saturated in the cold yields, by spontaneous evaporation, large striated triclinic crystals containing 38.88 per cent. (18 at.) water, which they give off at 160° . (Erdmann and Marchand.)

Mellitate of Strontium.—White precipitate, soluble in hydrochloric acid, obtained by adding mellitic acid to strontia-water.

Respecting the acids derived from mellitic acid, see SUPPLEMENT, pp. 800–814.

MELLITIC ACID, AMIDES OF. (Wöhler, Ann. Ch. Pharm. xxxvii. 268.—R. Schwarz, *ibid.* lxi. 52.)—Two of these compounds are obtained by the dehydration of mellitate of ammonium, viz. mellitimide or paramido, which has the composition of triammonic mellitate minus 2 at. water:

and euchroic acid, which is a mellitanic acid, derived from diammonic mellitate of ammonium by abstraction of 4 at. water:

Mellitimide ($C^{12}O^6$)¹.H².N³ and mellitamic acid ($C^{12}O^6$)¹. $\left\{ \begin{smallmatrix} H^4 \\ H^2 \end{smallmatrix} \right\}$.N³ are obtained, according to Limpricht and Scheibler, by the action of ammonia on neutral mellitate of ethyl.

Paramide and euchroic acid are obtained by heating neutral mellitate of ammonium to 150° – 160° as long as ammonia continues to escape, and exhausting the residuum with water. Paramide then remains undissolved, and the solution contains euchroate of ammonium.

Euchroic acid has already been described (ii. 601).

Paramide or Mellitimide, ($C^{12}O^6$)¹. $\left\{ \begin{smallmatrix} H^4 \\ H^2 \end{smallmatrix} \right\}$.N³, is a white amorphous powder, insoluble in water and in alcohol, but soluble in sulphuric acid, whence it is precipitated by water. When heated with water to 200° in a sealed tube, or boiled for some time with water, fixed alkalis, or ammonia, it is converted into acid mellitate of ammonium. By the action of alkalis restricted to a shorter time, it is transformed into euchroic acid:

An ammoniacal solution of paramide, mixed with nitrate of silver, forms a gelatinous precipitate, whose composition (at 150°) agrees best with the formula

$C^3H^{11}Ag^*(NH^*Ag)^*N^*$: at 200° it gives off ammonia, and then contains a quantity of silver, corresponding nearly with the formula of argento-paramide, $C^{12}Ag^*N^*O^6$.

Paramic acid.—This name is given by Schwarz to a white crystalline precipitate obtained by dropping an ammoniacal solution of paramide into hydrochloric acid. It is sparingly soluble in boiling water, and gives with zinc the reaction of euchroic acid. Its ammoniacal solution is converted by boiling into mellitate of ammonium. Schwarz found in it (at 179°) 47.25 per cent. carbon, 2.18 hydrogen, and 13.78 nitrogen; a result which may be approximately represented by the formula $C^{12}H^3N^*O^7$.

MELLITIC ANHYDRIDE. $C^{12}O^6$.—This is probably the composition of the white substance, insoluble in water and in alkalis, produced by heating chloride of mellityl with mellitic acid, and treating the product with water.

MELLITIC ETHERS. *Ethyl-mellitic acid*, $C^{12}H^3(C^2H^5)^3O^{12}$, is obtained, by boiling mellitic acid for a considerable time with alcohol and sulphuric acid. On saturating with baryta-water, leaving the liquid to stand for some days in order that the excess of baryta may be precipitated as carbonate, then filtering to separate sulphate, mellitate, and carbonate of barium, a solution of ethyl-mellitate of barium is obtained, which, when evaporated in a vacuum over sulphuric acid, leaves the salt as an amorphous gummy mass, very soluble in water, and rotating on the surface of water like butyrate of barium. It is partly decomposed by drying at 100° . Its solution does not precipitate other metallic salts. (Erdmann and Marchand, J. pr. Chem. xlii. 129.)

Neutral Mellitate of Ethyl, $C^2(C^2H^5)^6O^{12}$, is obtained, according to Limpricht and Scheibler (*Limpricht's Lehrb. d. org. Chemie*, p. 1095), as a viscid liquid, by the action of iodide of ethyl on mellitate of silver. Kraut (Jahresb. 1863, p. 281) by the same reaction, obtained the *neutral mellitates of methyl, ethyl, and amyl*, the two former crystallised. H. Müller (*Kekulé's Lehrb. d. org. Chem.* p. 495) obtained the ethers of mellitic acid by the action of chloride of mellityl on the corresponding alcohols. The methylic ether thus obtained was crystallised; the ethylic ether liquid.

According to Limpricht and Scheibler, mellitate of ethyl treated with aqueous ammonia immediately produces a crystalline precipitate of mellitamido, $(C^{12}O^6)^{11}H^{12}N^*$, and the solution, when evaporated, yields mellitamato of am-

MELLITYL CHLORIDE OF. $(C^{12}O^6)^{11}Cl^6$.—Obtained, together with hydrochloric acid and oxychloride of phosphorus, by heating mellitic acid with pentachloride of phosphorus. It is a crystalline non-volatile solid, which with water forms mellitic acid; with alcohols, mellitic ethers; and with mellitic acid, mellitic anhydride. (H. Müller, *loc. cit.*)

MELLONE. (Liebig, Ann. Ch. Pharm. x. 4; xxx. 149; l. 337; lvii. 93; lviii. 227; lxi. 262.—L. Gmelin, *ibid.* xv. 252.—Vöckel, Pogg. Ann. lviii. 151; lxi. 375.—Gerhardt, Compt. Chim. 1845, p. 24, and 1850, p. 104; *Travail*, i. 473.—Laurent and Gerhardt, Ann. Ch. Phys. [3] xix. 85.)—A substance produced by the action of heat on various cyanogen-compounds; e.g., pseudosulphocyanogen, melamine, melam, ammeline, ammelide, and chlorocyanamide. Liebig represents it by the formula C^3N^6 or C^6N^3 ; but according to the analyses of Vöckel, and of Laurent and Gerhardt, the substance thus produced contains hydrogen (at least 1.5 per cent.), and may be represented by the formula $C^3N^5H^1$, the 3 at. H being replaceable by metals. Gerhardt designated this hydrated compound (Liebig's *crude mellone*) by the name hydromellone or hydromellonic acid, reserving the term mellone for the non-hydrogenous compound, which, according to Liebig, is produced by heating mellonide of mercury.

Mellone or hydromellone, heated with potassium or with iodide, bromide, or sulphocyanate of potassium, yields mellonide of potassium, which Liebig originally regarded as a compound of potassium with mellone, C^3N^5K or $C^6N^3K^2$: Laurent and Gerhardt, on the other hand, assigning to hydromellone the formula $C^3N^5H^1$, supposed that mellonide of potassium is produced by the substitution of 2 at. K for H, making the compound $C^3N^5HK^2$. Liebig, by later experiments (Ann. Ch. Pharm. xcv. 257), has come to the conclusion that his original formula of mellonide of potassium was incorrect, and that the true formula of the neutral mellonide is $C^3N^5M^2$.

Preparation of Hydromellone or Crude Mellone.—Liebig prepared this compound chiefly by heating dried pseudosulphocyanogen to low redness, or by gently heating a mixture of sulphocyanate of potassium and dry chloride of sodium in a stream of chlorine gas, and dissolving out the chlorides of potassium and sodium from the residue by water. According to Henneberg, it is best to heat the dry pseudosulphocyanogen, first in an open porcelain basin, and afterwards in a covered porcelain crucible; because, if it be heated in a retort, the sulphur which is given off flows back

again, and causes the mellone to cake together. Too much heat must also be avoided, as the mellone then bakes together in hard lumps. The product thus obtained has a light-yellow colour with a tinge of grey; a grey or red-brown product may be regarded as a failure. As the complete expulsion of the sulphur from the preceding compounds requires strong ignition, and a large portion of the mellone is thereby decomposed, Laurent and Gerhardt prefer preparing it by heating chlorocyanamide till it ceases to give off hydrochloric acid and sal-ammoniac; or ammeline, as long as it gives off ammonia and water; or ammelide, as long as ammonia, cyanic, and cyanuric acids are evolved from it.

The product obtained by either of these processes is a loose, light-yellow, strongly staining powder, destitute of taste and smell. The following table exhibits its composition as determined by calculation and by analysis.

Liebig based his formula on the combustion of crude mellone obtained from pseudo-sulphocyanogen with oxide of copper, which yielded 3 vol. carbonic anhydride to 2 vol. nitrogen, and on the decomposition of mellone by simple ignition, whereby he obtained 1 vol. nitrogen gas to 3 vol. cyanogen. Laurent and Gerhardt ignited their mellone for some time in a platinum crucible before analysing it: *a* was prepared from pseudo-sulphocyanogen, *b* from ammeline, *c* from ammelide, and *d* from chlorocyanamide. The crude mellone, *e, f, g*, analysed by Vöckel, was obtained by variously long ignition of pseudosulphocyanogen prepared with nitric acid; *h*, with sulphocyanate of potassium and chlorine gas; *i* and *k*, from persulphocyanic acid; *l*, from Vöckel's *poliene* (i.e. from the residue obtained by heating sulphocyanate of ammonium); *m* and *n*, from sulphocyanate of mercury.

It follows from the preceding analyses, that crude mellone, if the decomposition is stopped at a certain point, has a composition represented by the formula C^aN^aH^a, which

is that of dicyanuramide, $\left. \begin{matrix} \text{C}^{\text{a}}\text{N}^{\text{a}} \\ \text{H}^{\text{a}} \end{matrix} \right\}^{\text{m}} \text{N}^{\text{a}}$. The product when further heated still

gives off ammonia and becomes continually richer in carbon. Whether it is possible, by continued heating, to expel the whole of the hydrogen in the form of ammonia, and

thus to obtain a body having the composition of tricyanuramide (C^aN^a)₃N^a (which is Liebig's original formula, C^aN^a, tripled,) is not yet distinctly made out; but it is probable that such is the case: at all events, the following formulae show that melamine (cyanuramide) may, by loss of ammonia, be successively converted into melam, dicyanuramide, mellonide of hydrogen (according to Liebig's new formula), and ultimately into tricyanuramide:

According to Liebig, pure mellone or tricyanuramide may also be obtained by heating mellonide of mercury till the evolved mixture of cyanogen and nitrogen gases is three-fourths absorbed by potash.

Decompositions.—1. Mellone heated in a closed vessel is gradually but completely resolved into a mixture of 1 vol. nitrogen gas and 3 vol. cyanogen (Liebig):

According to Vöckel, it is resolved hereby into nitrogen, cyanogen, and hydrocyanic acid:

When mellone obtained from ammelide or chlorocyanamide is ignited in a tube, it disappears completely, giving off vapours which smell of ammonia and hydrocyanic acid, and deposit first a red, then a yellow, and lastly a red-brown sublimate. The sublimate gives off ammonia when treated with potash, and precipitates nitrate of silver. The gaseous mixture evolved at the same time contains a gas (ammonia) which is absorbed by hydrochloric acid, another (cyanogen) which is absorbed by potash, and a non-absorbable gas (nitrogen), the relative quantities of the three being at the beginning of the experiment = 9 : 51 : 40, and at the end = 10 : 30 : 60. (Laurent and Gerhardt.)

2. Mellone heated in dry chlorine gas forms a white volatile substance having a powerful odour, and attacking the eyes very strongly.—3. Mellone dissolves gradually in boiling nitric acid, continually giving off a gas which contains very little or no nitric oxide, and is resolved into ammonia and cyanic acid (ii. 294), which crystallises in long needles:

Or,

4. Mellone dissolves in strong sulphuric acid, with evolution of ammonia; water added to the solution throws down a white substance different from mellone.

5. Crude mellone heated with potassium, or with iodide, bromide, or sulphocyanate of potassium, is converted into mellonide of potassium.

6. With a cold solution of caustic potash, it forms mellonide of potassium, which at the boiling heat is converted, with evolution of ammonia and formation of ammelide, into cyamelurate of potassium (ii. 187):

MELLONHYDRIC ACID. See the next article.

MELLONIDES. $\text{C}^3\text{N}^4\text{M}^3$, according to Gerhardt; $\text{C}^3\text{N}^4\text{M}^3$, according to Liebig's latest experiments (Ann. Ch. Pharm. xcv. 257). Mellonide of potassium is obtained, as already observed, by the action of potassium, or of iodide, bromide or sulphocyanate of potassium, on crude mellone. This and the corresponding salts of sodium and ammonium are soluble in water; the other mellonides are insoluble or sparingly soluble, and are obtained by precipitation. The sodium- and ammonium-salts are obtained by decomposing mellonide of barium with carbonate of sodium or of ammonium.

Mellonide of Ammonium crystallises in needles like the potassium-salt: it contains water of crystallisation.

Mellonide of Barium is obtained by treating the solution of the potassium-salt with chloride of barium, as a white precipitate which dissolves in a large quantity of boiling water. The saturated solution deposits the salt in transparent, shortened needles containing 20.37 per cent. water of crystallisation, which it gives off at 120°.

Mellonide of Calcium, obtained in like manner, is more soluble in boiling water than the barium-salt. The crystals contain 18.05 per cent. water, which they give off at 120°.

The following are obtained as precipitates: *mellonide of cadmium*, white; *chromium*, bluish-white; *cobalt*, peach-blossom-coloured; *copper*, parrot-green; *gold*, whitish-yellow.

Mellonide of Hydrogen. *Mellonhydric* or *Hydromellonic acid*, $\text{C}^3\text{N}^4\text{H}^3$.—By mixing a warm solution of mercuric chloride with mellonide of potassium, a fine-grained, dazzling white precipitate of mellonide of mercury is obtained, which, after washing, dissolves in dilute hydrocyanic acid, even in the cold. Sulphylic acid passed through this solution throws down all the mercury in the form of sulphide; and after driving off the hydrocyanic acid by a gentle heat, there remains an aqueous solution of hydromellonic acid, which has a strong acid taste and reaction, mixes with alcohol without

turbidity, expels carbonic acid from carbonates with effervescence, and yields, when neutralised with potash, crystallised mellonide of potassium, exhibiting all the properties of the original salt (Liebig). L. Gmelin prepared the acid by decomposing the lead or copper salt with sulphydric acid.

When a solution of hydromellonic acid is evaporated, in vacuo or in the air, either at ordinary or at higher temperatures, it deposits white films or flakes, and leaves a somewhat crystalline residue, which redissolves but partially in cold water. The acid is not, however, completely decomposed under these circumstances; but the portion soluble in water still yields a certain quantity of mellonide of potassium when saturated with potash and mixed with alcohol. (Liebig.)

Mellonides of Iron.—The *ferrie salt* is a dark-yellow precipitate; the *ferrous salt*, a white precipitate with greenish reflex.

Mellonide of Lead is a white precipitate which, after drying in the air, gives off 14.1 per cent. water when heated in a bath of chloride of calcium. The air-dried salt gives, according to L. Gmelin's analysis, 42.45 per cent. lead, agreeing nearly with the formula $C^{\text{N}}N^{\text{M}}Pb^{\text{L}}.15H_2O$, which requires 42.58 per cent.

Mellonide of Magnesium is deposited, after some time, in small interlaced needles, from a mixture of mellonide of potassium and sulphate of magnesium.

Mellonide of Manganese is a white precipitate.

Mellonides of Mercury.—The *mercuric salt* is a white precipitate deposited on cooling from a boiling mixture of the solutions of mellonide of potassium and mercuric chloride; if the solutions are mixed cold, the precipitate contains potassium. The salt when heated first gives off nitrogen, cyanogen, and hydrocyanic acid; then nitrogen and cyanogen, in the proportion of 1 vol. of the former to 3 vol. of the latter. (Liebig.)

The *mercurous salt*, also obtained by precipitation, forms thick white flocks.

Mellonide of Platinum is a brownish-yellow precipitate.

Mellonides of Potassium.—Three of these salts have been obtained, viz the neutral salt, $C^{\text{N}}N^{\text{M}}K^{\text{L}}$, and the two acid salts, $C^{\text{N}}N^{\text{M}}HK^{\text{L}}$ and $C^{\text{N}}N^{\text{M}}H^{\text{L}}K^{\text{L}}$.

a. *Neutral mellonide of potassium* is obtained in many reactions besides those above mentioned (p. 875), viz. by the action of amidated compounds of cyanogen on potassium-salts; by the action of sulphocyanates on potassium-salts; and by the decomposition of sulphocyanate of potassium under particular circumstances. When, for example, crude mellone (or calcined melam, &c.) is added to fused sulphocyanate of potassium, mellonide of potassium is produced, with evolution of sulphide of carbon, not only from the mellone, but also from the elements of the sulphocyanate. Again, when sulphocyanate of copper is added to melting sulphocyanate of potassium, sulphide of carbon is evolved, and mellonide of potassium remains mixed with metallic sulphide. Mellonide of potassium is also formed by heating sulphur with ferrocyanide of potassium (e.g. when the mixture used for preparing sulphocyanate of potassium is too strongly heated), its formation being due to the mutual action of the sulphocyanates of potassium and iron formed in the first instance. All these modes of formation of mellonide of potassium from sulphocyanates become intelligible on observing that a sulphocyanate contains the elements of sulphide of carbon, a metallic sulphide, and a mellonide, thus:

Preparation of Mellonide of Potassium.—a. From the *Sulphocyanate*. The preparation is considerably facilitated by the presence of a metal capable of taking up a portion of the sulphur which is set free as sulphide of carbon. The following processes are recommended by Liebig (Ann. Ch. Pharm. xcv. 257):

1. With *Antimonious chloride* (*butter of antimony*).—7 pts. of sulphocyanate of potassium are fused in a wide and deep porcelain crucible till the whole runs quietly and without frothing, and 3 pts. of recently-prepared butter of antimony then added and without frothing, and 3 pts. of recently-prepared butter of antimony then added by small portions. Strong intumescence then takes place, accompanied by brisk evolution of sulphide of carbon, which breaks out in flames, and must be extinguished by covering the crucible with a shallow dish; and a red-brown, porous mass is obtained, which must be pulverised and heated, with constant stirring, in an iron crucible, till part of the resulting sulphide of antimony melts in the softened pulver mass, and collects at the bottom. The mass is then immediately dissolved in boiling water; the filtrate boiled with hydrated oxide of lead as long as the oxide turns black; to remove sulphide of potassium and dissolved sulphide of antimony; and the liquid again filtered and left to cool, whereupon it generally solidifies to a crystalline magma of snow-white mellonide of potassium. This product is thrown on a filter, the liquid allowed to drain off, and the mass, without being washed, is wrapped up with the filter in unsized paper, and placed over-night between two bricks, which are gradually

loaded with weights. The mass, when dry, is again dissolved in hot water, and the same process repeated. At the third crystallisation, the hot filtered liquid is mixed with a small quantity of alcohol, till a faint transient turbidity makes its appearance. The crystalline magma which settles down is washed with alcohol after the mother-liquor has drained off, till a drop of the liquid which runs off no longer reddens sesquichloride of iron, and therefore no longer contains sulphocyanate of potassium.—2. The chloride of antimony used in this process may, with equal advantage, be replaced by *chloride of bismuth*. This compound is prepared by passing chlorine gas over commercial bismuth, heated in a tube of hard glass, which is bent half an inch upwards at one end, then again downwards, and lies horizontally in a combustion furnace; the chloride of bismuth, which distils over, is purified from the chlorides of other metals by rectification in the same apparatus. Before being used, it is again melted, pulverised while still hot after solidification, and the powder added to the fused sulphocyanide. The proportions used are 1 pt. of bismuth-chloride to 2 pts. sulphocyanate of potassium; with a larger proportion of the former the mass will not melt.

b. From Melam.—8 pts. of sulphocyanate of potassium are fused with 4 pts. of melam, previously slightly ignited, and added in successive small portions. The temperature must not be allowed to rise too high; if the gas-bubbles which rise from the melted mass do not burn with a blue flame (sulphide of carbon), but with a red colour, indicating the formation of cyanogen, the heat must be moderated.

Pure mellonide of potassium forms soft, white, very slender interlaced needles, having a silky lustre, and scarcely distinguishable in appearance from sulphate of quinine.—1 pt. of the salt dissolves in 37·4 pts. of water at ordinary temperatures, and in a much smaller quantity of hot water: it is insoluble in alcohol; crystallises with difficulty, even from a solution saturated while warm, but very easily on addition of alcohol. Its solubility in cold water is greatly diminished by the presence of other salts. A warm saturated solution, which would stand for days after cooling without crystallising, instantly deposits crystals on addition of a few drops of solution of sulphocyanate of potassium.—The aqueous solution tastes as bitter as sulphate of quinine. In doses of a drachm, the salt exhibits no decided action on man or other animals, none at least which would distinguish it from other bitter substances. The crystals heated to 200° give off 18·06 per cent. (5 at.) water.

The composition of the anhydrous and crystallised salts, as determined by Liebig, is given in the following table:—

	<i>Anhydrous.</i>			<i>Crystallised.</i>			
C ^o .	108·0	26·50	26·12	C ^o N ¹³ K ³	407·6	81·91	Liebig.

K ¹ .	117·6	28·85	28·72	C ^o N ¹³ K ³ ·5H ² O	497·6	100·00	
	407·6	100·00	99·22				

The dried salt burnt in a stream of oxygen yielded only 0·06 per cent. water: now, if it contained 1 at. hydrogen to 2 at. potassium, according to Gerhardt's formula, C^oN¹³HK², it should have yielded 2·19 per cent. water; it may therefore be concluded that the salt does not contain hydrogen.

Neutral mellonide of potassium, boiled with hydrochloric acid, yields sal-ammoniac, chloride of potassium, and cyanuric acid. Boiled with nitric acid, it yields cyanic acid. By continued boiling with potash, it gives off ammonia, and yields, first ammelide and cyameluric acid, then melanuric acid, and finally cyanuric acid (p. 876).

β. Soluble Acid salt. C^oN¹³HK²·3H²O.—Obtained by mixing a warm saturated solution of the neutral salt with an equal volume of strong acetic acid. It crystallises from this mixture in oblique rhombic laminae, which effloresce in a warm atmosphere. When boiled with water, it is resolved into the neutral salt *a*, and the insoluble acid salt *b*. The crystals, after drying in the air, give off 13·03 per cent. water (3 at. = 12·73 per cent.). The salt, dried at 150°, gave by analysis 28·75 per cent. carbon, 0·43 hydrogen, and 21·13 potassium; the formula C^oN¹³HK² requiring 29·23 carbon, 49·28 nitrogen, 0·27 hydrogen, and 21·22 potassium. (Liebig.)

γ. Insoluble Acid salt. C^oN¹³H²K.—This salt separates in the form of a white, chalky precipitate, on pouring a moderately dilute solution of neutral mellonide of potassium into warm dilute hydrochloric acid. It is insoluble in cold and sparingly soluble in boiling water; the solution has a strong acid reaction; easily soluble in a solution of acetate of potassium. It gave by analysis 31·97 per cent. carbon, 0·76 hydrogen, and 11·93, potassium; the formula requiring 32·61 per cent. carbon, 54·99 nitrogen, 0·60 hydrogen, and 11·84 potassium.

Mellonide of Silver, C^oN¹³Ag², is obtained as a white precipitate by mixing a boiling solution of neutral mellonide of potassium with nitrate of silver. It contains, according to the mean of Liebig's analyses, 17·48 per cent. carbon, 29·54 nitrogen,

and 52.48 silver (= 99.50), the formula requiring 17.50 carbon, 29.64 nitrogen, and 52.77 silver (= 100).

Laurent and Gerhardt found in this salt 17.01 to 17.8 per cent. carbon, 52.2 silver, and 0.4 to 0.5 hydrogen; whence they deduced the formula $C^{10}N^4HAg^2$, requiring 17.3 C, 52.0 Ag, and 0.2 H. Liebig, however, by burning the salt in a stream of oxygen, obtained, in two experiments only 0.4 and 0.3 per cent. water; whereas, according to the latter formula, the quantity of water should be 2.17 per cent., or about six times as great as that actually obtained. Hence it may be inferred that the salt does not contain hydrogen.

Mellonide of Sodium, obtained by decomposing the barium-salt with carbonate of sodium, crystallises in white silky needles, moderately soluble in water, insoluble in alcohol.

Mellonide of Strontium is more soluble in water than mellonide of barium; its solution, saturated at the boiling heat, solidifies, on cooling, to a magma composed of needles.

Mellonide of Zinc is a white precipitate.

MELONEMETIN. An emetic principle contained, according to Torosiewicz, in the root of the melon (*Cucumis Melo*). See *Cucumis* (ii. 172).

MELOPSITE. A yellowish- or greenish-white lithomarge from Neudeck in Bohemia. Hardness = 2 to 3. Specific gravity = 2.5 to 2.6. (Breithaupt.)

MENACCANITE. Titaniferous iron. (See TITANATES.)

MENAPHTOXIMIDE.

MENAPHTHYLAMINE.

} See NAPHTHYLAMINE, DERIVATIVES OF.

MENDIPITE. An oxychloride of lead, Pb^2ClFO_3 , found on the Mendip Hills in Somersetshire (p. 556).

MENECHINITE. A sulphide of lead and antimony, $4PbS.Sb_2S_3$, occurring, with Boulangerite and Jamesonite, at Bottino in Tuscany, generally in compact fibrous forms, but sometimes in distinct trimetric crystals, exhibiting the faces $\infty P\infty$ and ∞P ; cleavable parallel to $\infty P\infty$ and ∞P (Q. Sella, Jahresb. 1862, p. 712). Hardness = 2.5. Very lustrous. Contains, according to Bechi's analysis (Sill. Am. J. [2] xiv. 60), 17.52 per cent. sulphur, 19.28 antimony, 59.21 lead, 3.64 copper, and 0.34 iron (= 99.89).

MENGITE. A mineral containing zirconia, ferric oxide, and titanate acid, occurring in granite-veins in the Ilmen Mountains. It forms short trimetric prisms, often terminated by four-sided pyramids. $a : b : c = 0.8285 : 1 : 0.8660$. Angle $\infty P : \infty P = 100^\circ 28' : \infty P : P\infty = 133^\circ 42'$. No distinct cleavage. Hardness = 5 to 5.5. Specific gravity = 5.48. The crystals are iron-black, with submetallic lustre, subvitreous on the fractured surface. Streak chestnut-brown. Fracture uneven. Infusible before the blowpipe, but becomes magnetic. Greenish-yellow clear glass with phosphorous-salt in the outer flame; yellowish-red in the inner, deepened by adding tin. Manganesous reaction with carbonate of sodium.

This mineral is called ilmenite by Brooke; and the name mengite is applied by that mineralogist to monazite.

MENILITE. A brown opaque variety of opal, occurring in compact reniform masses, occasionally slaty.

MENISPERMIC ACID. A doubtful acid, said by Boullay to exist in the seeds of *Menispermum Cocculus*, and to be obtained by evaporation of the alcoholic mother-liquor from which picrotoxine has crystallised out. It is described as crystalline, tasteless, sparingly soluble in water, capable of reddening litmus, and forming crystallisable salts with alkalis. Neither Casaseca nor Pelletier was able to obtain this acid in the manner described by Boullay.

MENISPERMINE. An alkaloid discovered by Pelletier and Couerbe (Ann. Ch. Phys. [2] liv. 178) in the seeds of *Menispermum Cocculus*, in which it is accompanied by paramenispermine and picrotoxine.

To extract the menispermine, the alcoholic extract of the seeds is first treated with cold water, then exhausted with hot acidulated water; the brown solution is precipitated by an alkali; and the precipitate is exhausted with very weak acetic acid, which leaves a brown-black mass undissolved. Or the seeds may be made up into a heap, and exhausted with alcohol of specific gravity 0.833; the alcohol distilled off; the residue boiled with water; and the liquid filtered at the boiling heat; it then, on cooling, deposits crystals of picrotoxine, especially if a small quantity of acid has been added. The part insoluble in boiling water is then treated with acidulated water, and precipitated by an alkali; a granular precipitate is thereby formed, from which

alcohol extracts a peculiar yellow substance; and the residue is finally dissolved in ether, which deposits menispermine in the crystalline form. The ether leaves undissolved a viscous substance, which may be dissolved in absolute alcohol; and the solution, evaporated at 45° , ultimately yields crystals of paramenispermene.

Menispermine crystallises in prisms terminated by pyramidal faces. It is white, melts at 120° , and decomposes at a higher temperature. It does not appear to be poisonous. It is insoluble in water, but soluble in alcohol and ether, which deposit it in the crystalline state. It contains (mean of four analyses) 71.80 per cent. carbon, 8.01 hydrogen, 8.57 nitrogen, and 10.53 oxygen; whence Pelletier and Couerbe deduce the formula $C^{18}H^{12}NO$.

Menispermine dissolves easily in dilute acids. Hot strong nitric acid converts it into oxalic acid, and a yellow resinous substance.

Sulphate of menispermine crystallises in prismatic needles, containing 15 per cent. water and 6.87 per cent. sulphuric anhydride. It melts at 165° , and at a higher temperature reddens slightly and gives off sulphydric acid.

Paramenispermene has the same composition as menispermine. It melts at 250° , and volatilises in white vapours, which condense like snow on cold bodies. It is insoluble in water, sparingly soluble in ether, easily soluble in boiling alcohol. It dissolves also in dilute acids, but without neutralising them or forming definite salts.

MENTHENE. $C^{10}H^{18}$. (Walter, Ann. Ch. Pharm. xxxii. 288.—Oppenheim, Chem. Soc. J. xv. 29.)—A hydrocarbon produced by the action of phosphoric anhydride (Walter), or chloride of zinc (Oppenheim), on menthol or peppermint camphor, $C^{10}H^{16}O$. It is also found among the products of the decomposition of chloride of menthyl by ethylate of sodium (Oppenheim). To prepare it, menthol is melted in a tubulated retort, and phosphoric anhydride is added by small portions till it is in slight excess. The mass is then distilled, and the product is rectified by distillation over fresh portions of phosphoric anhydride.

Menthene is a transparent, very mobile liquid, having an agreeable odour and cooling taste. Boiling-point 163° . Specific gravity = 0.851 at 21° . Vapour-density, obs. = 4.93 to 4.95; calc. = 4.78. It is insoluble in water; forms a turbid mixture with a small quantity of alcohol or ether, a clear mixture with a larger quantity; dissolves with moderate facility in wood-spirit, very easily in oil of turpentine.

Menthene is scarcely, if at all, attacked by potassium; cold sulphuric acid has no action upon it; nitric acid ultimately converts it into an oily acid, soluble in water and in alcohol; with chlorine and bromine it forms substitution-products.

Bromomenthene. $C^{10}H^{17}Br$.—Bromine acts very violently on menthene, disengaging torrents of hydrobromic acid, and forming a number of very unstable substitution-products. By adding 2 at. bromine drop by drop to 1 at. menthene, monobromomenthene appears to be formed, the product treated with potash yielding the hydrocarbon $C^{10}H^{16}$ (Oppenheim):

Pentachloromenthene, $C^{10}H^{13}Cl^5$, is produced by the action of chlorine on menthene. Dry chlorine attacks menthene with great violence, hydrochloric acid being evolved, the liquid assuming first a green, then a yellow colour, and being ultimately converted into pentachloromenthene, which is a yellow syrupy liquid heavier than water. It dissolves at ordinary temperatures in alcohol and wood-spirit, more easily in ether and oil of turpentine. Strong sulphuric acid colours it deep red.

MENTHOL. $C^{10}H^{18}O = \begin{matrix} C^{10}H^{19} \\ H \end{matrix} \left\{ O. \right.$ Menthyl alcohol. Hydrate of Menthyl.

Camphor or Stearoptene of Peppermint-oil. (L. Gmelin, Handbuch, Aufl. 3, ii. 408.—Dumas, Ann. Ch. Pharm. vi. 252.—Blanchet and Sell, *ibid.* vi. 293.—Walter, *ibid.* xxxii. 288.—Kane, Phil. Mag. xvi. 418.—Faurent, Rev. scient. xiv. 341.—Oppenheim, Chem. Soc. J. xv. 24.)—The essential oil of peppermint, when kept for a long time, or cooled to very low temperatures, deposits this substance in crystals. American peppermint-oil yields this deposit at temperatures near 0° . This camphor is now imported in large quantities from Japan, in small, white, fragrant, prismatic crystals, resembling sulphate of magnesium, which salt is in fact used for adulterating the Japanese camphor, sometimes to the amount of 10 to 20 per cent.

The camphor from American oil of peppermint melts at 36.5° (Gmelin); at 25° (Dumas); 27° (Blanchet and Sell); 34° (Walter); the Japanese camphor melts at 36° , and volatilises without decomposition at 210° (Oppenheim). Vapour-density, obs. = 5.62; calc. = 5.41. It is laevo-rotatory. $[\alpha] = -59.6^{\circ}$ [? for the transition tint.]

It is but slightly soluble in water, but imparts to that liquid a strong smell and taste. It is very soluble in alcohol, ether, sulphide of carbon, and oils, both fixed and volatile; insoluble in aqueous alkalis. From an alcoholic soda-solution, it crystallises in long

needles. It is dissolved by a current of *sulphurous anhydride*, or *hydrochloric acid gas*, but the acid passes off on evaporation, leaving the menthol unaltered. Concentrated acids, especially *nitric*, *sulphuric*, *hydrochloric*, *formic*, *acetic*, and *butyric acids*, dissolve it freely; and from these solutions it is precipitated by water and by alkalis, as an oil, which soon solidifies, and then exhibits the original properties of the camphor.

Heated with strong hydrochloric to 100° for a considerable time, it is transformed into chloride of menthyl, $C^{10}H^{19}Cl$. The same compound is formed by the action of *pentachloride of phosphorus*:

With *iodide* and *bromide of phosphorus*, it yields iodide and bromide of menthyl; *hydriodic acid* also acts upon it at 200°, forming iodide of menthyl.

Heated with concentrated *acetic acid* in a sealed tube, it is converted into acetate of menthyl, $\left. \begin{matrix} C^{10}H^{19} \\ C^2H^3O \end{matrix} \right\} O$. With *butyric acid* it forms, in like manner, butyrate of menthyl, $\left. \begin{matrix} C^{10}H^{19} \\ C^4H^7O \end{matrix} \right\} O$.

These reactions show that peppermint-camphor is an alcohol containing the radicle $C^{10}H^{19}$ (menthyl); it is homologous with allylic alcohol, C^3H^7O , and isologous with campholic alcohol or camphol, $C^{10}H^{19}O$ (i.e. differs from the latter by 2 at. H); hence the names *menthylic* or *mentholic alcohol*, and *menthol* applied to it.

Sodium acts very energetically on menthol, with evolution of hydrogen and formation of a substitution-product, which is a white, vitreous, transparent mass, becoming brown on exposure to the air, insoluble in water, but soluble in absolute alcohol and iodide of ethyl. The latter body acts on the sodium compound; but the action is complicated, and does not appear to give rise to the formation of a compound ether, as with most sodium-alcohols.

Menthol is dehydrated by *phosphoric anhydride* or *chloride of zinc*, yielding menthene.

MENTHYL. $C^{10}H^{19}$. The radicle of menthylic alcohol, &c.

Acetate of Menthyl, $\left. \begin{matrix} C^{10}H^{19} \\ C^2H^3O \end{matrix} \right\} O$, prepared by heating menthol with strong acetic acid to 120° in a sealed tube for ten or twelve hours, then washing with carbonate of sodium, and drying over chloride of calcium, is a light oil which boils without decomposition between 222° and 224°. It is highly refractive, and levo-rotatory; $[\alpha] = -114^\circ$. It is not decomposed by water, or by cold solutions of the alkalis, or by baryta, but when heated to 120°, with an alcoholic solution of soda, it is completely resolved into sodic acetate and menthol. (Oppenheim, Chem. Soc. J. xv. 26.)

Butyrate of Menthyl, $\left. \begin{matrix} C^{10}H^{19} \\ C^4H^7O \end{matrix} \right\} O$, is prepared by heating menthol with butyric acid, in a sealed tube, to 200° for thirty hours; then distilling and collecting the portion which passes over between 230° and 240°. Rotatory power $[\alpha] = 88.8^\circ$ nearly.

Chloride of Menthyl, $C^{10}H^{19}Cl$. Obtained by treating menthol with pentachloride of phosphorus (Walter), or with concentrated hydrochloric acid for a week, at 100°, or for twenty-four hours at 120° (Oppenheim). It is a very pale yellow liquid, lighter than water, heavier than alcohol, and having an odour like that of mace; boils at about 204°, decomposing and turning brown at the same time. It is slightly soluble in water, more soluble in alcohol. It is rapidly decomposed by potassium, but strong alcoholic potash has no action upon it, even at the boiling heat. (Walter.)

Bromide and Iodide of Menthyl are obtained by the action of bromide and iodide of phosphorus on menthol; the latter also by the action of strong hydriodic acid. Both compounds are decomposed by distillation. (Oppenheim.)

MENYANTHIN. $C^{22}H^{36}O^{11}$. A bitter substance discovered by Brandes in buckbean (*Menyanthes trifoliata*), and further examined by Kromayer (Zeitschr. Anal. Chem. i. 15; Jahresh. 1861, 747). It may be prepared by a process similar to that described for the extraction of marrubiin (p. 851). It is thus obtained as a nearly colourless resinous mass, which, after drying over sulphuric acid, is amorphous, friable, permanent in the air, neutral, and has an intense and purely bitter taste. It begins to soften between 60° and 65°, becomes quite fluid at 115°, and solidifies on cooling to a hard yellowish transparent mass. At higher temperatures it gives off first aromatic, then pungent vapours, smelling like oil of mustard. It dissolves sparingly in cold water, easily in hot water and in alcohol, but is insoluble in ether; alkalis dissolve it apparently without alteration. It dissolves with various shades of colour in strong sulphurous, nitric, and hydrochloric acids. The aqueous solution is not precipitated by metallic salts, but form with gallicanic acid a precipitate having the

composition $C^6H^8O^2 = C^2H^4O^{11}.2C^2H^4O^6$. Menyanthin is isomeric with pini-picin, which it also resembles in many of its properties. (Kromayer.)

The name *menyanthin* has also been applied to a neutral amylaceous substance contained in buckbean; probably identical with inulin (p. 277).

MENYANTHOL. An oily body, obtained by distilling menyanthin with dilute sulphuric acid. The residue in the retort contains fermentable sugar. It is heavy, colourless, smells like bitter almond oil; has a faint acid reaction, and reduces an ammoniacal silver solution. (Kromayer.)

MERCAPTANS. Sulphydrates of the alcohol-radicles, e.g., sulphydrate of ethyl C^2H^5 $\left\{ \begin{smallmatrix} S \\ H \end{smallmatrix} \right.$. (See the several Alcohol-radicles, e.g., ETHEYL, ii. 547.)

MERCAPTIDES. Compounds formed by the substitution of metals for hydrogen in the mercaptans.

MERCURAMINES AND MERCURAMMONIUMS. See MERCURY-BASES, AMMONIACAL.

MERCURIALIS. The ash of *Mercurialis perennis* (the herb together with the fruit) has been analysed by N. Reitler (Jahresb. 1860, p. 543). The air-dried plants yielded 84.4 per cent. dry residue at 100°. The ash amounted to 11.6 per cent. of the air-dried plant, and 13.09 per cent. of the plant dried at 100°. It contained 27.14 per cent. CO_2 , 9.18 Cl, 0.98 SO_4 , 0.84 SiO_2 , 2.74 P_2O_5 , 0.27 Fe_2O_3 , 31.57 CaO, 6.59 MgO, 14.35 K_2O , 6.84 Na_2O , with a trace of copper (loss 0.50).

MERCURIC AMYLIDE, ETHIDE, &c. See MERCURY-RADICLES, ORGANIC.

MERCURIUS. This term was applied by the alchemists to all volatile substances: thus quicksilver was called *Mercurius communis*; alcohol, *Mercurius vegetabilis*. At present it is applied only to quicksilver.

Mercurius dulcis. Syn. with calomel (p. 893).

Mercurius cinereus Blackii, blackish-grey mercurial precipitate, is a mixture of mercurous carbonate with *Mercurius solubilis Hahnemanni*, obtained by precipitating mercurous nitrate with carbonate of ammonium.

Mercurius cinereus Moscati, the *Mercurius solubilis* of the Swedes, consists of black mercurous oxide, obtained by decomposing calomel with caustic potash or soda.

Mercurius cinereus Saunderi. An almost obsolete pharmaceutical preparation consisting of chloride of mercurousammonium (Hg^2H^3N)Cl, obtained by decomposing calomel with ammonia. (See MERCURY-BASES, AMMONIACAL.)

Mercurius phosphatus Fuchsii. An obsolete preparation obtained by precipitating a solution of mercury in nitric acid with phosphate of sodium.

Mercurius præcipitatus albus. *Hydrargyrum amido-bichloratum*, *Hydrargyrum amido-muriaticum*, *Hydrargyrum præcipitatum album*, *Mercurius cosmeticus*, *Calx hydrargyri alba*, *Lac mercuriale*.—*White precipitate*. Of this mercurial preparation there are two varieties, distinguished as fusible and infusible. The former consists of chloride of mercurammonium, $Hg^2H^4N^2Cl^2$, obtained by precipitating ammonio-mercuric chloride with potash, or by dropping a solution of mercuric chloride into a solution of sal-ammoniac mixed with ammonia, as long as the precipitate first formed is redissolved; the latter, of chloride of dimercurammonium Hg^2H^3NCl , obtained by adding ammonia to mercuric chloride.

Mercurius præcipitatus ruber. *Oxydum hydrargyricum*. Mercuric oxide obtained either by oxidising mercury in contact with the air at the boiling heat, or by heating it with nitric acid. The product obtained by the first of these methods is also called *Mercurius præcipitatus per se* (see p. 907).

Mercurius solubilis Hahnemanni. *Hydrargyrum oxydulatum nigrum*. *Nitrus ammonicus cum oxydo hydrargyrico*. Basic nitrate of mercurousammonia. See MERCURY-BASES, AMMONIACAL.

Mercurius violaceus. A form of mercuric sulphide, obtained by triturating together 6 pts. melted flowers of sulphur, 6 pts. mercury, and 4 pts. sal-ammoniac, pulverising the cooled mass, subliming it in a flask, removing the upper white deposit, consisting of sal-ammoniac, and resubliming the lower, heavier sublimate three times. The upper part of the sublimate, thus obtained, is usually light and yellow; the lower heavy and violet. The latter, after it has been finely pounded and alcohol burnt upon it, constitutes *Mercurius violaceus*.

Mercurius vitæ. Powder of Algaroth (oxychloride of antimony, i. 327).

Mercurius vivus. Metallic mercury.

MERCURIO-TETRETHYL-AMMONIUM. $Hg(C_2H_5N)^+$. A base, the iodide of which is obtained, according to Sonnenschein, together with several other compounds, by the action of iodide of ethyl on white precipitate (ii. 636).

MERCURY. Synonymes: *Quicksilver*, *Hydrargyrum*, *Argentum vivum*, *Mercurius vivus*. Symbol Hg; Atomic Weight = 200.

This metal has been known from the earliest times; cinnabar was used as a pigment by the ancients; corrosive sublimate was known to the Arabians, and calomel to the alchemists.
